

The Julia Language

V1.10.2

The Julia Project

March 2, 2024

Contents

Contents	i
I Manual	1
1 Julia 1.10 Documentation	2
1.1 Important Links	2
1.2 Introduction	2
1.3 Julia Compared to Other Languages	3
2 Getting Started	5
2.1 Resources	6
3 Variables	7
3.1 Allowed Variable Names	8
3.2 Assignment expressions and assignment versus mutation	9
3.3 Stylistic Conventions	10
4 Integers and Floating-Point Numbers	12
4.1 Integers	13
4.2 Floating-Point Numbers	17
4.3 Arbitrary Precision Arithmetic	22
4.4 Numeric Literal Coefficients	23
4.5 Literal zero and one	25
5 Mathematical Operations and Elementary Functions	26
5.1 Arithmetic Operators	26
5.2 Boolean Operators	27
5.3 Bitwise Operators	27
5.4 Updating operators	28
5.5 Vectorized "dot" operators	29
5.6 Numeric Comparisons	30
5.7 Operator Precedence and Associativity	33
5.8 Numerical Conversions	34
6 Complex and Rational Numbers	38
6.1 Complex Numbers	38
6.2 Rational Numbers	41
7 Strings	44
7.1 Characters	45
7.2 String Basics	47
7.3 Unicode and UTF-8	48
7.4 Concatenation	52
7.5 Interpolation	53
7.6 Triple-Quoted String Literals	54

7.7	Common Operations	56
7.8	Non-Standard String Literals	57
7.9	Regular Expressions	57
7.10	Byte Array Literals	62
7.11	Version Number Literals	64
7.12	Raw String Literals	64
8	Functions	66
8.1	Argument Passing Behavior	67
8.2	Argument-type declarations	68
8.3	The return Keyword	69
8.4	Operators Are Functions	70
8.5	Operators With Special Names	71
8.6	Anonymous Functions	71
8.7	Tuples	73
8.8	Named Tuples	73
8.9	Deconstructing Assignment and Multiple Return Values	73
8.10	Property destructuring	76
8.11	Argument destructuring	77
8.12	Varargs Functions	77
8.13	Optional Arguments	80
8.14	Keyword Arguments	80
8.15	Evaluation Scope of Default Values	82
8.16	Do-Block Syntax for Function Arguments	82
8.17	Function composition and piping	83
8.18	Dot Syntax for Vectorizing Functions	85
8.19	Further Reading	87
9	Control Flow	88
9.1	Compound Expressions	88
9.2	Conditional Evaluation	89
9.3	Short-Circuit Evaluation	92
9.4	Repeated Evaluation: Loops	95
9.5	Exception Handling	98
9.6	Tasks (aka Coroutines)	103
10	Scope of Variables	104
10.1	Global Scope	105
10.2	Local Scope	105
10.3	Constants	115
10.4	Typed Globals	118
11	Types	119
11.1	Type Declarations	120
11.2	Abstract Types	122
11.3	Primitive Types	123
11.4	Composite Types	124
11.5	Mutable Composite Types	126
11.6	Declared Types	128
11.7	Type Unions	128
11.8	Parametric Types	129
11.9	UnionAll Types	137
11.10	Singleton types	138

11.11	Types of functions	139
11.12	Type{T} type selectors	140
11.13	Type Aliases	142
11.14	Operations on Types	142
11.15	Custom pretty-printing	143
11.16	"Value types"	146
12	Methods	148
12.1	Defining Methods	149
12.2	Method specializations	152
12.3	Method Ambiguities	153
12.4	Parametric Methods	154
12.5	Redefining Methods	157
12.6	Design Patterns with Parametric Methods	159
12.7	Parametrically-constrained Varargs methods	163
12.8	Note on Optional and keyword Arguments	163
12.9	Function-like objects	164
12.10	Empty generic functions	165
12.11	Method design and the avoidance of ambiguities	165
12.12	Defining methods in local scope	168
13	Constructors	170
13.1	Outer Constructor Methods	171
13.2	Inner Constructor Methods	171
13.3	Incomplete Initialization	173
13.4	Parametric Constructors	175
13.5	Case Study: Rational	177
13.6	Outer-only constructors	179
14	Conversion and Promotion	181
14.1	Conversion	182
14.2	Promotion	184
15	Interfaces	188
15.1	Iteration	188
15.2	Indexing	191
15.3	Abstract Arrays	192
15.4	Strided Arrays	194
15.5	Customizing broadcasting	195
15.6	Instance Properties	200
16	Modules	204
16.1	Namespace management	205
16.2	Submodules and relative paths	210
16.3	Module initialization and precompilation	212
17	Documentation	216
17.1	Accessing Documentation	216
17.2	Writing Documentation	216
17.3	Functions & Methods	220
17.4	Advanced Usage	221
17.5	Syntax Guide	222
18	Metaprogramming	227
18.1	Program representation	227
18.2	Expressions and evaluation	230

18.3	Macros	235
18.4	Code Generation	243
18.5	Non-Standard String Literals	244
18.6	Generated functions	246
19	Single- and multi-dimensional Arrays	253
19.1	Basic Functions	253
19.2	Construction and Initialization	253
19.3	Array literals	254
19.4	Comprehensions	259
19.5	Generator Expressions	260
19.6	Indexing	261
19.7	Indexed Assignment	263
19.8	Supported index types	264
19.9	Iteration	269
19.10	Array traits	270
19.11	Array and Vectorized Operators and Functions	270
19.12	Broadcasting	271
19.13	Implementation	272
20	Missing Values	275
20.1	Propagation of Missing Values	275
20.2	Equality and Comparison Operators	276
20.3	Logical operators	277
20.4	Control Flow and Short-Circuiting Operators	278
20.5	Arrays With Missing Values	279
20.6	Skipping Missing Values	280
20.7	Logical Operations on Arrays	281
21	Networking and Streams	283
21.1	Basic Stream I/O	283
21.2	Text I/O	284
21.3	IO Output Contextual Properties	285
21.4	Working with Files	285
21.5	A simple TCP example	286
21.6	Resolving IP Addresses	288
21.7	Asynchronous I/O	288
21.8	Multicast	289
22	Parallel Computing	291
23	Asynchronous Programming	292
23.1	Basic Task operations	292
23.2	Communicating with Channels	293
23.3	More task operations	297
23.4	Tasks and events	297
24	Multi-Threading	299
24.1	Starting Julia with multiple threads	299
24.2	Threadpools	300
24.3	Communication and synchronization	301
24.4	The @threads Macro	302
24.5	Atomic Operations	304
24.6	Per-field atomics	305
24.7	Side effects and mutable function arguments	306

24.8	@threadcall	306
24.9	Caveats	306
24.10	Task Migration	307
24.11	Safe use of Finalizers	307
25	Multi-processing and Distributed Computing	309
25.1	Code Availability and Loading Packages	311
25.2	Starting and managing worker processes	313
25.3	Data Movement	314
25.4	Global variables	314
25.5	Parallel Map and Loops	316
25.6	Remote References and AbstractChannels	318
25.7	Channels and RemoteChannels	318
25.8	Local invocations	320
25.9	Shared Arrays	322
25.10	ClusterManagers	325
25.11	Specifying Network Topology (Experimental)	331
25.12	Noteworthy external packages	332
26	Running External Programs	335
26.1	Interpolation	336
26.2	Quoting	338
26.3	Pipelines	339
26.4	Cmd Objects	341
27	Calling C and Fortran Code	343
27.1	Creating C-Compatible Julia Function Pointers	345
27.2	Mapping C Types to Julia	347
27.3	Mapping C Functions to Julia	353
27.4	C Wrapper Examples	355
27.5	Fortran Wrapper Example	356
27.6	Garbage Collection Safety	357
27.7	Non-constant Function Specifications	357
27.8	Indirect Calls	358
27.9	Closure cfunctions	358
27.10	Closing a Library	359
27.11	Variadic function calls	359
27.12	ccall interface	359
27.13	Calling Convention	360
27.14	Accessing Global Variables	360
27.15	Accessing Data through a Pointer	361
27.16	Thread-safety	361
27.17	More About Callbacks	362
27.18	C++	362
28	Handling Operating System Variation	365
29	Environment Variables	366
29.1	File locations	366
29.2	Pkg.jl	369
29.3	Network transport	370
29.4	External applications	370
29.5	Parallelization	371
29.6	REPL formatting	372

29.7	System and Package Image Building	373
29.8	Debugging and profiling	373
30	Embedding Julia	376
30.1	High-Level Embedding	376
30.2	High-Level Embedding on Windows with Visual Studio	378
30.3	Converting Types	379
30.4	Calling Julia Functions	380
30.5	Memory Management	380
30.6	Working with Arrays	383
30.7	Exceptions	385
31	Code Loading	388
31.1	Definitions	388
31.2	Federation of packages	389
31.3	Environments	390
31.4	Conclusion	400
32	Profiling	401
32.1	Basic usage	401
32.2	Accumulation and clearing	405
32.3	Options for controlling the display of profile results	405
32.4	Configuration	406
32.5	Memory allocation analysis	406
32.6	External Profiling	408
33	Stack Traces	409
33.1	Viewing a stack trace	409
33.2	Extracting useful information	410
33.3	Error handling	411
33.4	Exception stacks and <code>current_exceptions</code>	412
33.5	Comparison with <code>backtrace</code>	413
34	Performance Tips	415
34.1	Performance critical code should be inside a function	415
34.2	Avoid untyped global variables	415
34.3	Measure performance with <code>@time</code> and pay attention to memory allocation	416
34.4	Tools	418
34.5	Avoid containers with abstract type parameters	418
34.6	Type declarations	419
34.7	Break functions into multiple definitions	425
34.8	Write "type-stable" functions	426
34.9	Avoid changing the type of a variable	426
34.10	Separate kernel functions (aka, function barriers)	427
34.11	Types with values-as-parameters	428
34.12	The dangers of abusing multiple dispatch (aka, more on types with values-as-parameters)	429
34.13	Access arrays in memory order, along columns	430
34.14	Pre-allocating outputs	432
34.15	More dots: Fuse vectorized operations	433
34.16	Consider using views for slices	434
34.17	Copying data is not always bad	434
34.18	Consider <code>StaticArrays.jl</code> for small fixed-size vector/matrix operations	435
34.19	Avoid string interpolation for I/O	435
34.20	Optimize network I/O during parallel execution	436

34.21	Fix deprecation warnings	436
34.22	Tweaks	436
34.23	Performance Annotations	437
34.24	Treat Subnormal Numbers as Zeros	440
34.25	@code_warntype	441
34.26	Performance of captured variable	443
34.27	Multithreading and linear algebra	444
34.28	Alternative linear algebra backends	444
35	Workflow Tips	445
35.1	REPL-based workflow	445
35.2	Browser-based workflow	446
35.3	Revise-based workflows	446
36	Style Guide	448
36.1	Indentation	448
36.2	Write functions, not just scripts	448
36.3	Avoid writing overly-specific types	448
36.4	Handle excess argument diversity in the caller	449
36.5	Append ! to names of functions that modify their arguments	449
36.6	Avoid strange type Unions	450
36.7	Avoid elaborate container types	450
36.8	Prefer exported methods over direct field access	450
36.9	Use naming conventions consistent with Julia base/	451
36.10	Write functions with argument ordering similar to Julia Base	451
36.11	Don't overuse try-catch	452
36.12	Don't parenthesize conditions	452
36.13	Don't overuse ...	452
36.14	Don't use unnecessary static parameters	452
36.15	Avoid confusion about whether something is an instance or a type	453
36.16	Don't overuse macros	453
36.17	Don't expose unsafe operations at the interface level	453
36.18	Don't overload methods of base container types	454
36.19	Avoid type piracy	454
36.20	Be careful with type equality	454
36.21	Don't write a trivial anonymous function $x \rightarrow f(x)$ for a named function f	454
36.22	Avoid using floats for numeric literals in generic code when possible	455
37	Frequently Asked Questions	456
37.1	General	456
37.2	Public API	457
37.3	Sessions and the REPL	457
37.4	Scripting	458
37.5	Variables and Assignments	459
37.6	Functions	459
37.7	Types, type declarations, and constructors	463
37.8	Troubleshooting "method not matched": parametric type invariance and MethodErrors	470
37.9	Packages and Modules	471
37.10	Nothingness and missing values	471
37.11	Memory	472
37.12	Asynchronous IO and concurrent synchronous writes	472
37.13	Arrays	473

37.14	Computing cluster	475
37.15	Julia Releases	475

Manual

Chapter 1

Julia 1.10 Documentation

Welcome to the documentation for Julia 1.10.

Please read the [release notes](#) to see what has changed since the last release.

Note

The documentation is also available in PDF format: [julia-1.10.2.pdf](#).

1.1 Important Links

Below is a non-exhasutive list of links that will be useful as you learn and use the Julia programming language.

- [Julia Homepage](#)
- [Download Julia](#)
- [Discussion forum](#)
- [Julia YouTube](#)
- [Find Julia Packages](#)
- [Learning Resources](#)
- [Read and write blogs on Julia](#)

1.2 Introduction

Scientific computing has traditionally required the highest performance, yet domain experts have largely moved to slower dynamic languages for daily work. We believe there are many good reasons to prefer dynamic languages for these applications, and we do not expect their use to diminish. Fortunately, modern language design and compiler techniques make it possible to mostly eliminate the performance trade-off and provide a single environment productive enough for prototyping and efficient enough for deploying performance-intensive applications. The Julia programming language fills this role: it is a flexible dynamic language, appropriate for scientific and numerical computing, with performance comparable to traditional statically-typed languages.

Because Julia's compiler is different from the interpreters used for languages like Python or R, you may find that Julia's performance is unintuitive at first. If you find that something is slow, we highly recommend reading through the [Performance Tips](#) section before trying anything else. Once you understand how Julia works, it is easy to write code that is nearly as fast as C.

1.3 Julia Compared to Other Languages

Julia features optional typing, multiple dispatch, and good performance, achieved using type inference and [just-in-time \(JIT\) compilation](#) (and [optional ahead-of-time compilation](#)), implemented using [LLVM](#). It is multi-paradigm, combining features of imperative, functional, and object-oriented programming. Julia provides ease and expressiveness for high-level numerical computing, in the same way as languages such as R, MATLAB, and Python, but also supports general programming. To achieve this, Julia builds upon the lineage of mathematical programming languages, but also borrows much from popular dynamic languages, including [Lisp](#), [Perl](#), [Python](#), [Lua](#), and [Ruby](#).

The most significant departures of Julia from typical dynamic languages are:

- The core language imposes very little; Julia Base and the standard library are written in Julia itself, including primitive operations like integer arithmetic
- A rich language of types for constructing and describing objects, that can also optionally be used to make type declarations
- The ability to define function behavior across many combinations of argument types via [multiple dispatch](#)
- Automatic generation of efficient, specialized code for different argument types
- Good performance, approaching that of statically-compiled languages like C

Although one sometimes speaks of dynamic languages as being "typeless", they are definitely not. Every object, whether primitive or user-defined, has a type. The lack of type declarations in most dynamic languages, however, means that one cannot instruct the compiler about the types of values, and often cannot explicitly talk about types at all. In static languages, on the other hand, while one can – and usually must – annotate types for the compiler, types exist only at compile time and cannot be manipulated or expressed at run time. In Julia, types are themselves run-time objects, and can also be used to convey information to the compiler.

What Makes Julia, Julia?

While the casual programmer need not explicitly use types or multiple dispatch, they are the core unifying features of Julia: functions are defined on different combinations of argument types, and applied by dispatching to the most specific matching definition. This model is a good fit for mathematical programming, where it is unnatural for the first argument to "own" an operation as in traditional object-oriented dispatch. Operators are just functions with special notation – to extend addition to new user-defined data types, you define new methods for the `+` function. Existing code then seamlessly applies to the new data types.

Partly because of run-time type inference (augmented by optional type annotations), and partly because of a strong focus on performance from the inception of the project, Julia's computational efficiency exceeds that of other dynamic languages, and even rivals that of statically-compiled languages. For large scale numerical problems, speed always has been, continues to be, and probably always will be crucial: the amount of data being processed has easily kept pace with Moore's Law over the past decades.

Advantages of Julia

Julia aims to create an unprecedented combination of ease-of-use, power, and efficiency in a single language. In addition to the above, some advantages of Julia over comparable systems include:

- Free and open source ([MIT licensed](#))
- User-defined types are as fast and compact as built-ins
- No need to vectorize code for performance; devectorized code is fast
- Designed for parallelism and distributed computation
- Lightweight "green" threading ([coroutines](#))
- Unobtrusive yet powerful type system
- Elegant and extensible conversions and promotions for numeric and other types
- Efficient support for [Unicode](#), including but not limited to [UTF-8](#)
- Call C functions directly (no wrappers or special APIs needed)
- Powerful shell-like capabilities for managing other processes
- Lisp-like macros and other metaprogramming facilities

Getting Started

If you are coming to Julia from one of the following languages, then you should start by reading the section on noteworthy differences from [MATLAB](#), [R](#), [Python](#), [C/C++](#) or [Common Lisp](#). This will help you avoid some common pitfalls since Julia differs from those languages in many subtle ways.

```
$ julia

      _       _
     (_      | (_) (_
      _ _    | | _ _ _
     | | | | | | / _ |
     | | | _ | | | (_ |
    _/ | \ _ ' _ | \ _ ' _ |
   | _/

Documentation: https://docs.julialang.org
Type "?" for help, "]"? for Pkg help.
Version 1.10.2 (2024-03-01)
Official https://julialang.org/ release

julia> 1 + 2
3

julia> ans
3
```

To evaluate expressions written in a source file `file.jl`, write `include("file.jl")`.

To run code in a file non-interactively, you can give it as the first argument to the `julia` command:

```
| $ julia script.jl
```

You can pass additional arguments to Julia, and to your program `script.jl`. A detailed list of all the available options can be found under [Command-line Interface](#).

2.1 Resources

A curated list of useful learning resources to help new users get started can be found on the [learning](#) page of the main Julia website.

You can use the REPL as a learning resource by switching into the help mode. Switch to help mode by pressing `?` at an empty `julia>` prompt, before typing anything else. Typing a keyword in help mode will fetch the documentation for it, along with examples. Similarly for most functions or other objects you might encounter!

```
| help?> begin
| search: begin disable_sigint reenable_sigint
|
|     begin
|
|     begin...end denotes a block of code.
```

If you already know Julia a bit, you might want to peek ahead at [Performance Tips](#) and [Workflow Tips](#).

Chapter 3

Variables

A variable, in Julia, is a name associated (or bound) to a value. It's useful when you want to store a value (that you obtained after some math, for example) for later use. For example:

```
# Assign the value 10 to the variable x
julia> x = 10
10

# Doing math with x's value
julia> x + 1
11

# Reassign x's value
julia> x = 1 + 1
2

# You can assign values of other types, like strings of text
julia> x = "Hello World!"
"Hello World!"
```

Julia provides an extremely flexible system for naming variables. Variable names are case-sensitive, and have no semantic meaning (that is, the language will not treat variables differently based on their names).

```
julia> x = 1.0
1.0

julia> y = -3
-3

julia> Z = "My string"
"My string"

julia> customary_phrase = "Hello world!"
"Hello world!"

julia> UniversalDeclarationOfHumanRightsStart = ""
""
```

Unicode names (in UTF-8 encoding) are allowed:

```
julia> δ = 0.00001
1.0e-5

julia> = "Hello"
"Hello"
```

In the Julia REPL and several other Julia editing environments, you can type many Unicode math symbols by typing the backslashed LaTeX symbol name followed by tab. For example, the variable name δ can be entered by typing `\delta-tab`, or even $\alpha^{\hat{2}}$ by `\alpha-tab-\hat-tab-\^(2)-tab`. (If you find a symbol somewhere, e.g. in someone else's code, that you don't know how to type, the REPL help will tell you: just type `?` and then paste the symbol.)

Julia will even let you redefine built-in constants and functions if needed (although this is not recommended to avoid potential confusions):

```
julia> pi = 3
3

julia> pi
3

julia> sqrt = 4
4
```

However, if you try to redefine a built-in constant or function already in use, Julia will give you an error:

```
julia> pi
π = 3.1415926535897...

julia> pi = 3
ERROR: cannot assign a value to imported variable Base.pi from module Main

julia> sqrt(100)
10.0

julia> sqrt = 4
ERROR: cannot assign a value to imported variable Base.sqrt from module Main
```

3.1 Allowed Variable Names

Variable names must begin with a letter (A-Z or a-z), underscore, or a subset of Unicode code points greater than 00A0; in particular, [Unicode character categories](#) Lu/Ll/Lt/Lm/Lo/Nl (letters), Sc/So (currency and other symbols), and a few other letter-like characters (e.g. a subset of the Sm math symbols) are allowed. Subsequent characters may also include `!` and digits (0-9 and other characters in categories Nd/No), as well as other Unicode code points: diacritics and other modifying marks (categories Mn/Mc/Me/Sk), some punctuation connectors (category Pc), primes, and a few other characters.

Operators like `+` are also valid identifiers, but are parsed specially. In some contexts, operators can be used just like variables; for example `(+)` refers to the addition function, and `(+) = f` will reassign it. Most

of the Unicode infix operators (in category Sm), such as \otimes , are parsed as infix operators and are available for user-defined methods (e.g. you can use `const \otimes = kron` to define \otimes as an infix Kronecker product). Operators can also be suffixed with modifying marks, primes, and sub/superscripts, e.g. `+â` is parsed as an infix operator with the same precedence as `+`. A space is required between an operator that ends with a subscript/superscript letter and a subsequent variable name. For example, if `+a` is an operator, then `+ax` must be written as `+a x` to distinguish it from `+ ax` where `ax` is the variable name.

A particular class of variable names is one that contains only underscores. These identifiers can only be assigned values, which are immediately discarded, and cannot therefore be used to assign values to other variables (i.e., they cannot be used as *rvalues*) or use the last value assigned to them in any way.

```
julia> x, __ = size([2 2; 1 1])
(2, 2)

julia> y = __
ERROR: syntax: all-underscore identifier used as rvalue

julia> println(__)
ERROR: syntax: all-underscore identifier used as rvalue
```

The only explicitly disallowed names for variables are the names of the built-in [Keywords](#):

```
julia> else = false
ERROR: syntax: unexpected "else"

julia> try = "No"
ERROR: syntax: unexpected "="
```

Some Unicode characters are considered to be equivalent in identifiers. Different ways of entering Unicode combining characters (e.g., accents) are treated as equivalent (specifically, Julia identifiers are *NFC*). Julia also includes a few non-standard equivalences for characters that are visually similar and are easily entered by some input methods. The Unicode characters ϵ (U+025B: Latin small letter open e) and μ (U+00B5: micro sign) are treated as equivalent to the corresponding Greek letters. The middle dot \cdot (U+00B7) and the Greek *interpunct* \cdot (U+0387) are both treated as the mathematical dot operator \cdot (U+22C5). The minus sign $-$ (U+2212) is treated as equivalent to the hyphen-minus sign $-$ (U+002D).

3.2 Assignment expressions and assignment versus mutation

An assignment `variable = value` "binds" the name `variable` to the value computed on the right-hand side, and the whole assignment is treated by Julia as an expression equal to the right-hand-side value. This means that assignments can be chained (the same value assigned to multiple variables with `variable1 = variable2 = value`) or used in other expressions, and is also why their result is shown in the REPL as the value of the right-hand side. (In general, the REPL displays the value of whatever expression you evaluate.) For example, here the value 4 of `b = 2+2` is used in another arithmetic operation and assignment:

```
julia> a = (b = 2+2) + 3
7

julia> a
```

```

7
julia> b
4

```

A common confusion is the distinction between assignment (giving a new "name" to a value) and mutation (changing a value). If you run `a = 2` followed by `a = 3`, you have changed the "name" `a` to refer to a new value 3 ... you haven't changed the number 2, so `2+2` will still give 4 and not 6! This distinction becomes more clear when dealing with mutable types like [arrays](#), whose contents can be changed:

```

julia> a = [1,2,3] # an array of 3 integers
3-element Vector{Int64}:
 1
 2
 3

julia> b = a # both b and a are names for the same array!
3-element Vector{Int64}:
 1
 2
 3

```

Here, the line `b = a` does not make a copy of the array `a`, it simply binds the name `b` to the same array `a`: both `b` and `a` "point" to one array `[1,2,3]` in memory. In contrast, an assignment `a[i] = value` changes the contents of the array, and the modified array will be visible through both the names `a` and `b`:

```

julia> a[1] = 42 # change the first element
42

julia> a = 3.14159 # a is now the name of a different object
3.14159

julia> b # b refers to the original array object, which has been mutated
3-element Vector{Int64}:
 42
 2
 3

```

That is, `a[i] = value` (an alias for [setindex!](#)) mutates an existing array object in memory, accessible via either `a` or `b`. Subsequently setting `a = 3.14159` does not change this array, it simply binds `a` to a different object; the array is still accessible via `b`. The other common syntax to mutate an existing object is `a.field = value` (an alias for [setproperty!](#)), which can be used to change a [mutable struct](#).

When you call a [function](#) in Julia, it behaves as if you assigned the argument values to new variable names corresponding to the function arguments, as discussed in [Argument-Passing Behavior](#). (By [convention](#), functions that mutate one or more of their arguments have names ending with `!`.)

3.3 Stylistic Conventions

While Julia imposes few restrictions on valid names, it has become useful to adopt the following conventions:

- Names of variables are in lower case.
- Word separation can be indicated by underscores ('_ '), but use of underscores is discouraged unless the name would be hard to read otherwise.
- Names of Types and Modules begin with a capital letter and word separation is shown with upper camel case instead of underscores.
- Names of functions and macros are in lower case, without underscores.
- Functions that write to their arguments have names that end in !. These are sometimes called "mutating" or "in-place" functions because they are intended to produce changes in their arguments after the function is called, not just return a value.

For more information about stylistic conventions, see the [Style Guide](#).

Chapter 4

Integers and Floating-Point Numbers

Integers and floating-point values are the basic building blocks of arithmetic and computation. Built-in representations of such values are called numeric primitives, while representations of integers and floating-point numbers as immediate values in code are known as numeric literals. For example, 1 is an integer literal, while 1.0 is a floating-point literal; their binary in-memory representations as objects are numeric primitives.

Julia provides a broad range of primitive numeric types, and a full complement of arithmetic and bitwise operators as well as standard mathematical functions are defined over them. These map directly onto numeric types and operations that are natively supported on modern computers, thus allowing Julia to take full advantage of computational resources. Additionally, Julia provides software support for [Arbitrary Precision Arithmetic](#), which can handle operations on numeric values that cannot be represented effectively in native hardware representations, but at the cost of relatively slower performance.

The following are Julia's primitive numeric types:

- **Integer types:**

Type	Signed?	Number of bits	Smallest value	Largest value
Int8	✓	8	-2^7	$2^7 - 1$
UInt8		8	0	$2^8 - 1$
Int16	✓	16	-2^{15}	$2^{15} - 1$
UInt16		16	0	$2^{16} - 1$
Int32	✓	32	-2^{31}	$2^{31} - 1$
UInt32		32	0	$2^{32} - 1$
Int64	✓	64	-2^{63}	$2^{63} - 1$
UInt64		64	0	$2^{64} - 1$
Int128	✓	128	-2^{127}	$2^{127} - 1$
UInt128		128	0	$2^{128} - 1$
Bool	N/A	8	false (0)	true (1)

- **Floating-point types:**

Additionally, full support for [Complex and Rational Numbers](#) is built on top of these primitive numeric types. All numeric types interoperate naturally without explicit casting, thanks to a flexible, user-extensible [type promotion system](#).

Type	Precision	Number of bits
Float16	half	16
Float32	single	32
Float64	double	64

4.1 Integers

Literal integers are represented in the standard manner:

```
julia> 1
1

julia> 1234
1234
```

The default type for an integer literal depends on whether the target system has a 32-bit architecture or a 64-bit architecture:

```
# 32-bit system:
julia> typeof(1)
Int32

# 64-bit system:
julia> typeof(1)
Int64
```

The Julia internal variable `Sys.WORD_SIZE` indicates whether the target system is 32-bit or 64-bit:

```
# 32-bit system:
julia> Sys.WORD_SIZE
32

# 64-bit system:
julia> Sys.WORD_SIZE
64
```

Julia also defines the types `Int` and `UInt`, which are aliases for the system's signed and unsigned native integer types respectively:

```
# 32-bit system:
julia> Int
Int32
julia> UInt
UInt32

# 64-bit system:
julia> Int
Int64
julia> UInt
UInt64
```

Larger integer literals that cannot be represented using only 32 bits but can be represented in 64 bits always create 64-bit integers, regardless of the system type:

```
# 32-bit or 64-bit system:  
julia> typeof(30000000000)  
Int64
```

Unsigned integers are input and output using the 0x prefix and hexadecimal (base 16) digits 0-9a-f (the capitalized digits A-F also work for input). The size of the unsigned value is determined by the number of hex digits used:

```
julia> x = 0x1  
0x01  
  
julia> typeof(x)  
UInt8  
  
julia> x = 0x123  
0x0123  
  
julia> typeof(x)  
UInt16  
  
julia> x = 0x1234567  
0x01234567  
  
julia> typeof(x)  
UInt32  
  
julia> x = 0x123456789abcdef  
0x0123456789abcdef  
  
julia> typeof(x)  
UInt64  
  
julia> x = 0x11112222333344445555666677778888  
0x11112222333344445555666677778888  
  
julia> typeof(x)  
UInt128
```

This behavior is based on the observation that when one uses unsigned hex literals for integer values, one typically is using them to represent a fixed numeric byte sequence, rather than just an integer value.

Binary and octal literals are also supported:

```
julia> x = 0b10  
0x02  
  
julia> typeof(x)  
UInt8
```

```
julia> x = 0o010
0x08

julia> typeof(x)
UInt8

julia> x = 0x00000000000000001111222233334444
0x00000000000000001111222233334444

julia> typeof(x)
UInt128
```

As for hexadecimal literals, binary and octal literals produce unsigned integer types. The size of the binary data item is the minimal needed size, if the leading digit of the literal is not 0. In the case of leading zeros, the size is determined by the minimal needed size for a literal, which has the same length but leading digit 1. It means that:

- 0x1 and 0x12 are UInt8 literals,
- 0x123 and 0x1234 are UInt16 literals,
- 0x12345 and 0x12345678 are UInt32 literals,
- 0x123456789 and 0x1234567890abcdef are UInt64 literals, etc.

Even if there are leading zero digits which don't contribute to the value, they count for determining storage size of a literal. So 0x01 is a UInt8 while 0x0001 is a UInt16.

That allows the user to control the size.

Unsigned literals (starting with 0x) that encode integers too large to be represented as UInt128 values will construct BigInt values instead. This is not an unsigned type but it is the only built-in type big enough to represent such large integer values.

Binary, octal, and hexadecimal literals may be signed by a - immediately preceding the unsigned literal. They produce an unsigned integer of the same size as the unsigned literal would do, with the two's complement of the value:

```
julia> -0x2
0xfe

julia> -0x0002
0xffff
```

The minimum and maximum representable values of primitive numeric types such as integers are given by the `typemin` and `typemax` functions:

```
julia> (typemin{Int32}, typemax{Int32})
(-2147483648, 2147483647)
```

```
julia> for T in [Int8, Int16, Int32, Int64, Int128, UInt8, UInt16, UInt32, UInt64, UInt128]
    println("${lpad(T, 7)}: [$(typemin(T)), $(typemax(T))]")
end
Int8: [-128, 127]
Int16: [-32768, 32767]
Int32: [-2147483648, 2147483647]
Int64: [-9223372036854775808, 9223372036854775807]
Int128: [-170141183460469231731687303715884105728, 170141183460469231731687303715884105727]
UInt8: [0, 255]
UInt16: [0, 65535]
UInt32: [0, 4294967295]
UInt64: [0, 18446744073709551615]
UInt128: [0, 340282366920938463463374607431768211455]
```

The values returned by `typemin` and `typemax` are always of the given argument type. (The above expression uses several features that have yet to be introduced, including `for` loops, `Strings`, and `Interpolation`, but should be easy enough to understand for users with some existing programming experience.)

Overflow behavior

In Julia, exceeding the maximum representable value of a given type results in a wraparound behavior:

```
julia> x = typemax(Int64)
9223372036854775807

julia> x + 1
-9223372036854775808

julia> x + 1 == typemin(Int64)
true
```

Thus, arithmetic with Julia integers is actually a form of `modular arithmetic`. This reflects the characteristics of the underlying arithmetic of integers as implemented on modern computers. In applications where overflow is possible, explicit checking for wraparound produced by overflow is essential; otherwise, the `BigInt` type in `Arbitrary Precision Arithmetic` is recommended instead.

An example of overflow behavior and how to potentially resolve it is as follows:

```
julia> 10^19
-8446744073709551616

julia> big(10)^19
10000000000000000000
```

Division errors

Integer division (the `div` function) has two exceptional cases: dividing by zero, and dividing the lowest negative number (`typemin`) by `-1`. Both of these cases throw a `DivideError`. The remainder and modulus functions (`rem` and `mod`) throw a `DivideError` when their second argument is zero.

4.2 Floating-Point Numbers

Literal floating-point numbers are represented in the standard formats, using [E-notation](#) when necessary:

```
julia> 1.0
1.0

julia> 1.
1.0

julia> 0.5
0.5

julia> .5
0.5

julia> -1.23
-1.23

julia> 1e10
1.0e10

julia> 2.5e-4
0.00025
```

The above results are all [Float64](#) values. Literal [Float32](#) values can be entered by writing an `f` in place of `e`:

```
julia> x = 0.5f0
0.5f0

julia> typeof(x)
Float32

julia> 2.5f-4
0.00025f0
```

Values can be converted to [Float32](#) easily:

```
julia> x = Float32(-1.5)
-1.5f0

julia> typeof(x)
Float32
```

Hexadecimal floating-point literals are also valid, but only as [Float64](#) values, with `p` preceding the base-2 exponent:

```
julia> 0x1p0
1.0
```

```
julia> 0x1.8p3
12.0

julia> x = 0x.4p-1
0.125

julia> typeof(x)
Float64
```

Half-precision floating-point numbers are also supported ([Float16](#)), but they are implemented in software and use [Float32](#) for calculations.

```
julia> sizeof(Float16(4.))
2

julia> 2*Float16(4.)
Float16(8.0)
```

The underscore `_` can be used as digit separator:

```
julia> 10_000, 0.000_000_005, 0xdead_beef, 0b1011_0010
(10000, 5.0e-9, 0xdeadbeef, 0xb2)
```

Floating-point zero

Floating-point numbers have **two zeros**, positive zero and negative zero. They are equal to each other but have different binary representations, as can be seen using the **bitstring** function:

[illegible]

Special floating-point values

There are three specified standard floating-point values that do not correspond to any point on the real number line:

For further discussion of how these non-finite floating-point values are ordered with respect to each other and other floats, see [Numeric Comparisons](#). By the [IEEE 754 standard](#), these floating-point values are the results of certain arithmetic operations:

```
julia> 1/Inf
0.0
```

Float16	Float32	Float64	Name	Description
Inf16	Inf32	Inf	positive infinity	a value greater than all finite floating-point values
-Inf16	-Inf32	-Inf	negative infinity	a value less than all finite floating-point values
NaN16	NaN32	NaN	not a number	a value not == to any floating-point value (including itself)

```

julia> 1/0
Inf

julia> -5/0
-Inf

julia> 0.000001/0
Inf

julia> 0/0
NaN

julia> 500 + Inf
Inf

julia> 500 - Inf
-Inf

julia> Inf + Inf
Inf

julia> Inf - Inf
NaN

julia> Inf * Inf
Inf

julia> Inf / Inf
NaN

julia> 0 * Inf
NaN

julia> NaN == NaN
false

julia> NaN != NaN
true

julia> NaN < NaN
false

julia> NaN > NaN
false

```

The `typemin` and `typemax` functions also apply to floating-point types:

```
julia> (typemin(Float16), typemax(Float16))
(-Inf16, Inf16)

julia> (typemin(Float32), typemax(Float32))
(-Inf32, Inf32)

julia> (typemin(Float64), typemax(Float64))
(-Inf, Inf)
```

Machine epsilon

Most real numbers cannot be represented exactly with floating-point numbers, and so for many purposes it is important to know the distance between two adjacent representable floating-point numbers, which is often known as *machine epsilon*.

Julia provides `eps`, which gives the distance between `1.0` and the next larger representable floating-point value:

```
julia> eps(Float32)
1.1920929f-7

julia> eps(Float64)
2.220446049250313e-16

julia> eps() # same as eps(Float64)
2.220446049250313e-16
```

These values are 2.0^{-23} and 2.0^{-52} as `Float32` and `Float64` values, respectively. The `eps` function can also take a floating-point value as an argument, and gives the absolute difference between that value and the next representable floating point value. That is, `eps(x)` yields a value of the same type as `x` such that `x + eps(x)` is the next representable floating-point value larger than `x`:

```
julia> eps(1.0)
2.220446049250313e-16

julia> eps(1000.)
1.1368683772161603e-13

julia> eps(1e-27)
1.793662034335766e-43

julia> eps(0.0)
5.0e-324
```

The distance between two adjacent representable floating-point numbers is not constant, but is smaller for smaller values and larger for larger values. In other words, the representable floating-point numbers are densest in the real number line near zero, and grow sparser exponentially as one moves farther away from zero. By definition, `eps(1.0)` is the same as `eps(Float64)` since `1.0` is a 64-bit floating-point value.

Julia also provides the `nextfloat` and `prevfloat` functions which return the next largest or smallest representable floating-point number to the argument respectively:

```
julia> x = 1.25f0
1.25f0

julia> nextfloat(x)
1.2500001f0

julia> prevfloat(x)
1.2499999f0

julia> bitstring(prevfloat(x))
"00111111100111111111111111111111"

julia> bitstring(x)
"00111111101000000000000000000000"

julia> bitstring(nextfloat(x))
"00111111101000000000000000000001"
```

This example highlights the general principle that the adjacent representable floating-point numbers also have adjacent binary integer representations.

Rounding modes

If a number doesn't have an exact floating-point representation, it must be rounded to an appropriate representable value. However, the manner in which this rounding is done can be changed if required according to the rounding modes presented in the [IEEE 754 standard](#).

The default mode used is always `RoundNearest`, which rounds to the nearest representable value, with ties rounded towards the nearest value with an even least significant bit.

Background and References

Floating-point arithmetic entails many subtleties which can be surprising to users who are unfamiliar with the low-level implementation details. However, these subtleties are described in detail in most books on scientific computation, and also in the following references:

- The definitive guide to floating point arithmetic is the [IEEE 754-2008 Standard](#); however, it is not available for free online.
- For a brief but lucid presentation of how floating-point numbers are represented, see John D. Cook's [article](#) on the subject as well as his [introduction](#) to some of the issues arising from how this representation differs in behavior from the idealized abstraction of real numbers.
- Also recommended is Bruce Dawson's [series of blog posts on floating-point numbers](#).
- For an excellent, in-depth discussion of floating-point numbers and issues of numerical accuracy encountered when computing with them, see David Goldberg's paper [What Every Computer Scientist Should Know About Floating-Point Arithmetic](#).

- For even more extensive documentation of the history of, rationale for, and issues with floating-point numbers, as well as discussion of many other topics in numerical computing, see the [collected writings](#) of [William Kahan](#), commonly known as the "Father of Floating-Point". Of particular interest may be [An Interview with the Old Man of Floating-Point](#).

4.3 Arbitrary Precision Arithmetic

To allow computations with arbitrary-precision integers and floating point numbers, Julia wraps the [GNU Multiple Precision Arithmetic Library \(GMP\)](#) and the [GNU MPFR Library](#), respectively. The [BigInt](#) and [BigFloat](#) types are available in Julia for arbitrary precision integer and floating point numbers respectively.

Constructors exist to create these types from primitive numerical types, and the `string literal @big_str` or `parse` can be used to construct them from AbstractStrings. BigInts can also be input as integer literals when they are too big for other built-in integer types. Note that as there is no unsigned arbitrary-precision integer type in Base (BigInt is sufficient in most cases), hexadecimal, octal and binary literals can be used (in addition to decimal literals).

Once created, they participate in arithmetic with all other numeric types thanks to Julia's [type promotion and conversion mechanism](#):

[illegible]

However, type promotion between the primitive types above and `BigInt/BigFloat` is not automatic and must be explicitly stated.

```
julia> x = typemin(Int64)
-9223372036854775808

julia> x = x - 1
9223372036854775807

julia> typeof(x)
Int64

julia> y = BigInt(typemin(Int64))
-9223372036854775808

julia> y = y - 1
-9223372036854775809

julia> typeof(y)
BigInt
```

The default precision (in number of bits of the significand) and rounding mode of `BigFloat` operations can be changed globally by calling `setprecision` and `setrounding`, and all further calculations will take these changes in account. Alternatively, the precision or the rounding can be changed only within the execution of a particular block of code by using the same functions with a `do` block:

[illegible]

4.4 Numeric Literal Coefficients

To make common numeric formulae and expressions clearer, Julia allows variables to be immediately preceded by a numeric literal, implying multiplication. This makes writing polynomial expressions much cleaner:

```
julia> x = 3
3
julia> 2x^2 - 3x + 1
```

```
10
julia> 1.5x^2 - .5x + 1
13.0
```

It also makes writing exponential functions more elegant:

```
julia> 2^2x
64
```

The precedence of numeric literal coefficients is slightly lower than that of unary operators such as negation. So $-2x$ is parsed as $(-2) * x$ and $\sqrt{2}x$ is parsed as $(\sqrt{2}) * x$. However, numeric literal coefficients parse similarly to unary operators when combined with exponentiation. For example 2^3x is parsed as $2^{(3x)}$, and $2x^3$ is parsed as $2*(x^3)$.

Numeric literals also work as coefficients to parenthesized expressions:

```
julia> 2(x-1)^2 - 3(x-1) + 1
3
```

Note

The precedence of numeric literal coefficients used for implicit multiplication is higher than other binary operators such as multiplication ($*$), and division ($/$, \backslash , and $//$). This means, for example, that $1 / 2im$ equals $-0.5im$ and $6 // 2(2 + 1)$ equals $1 // 1$.

Additionally, parenthesized expressions can be used as coefficients to variables, implying multiplication of the expression by the variable:

```
julia> (x-1)x
6
```

Neither juxtaposition of two parenthesized expressions, nor placing a variable before a parenthesized expression, however, can be used to imply multiplication:

```
julia> (x-1)(x+1)
ERROR: MethodError: objects of type Int64 are not callable

julia> x(x+1)
ERROR: MethodError: objects of type Int64 are not callable
```

Both expressions are interpreted as function application: any expression that is not a numeric literal, when immediately followed by a parenthetical, is interpreted as a function applied to the values in parentheses (see [Functions](#) for more about functions). Thus, in both of these cases, an error occurs since the left-hand value is not a function.

The above syntactic enhancements significantly reduce the visual noise incurred when writing common mathematical formulae. Note that no whitespace may come between a numeric literal coefficient and the identifier or parenthesized expression which it multiplies.

Syntax Conflicts

Juxtaposed literal coefficient syntax may conflict with some numeric literal syntaxes: hexadecimal, octal and binary integer literals and engineering notation for floating-point literals. Here are some situations where syntactic conflicts arise:

- The hexadecimal integer literal expression `0xff` could be interpreted as the numeric literal `0` multiplied by the variable `xff`. Similar ambiguities arise with octal and binary literals like `0o777` or `0b01001010`.
- The floating-point literal expression `1e10` could be interpreted as the numeric literal `1` multiplied by the variable `e10`, and similarly with the equivalent `E` form.
- The 32-bit floating-point literal expression `1.5f22` could be interpreted as the numeric literal `1.5` multiplied by the variable `f22`.

In all cases the ambiguity is resolved in favor of interpretation as numeric literals:

- Expressions starting with `0x/0o/0b` are always hexadecimal/octal/binary literals.
- Expressions starting with a numeric literal followed by `e` or `E` are always floating-point literals.
- Expressions starting with a numeric literal followed by `f` are always 32-bit floating-point literals.

Unlike `E`, which is equivalent to `e` in numeric literals for historical reasons, `F` is just another letter and does not behave like `f` in numeric literals. Hence, expressions starting with a numeric literal followed by `F` are interpreted as the numerical literal multiplied by a variable, which means that, for example, `1.5F22` is equal to `1.5 * F22`.

4.5 Literal zero and one

Julia provides functions which return literal `0` and `1` corresponding to a specified type or the type of a given variable.

Function	Description
<code>zero(x)</code>	Literal zero of type <code>x</code> or type of variable <code>x</code>
<code>one(x)</code>	Literal one of type <code>x</code> or type of variable <code>x</code>

These functions are useful in [Numeric Comparisons](#) to avoid overhead from unnecessary [type conversion](#).

Examples:

```
julia> zero(Float32)
0.0f0

julia> zero(1.0)
0.0

julia> one(Int32)
1

julia> one(BigFloat)
1.0
```

Chapter 5

Mathematical Operations and Elementary Functions

Julia provides a complete collection of basic arithmetic and bitwise operators across all of its numeric primitive types, as well as providing portable, efficient implementations of a comprehensive collection of standard mathematical functions.

5.1 Arithmetic Operators

The following [arithmetic operators](#) are supported on all primitive numeric types:

Expression	Name	Description
<code>+x</code>	unary plus	the identity operation
<code>-x</code>	unary minus	maps values to their additive inverses
<code>x + y</code>	binary plus	performs addition
<code>x - y</code>	binary minus	performs subtraction
<code>x * y</code>	times	performs multiplication
<code>x / y</code>	divide	performs division
<code>x ÷ y</code>	integer divide	x / y , truncated to an integer
<code>x \ y</code>	inverse divide	equivalent to y / x
<code>x ^ y</code>	power	raises x to the y th power
<code>x % y</code>	remainder	equivalent to <code>rem(x,y)</code>

A numeric literal placed directly before an identifier or parentheses, e.g. `2x` or `2(x+y)`, is treated as a multiplication, except with higher precedence than other binary operations. See [Numeric Literal Coefficients](#) for details.

Julia's promotion system makes arithmetic operations on mixtures of argument types "just work" naturally and automatically. See [Conversion and Promotion](#) for details of the promotion system.

The `÷` sign can be conveniently typed by writing `\div<tab>` to the REPL or Julia IDE. See the [manual section on Unicode input](#) for more information.

Here are some simple examples using arithmetic operators:

```
julia> 1 + 2 + 3
6
```

```
julia> 1 - 2
-1

julia> 3*2/12
0.5
```

(By convention, we tend to space operators more tightly if they get applied before other nearby operators. For instance, we would generally write `-x + 2` to reflect that first `x` gets negated, and then 2 is added to that result.)

When used in multiplication, `false` acts as a strong zero:

```
julia> NaN * false
0.0

julia> false * Inf
0.0
```

This is useful for preventing the propagation of NaN values in quantities that are known to be zero. See [Knuth \(1992\)](#) for motivation.

5.2 Boolean Operators

The following [Boolean operators](#) are supported on `Bool` types:

Expression	Name
<code>!x</code>	negation
<code>x && y</code>	short-circuiting and
<code>x y</code>	short-circuiting or

Negation changes `true` to `false` and vice versa. The short-circuiting operations are explained on the linked page.

Note that `Bool` is an integer type and all the usual promotion rules and numeric operators are also defined on it.

5.3 Bitwise Operators

The following [bitwise operators](#) are supported on all primitive integer types:

Here are some examples with bitwise operators:

```
julia> ~123
-124

julia> 123 & 234
106

julia> 123 | 234
```

Expression	Name
<code>~x</code>	bitwise not
<code>x & y</code>	bitwise and
<code>x y</code>	bitwise or
<code>x ⊕ y</code>	bitwise xor (exclusive or)
<code>x y</code>	bitwise nand (not and)
<code>x y</code>	bitwise nor (not or)
<code>x >>> y</code>	logical shift right
<code>x >> y</code>	arithmetic shift right
<code>x << y</code>	logical/arithmetic shift left

```

251
julia> 123 ⊕ 234
145
julia> xor(123, 234)
145
julia> nand(123, 123)
-124
julia> 123 123
-124
julia> nor(123, 124)
-128
julia> 123 124
-128
julia> ~UInt32(123)
0xffffffff84
julia> ~UInt8(123)
0x84

```

5.4 Updating operators

Every binary arithmetic and bitwise operator also has an updating version that assigns the result of the operation back into its left operand. The updating version of the binary operator is formed by placing a `=` immediately after the operator. For example, writing `x += 3` is equivalent to writing `x = x + 3`:

```

julia> x = 1
1
julia> x += 3
4

```

```
julia> x
4
```

The updating versions of all the binary arithmetic and bitwise operators are:

```
+= -= *= /= \= += %= ^= &= |= ⊔= >>= >> <<=
```

Note

An updating operator rebinds the variable on the left-hand side. As a result, the type of the variable may change.

```
julia> x = 0x01; typeof(x)
UInt8

julia> x *= 2 # Same as x = x * 2
2

julia> typeof(x)
Int64
```

5.5 Vectorized "dot" operators

For every binary operation like \wedge , there is a corresponding "dot" operation $\wedge\cdot$ that is automatically defined to perform \wedge element-by-element on arrays. For example, $[1,2,3] \wedge 3$ is not defined, since there is no standard mathematical meaning to "cubing" a (non-square) array, but $[1,2,3] \wedge\cdot 3$ is defined as computing the elementwise (or "vectorized") result $[1^3, 2^3, 3^3]$. Similarly for unary operators like $!$ or $\sqrt{}$, there is a corresponding $\cdot\sqrt{}$ that applies the operator elementwise.

```
julia> [1,2,3] .^ 3
3-element Vector{Int64}:
 1
 8
27
```

More specifically, $a \wedge\cdot b$ is parsed as the "dot" call $(\wedge)\cdot(a,b)$, which performs a [broadcast](#) operation: it can combine arrays and scalars, arrays of the same size (performing the operation elementwise), and even arrays of different shapes (e.g. combining row and column vectors to produce a matrix). Moreover, like all vectorized "dot calls," these "dot operators" are fusing. For example, if you compute $2 \cdot\cdot * A \cdot\cdot^2 \cdot\cdot + \sin\cdot(A)$ (or equivalently $@. 2A^2 + \sin(A)$, using the [@.](#) macro) for an array A , it performs a single loop over A , computing $2a^2 + \sin(a)$ for each element a of A . In particular, nested dot calls like $f\cdot(g\cdot(x))$ are fused, and "adjacent" binary operators like $x \cdot\cdot + 3 \cdot\cdot * x \cdot\cdot^2$ are equivalent to nested dot calls $(+)\cdot(x, (*)\cdot(3, (\wedge)\cdot(x, 2)))$.

Furthermore, "dotted" updating operators like $a \cdot\cdot += b$ (or $@. a \cdot\cdot += b$) are parsed as $a \cdot\cdot = a \cdot\cdot + b$, where $\cdot\cdot =$ is a fused in-place assignment operation (see the [dot syntax documentation](#)).

Note the dot syntax is also applicable to user-defined operators. For example, if you define $\otimes(A,B) = \text{kron}(A,B)$ to give a convenient infix syntax $A \otimes B$ for Kronecker products ([kron](#)), then $[A,B] \cdot\cdot \otimes [C,D]$ will compute $[A \otimes C, B \otimes D]$ with no additional coding.

Combining dot operators with numeric literals can be ambiguous. For example, it is not clear whether `1.+x` means `1. + x` or `1 .+ x`. Therefore this syntax is disallowed, and spaces must be used around the operator in such cases.

5.6 Numeric Comparisons

Standard comparison operations are defined for all the primitive numeric types:

Operator	Name
<code>==</code>	equality
<code>!=</code> , <code>≠</code>	inequality
<code><</code>	less than
<code><=</code> , <code>≤</code>	less than or equal to
<code>></code>	greater than
<code>>=</code> , <code>≥</code>	greater than or equal to

Here are some simple examples:

```
julia> 1 == 1
true

julia> 1 == 2
false

julia> 1 != 2
true

julia> 1 == 1.0
true

julia> 1 < 2
true

julia> 1.0 > 3
false

julia> 1 >= 1.0
true

julia> -1 <= 1
true

julia> -1 <= -1
true

julia> -1 <= -2
false

julia> 3 < -0.5
false
```

Integers are compared in the standard manner – by comparison of bits. Floating-point numbers are compared according to the [IEEE 754 standard](#):

- Finite numbers are ordered in the usual manner.
- Positive zero is equal but not greater than negative zero.
- Inf is equal to itself and greater than everything else except NaN.
- -Inf is equal to itself and less than everything else except NaN.
- NaN is not equal to, not less than, and not greater than anything, including itself.

The last point is potentially surprising and thus worth noting:

```
julia> NaN == NaN
false

julia> NaN != NaN
true

julia> NaN < NaN
false

julia> NaN > NaN
false
```

and can cause headaches when working with [arrays](#):

```
julia> [1 NaN] == [1 NaN]
false
```

Julia provides additional functions to test numbers for special values, which can be useful in situations like hash key comparisons:

Function	Tests if
isequal(x, y)	x and y are identical
isfinite(x)	x is a finite number
isinf(x)	x is infinite
isnan(x)	x is not a number

[isequal](#) considers NaNs equal to each other:

```
julia> isequal(NaN, NaN)
true

julia> isequal([1 NaN], [1 NaN])
true

julia> isequal(NaN, NaN32)
true
```

`isequal` can also be used to distinguish signed zeros:

```
julia> -0.0 == 0.0
true

julia> isequal(-0.0, 0.0)
false
```

Mixed-type comparisons between signed integers, unsigned integers, and floats can be tricky. A great deal of care has been taken to ensure that Julia does them correctly.

For other types, `isequal` defaults to calling `==`, so if you want to define equality for your own types then you only need to add a `==` method. If you define your own equality function, you should probably define a corresponding `hash` method to ensure that `isequal(x,y)` implies `hash(x) == hash(y)`.

Chaining comparisons

Unlike most languages, with the [notable exception of Python](#), comparisons can be arbitrarily chained:

```
julia> 1 < 2 <= 2 < 3 == 3 > 2 >= 1 == 1 < 3 != 5
true
```

Chaining comparisons is often quite convenient in numerical code. Chained comparisons use the `&&` operator for scalar comparisons, and the `&` operator for elementwise comparisons, which allows them to work on arrays. For example, `0 .< A .< 1` gives a boolean array whose entries are true where the corresponding elements of `A` are between 0 and 1.

Note the evaluation behavior of chained comparisons:

```
julia> v(x) = (println(x); x)
v (generic function with 1 method)

julia> v(1) < v(2) <= v(3)
2
1
3
true

julia> v(1) > v(2) <= v(3)
2
1
false
```

The middle expression is only evaluated once, rather than twice as it would be if the expression were written as `v(1) < v(2) && v(2) <= v(3)`. However, the order of evaluations in a chained comparison is undefined. It is strongly recommended not to use expressions with side effects (such as printing) in chained comparisons. If side effects are required, the short-circuit `&&` operator should be used explicitly (see [Short-Circuit Evaluation](#)).

Elementary Functions

Julia provides a comprehensive collection of mathematical functions and operators. These mathematical operations are defined over as broad a class of numerical values as permit sensible definitions, including integers, floating-point numbers, rationals, and complex numbers, wherever such definitions make sense.

Moreover, these functions (like any Julia function) can be applied in "vectorized" fashion to arrays and other collections with the [dot syntax](#) `f.(A)`, e.g. `sin.(A)` will compute the sine of each element of an array `A`.

5.7 Operator Precedence and Associativity

Julia applies the following order and associativity of operations, from highest precedence to lowest:

Category	Operators	Associativity
Syntax	<code>.</code> followed by <code>:</code>	Left
Exponentiation	<code>^</code>	Right
Unary	<code>+</code> <code>-</code> <code>√</code>	Right ¹
Bitshifts	<code><<</code> <code>>></code> <code>>>></code>	Left
Fractions	<code>//</code>	Left
Multiplication	<code>*</code> <code>/</code> <code>%</code> <code>&</code> <code>\</code> <code>÷</code>	Left ²
Addition	<code>+</code> <code>-</code> <code> </code> <code>⊔</code>	Left ²
Syntax	<code>:</code> <code>..</code>	Left
Syntax	<code> ></code>	Left
Syntax	<code>< </code>	Right
Comparisons	<code>></code> <code><</code> <code>>=</code> <code><=</code> <code>==</code> <code>===</code> <code>!=</code> <code>!==</code> <code><:</code>	Non-associative
Control flow	<code>&&</code> followed by <code> </code> followed by <code>?</code>	Right
Pair	<code>=></code>	Right
Assignments	<code>=</code> <code>+=</code> <code>-=</code> <code>*=</code> <code>/=</code> <code>//=</code> <code>\=</code> <code>^=</code> <code>÷=</code> <code>%=</code> <code> =</code> <code>&=</code> <code>⊔=</code> <code><<=</code> <code>>>=</code> <code>>>>=</code>	Right

For a complete list of every Julia operator's precedence, see the top of this file: [src/julia-parser.scm](#). Note that some of the operators there are not defined in the Base module but may be given definitions by standard libraries, packages or user code.

You can also find the numerical precedence for any given operator via the built-in function `Base.operator_precedence`, where higher numbers take precedence:

```
julia> Base.operator_precedence(:+), Base.operator_precedence(:*), Base.operator_precedence(:.)
(11, 12, 17)

julia> Base.operator_precedence(:sin), Base.operator_precedence(:+=),
↳ Base.operator_precedence(:=) # (Note the necessary parens on `:(=)`)
(0, 1, 1)
```

A symbol representing the operator associativity can also be found by calling the built-in function `Base.operator_associativity`:

¹The unary operators `+` and `-` require explicit parentheses around their argument to disambiguate them from the operator `++`, etc. Other compositions of unary operators are parsed with right-associativity, e. g., `√√-a` as `√(√(-a))`.

²The operators `+`, `++` and `*` are non-associative. `a + b + c` is parsed as `+(a, b, c)` not `+(+(a, b), c)`. However, the fallback methods for `+(a, b, c, d...)` and `*(a, b, c, d...)` both default to left-associative evaluation.

```
julia> Base.operator_associativity(:-), Base.operator_associativity(:+),
↳ Base.operator_associativity(:^)
(:left, :none, :right)

julia> Base.operator_associativity(:*), Base.operator_associativity(:sin),
↳ Base.operator_associativity(:→)
(:left, :none, :right)
```

Note that symbols such as `:sin` return precedence 0. This value represents invalid operators and not operators of lowest precedence. Similarly, such operators are assigned associativity `:none`.

[Numeric literal coefficients](#), e.g. `2x`, are treated as multiplications with higher precedence than any other binary operation, with the exception of `^` where they have higher precedence only as the exponent.

```
julia> x = 3; 2x^2
18

julia> x = 3; 2^2x
64
```

Juxtaposition parses like a unary operator, which has the same natural asymmetry around exponents: `-x^y` and `2x^y` parse as `-(x^y)` and `2(x^y)` whereas `x^-y` and `x^2y` parse as `x^(-y)` and `x^(2y)`.

5.8 Numerical Conversions

Julia supports three forms of numerical conversion, which differ in their handling of inexact conversions.

- The notation `T(x)` or `convert(T, x)` converts `x` to a value of type `T`.
 - If `T` is a floating-point type, the result is the nearest representable value, which could be positive or negative infinity.
 - If `T` is an integer type, an `InexactError` is raised if `x` is not representable by `T`.
- `x % T` converts an integer `x` to a value of integer type `T` congruent to `x` modulo 2^n , where `n` is the number of bits in `T`. In other words, the binary representation is truncated to fit.
- The [Rounding functions](#) take a type `T` as an optional argument. For example, `round{Int}(x)` is a shorthand for `Int(round(x))`.

The following examples show the different forms.

```
julia> Int8(127)
127

julia> Int8(128)
ERROR: InexactError: trunc{Int8, 128}
Stacktrace:
[...]

```

```

julia> Int8(127.0)
127

julia> Int8(3.14)
ERROR: InexactError: Int8(3.14)
Stacktrace:
[...]

julia> Int8(128.0)
ERROR: InexactError: Int8(128.0)
Stacktrace:
[...]

julia> 127 % Int8
127

julia> 128 % Int8
-128

julia> round(Int8, 127.4)
127

julia> round(Int8, 127.6)
ERROR: InexactError: trunc(Int8, 128.0)
Stacktrace:
[...]

```

See [Conversion and Promotion](#) for how to define your own conversions and promotions.

Rounding functions

Function	Description	Return type
round(x)	round x to the nearest integer	<code>typeof(x)</code>
round(T, x)	round x to the nearest integer	T
floor(x)	round x towards -Inf	<code>typeof(x)</code>
floor(T, x)	round x towards -Inf	T
ceil(x)	round x towards +Inf	<code>typeof(x)</code>
ceil(T, x)	round x towards +Inf	T
trunc(x)	round x towards zero	<code>typeof(x)</code>
trunc(T, x)	round x towards zero	T

Division functions

Sign and absolute value functions

Powers, logs and roots

For an overview of why functions like [hypot](#), [expm1](#), and [log1p](#) are necessary and useful, see John D. Cook's excellent pair of blog posts on the subject: [expm1](#), [log1p](#), [erfc](#), and [hypot](#).

Function	Description
<code>div(x,y)</code> , $x \div y$	truncated division; quotient rounded towards zero
<code>fld(x,y)</code>	floored division; quotient rounded towards $-\text{Inf}$
<code>cld(x,y)</code>	ceiling division; quotient rounded towards $+\text{Inf}$
<code>rem(x,y)</code> , $x \% y$	remainder; satisfies $x == \text{div}(x,y)*y + \text{rem}(x,y)$; sign matches x
<code>mod(x,y)</code>	modulus; satisfies $x == \text{fld}(x,y)*y + \text{mod}(x,y)$; sign matches y
<code>mod1(x,y)</code>	mod with offset 1; returns $r \in (0,y]$ for $y > 0$ or $r \in [y,0)$ for $y < 0$, where $\text{mod}(r, y) == \text{mod}(x, y)$
<code>mod2pi(x)</code>	modulus with respect to 2π ; $0 \leq \text{mod2pi}(x) < 2\pi$
<code>divrem(x,y)</code>	returns $(\text{div}(x,y), \text{rem}(x,y))$
<code>fldmod(x,y)</code>	returns $(\text{fld}(x,y), \text{mod}(x,y))$
<code>gcd(x,y,...)</code>	greatest positive common divisor of x, y, \dots
<code>lcm(x,y,...)</code>	least positive common multiple of x, y, \dots

Function	Description
<code>abs(x)</code>	a positive value with the magnitude of x
<code>abs2(x)</code>	the squared magnitude of x
<code>sign(x)</code>	indicates the sign of x , returning $-1, 0$, or $+1$
<code>signbit(x)</code>	indicates whether the sign bit is on (true) or off (false)
<code>copysign(x,y)</code>	a value with the magnitude of x and the sign of y
<code>flipsign(x,y)</code>	a value with the magnitude of x and the sign of $x*y$

Function	Description
<code>sqrt(x)</code> , \sqrt{x}	square root of x
<code>cbrt(x)</code> , $\sqrt[3]{x}$	cube root of x
<code>hypot(x,y)</code>	hypotenuse of right-angled triangle with other sides of length x and y
<code>exp(x)</code>	natural exponential function at x
<code>expm1(x)</code>	accurate $\exp(x) - 1$ for x near zero
<code>ldexp(x,n)</code>	$x*2^n$ computed efficiently for integer values of n
<code>log(x)</code>	natural logarithm of x
<code>log(b,x)</code>	base b logarithm of x
<code>log2(x)</code>	base 2 logarithm of x
<code>log10(x)</code>	base 10 logarithm of x
<code>log1p(x)</code>	accurate $\log(1+x)$ for x near zero
<code>exponent(x)</code>	binary exponent of x
<code>significand(x)</code>	binary significand (a.k.a. mantissa) of a floating-point number x

Trigonometric and hyperbolic functions

All the standard trigonometric and hyperbolic functions are also defined:

<code>sin</code>	<code>cos</code>	<code>tan</code>	<code>cot</code>	<code>sec</code>	<code>csc</code>
<code>sinh</code>	<code>cosh</code>	<code>tanh</code>	<code>coth</code>	<code>sech</code>	<code>csch</code>
<code>asin</code>	<code>acos</code>	<code>atan</code>	<code>acot</code>	<code>asec</code>	<code>acsc</code>
<code>asinh</code>	<code>acosh</code>	<code>atanh</code>	<code>acoth</code>	<code>asech</code>	<code>acsch</code>
<code>sinc</code>	<code>cosc</code>				

These are all single-argument functions, with `atan` also accepting two arguments corresponding to a traditional `atan2` function.

Additionally, `sinpi(x)` and `cospi(x)` are provided for more accurate computations of `sin(pi*x)` and `cos(pi*x)` respectively.

In order to compute trigonometric functions with degrees instead of radians, suffix the function with `d`. For example, `sind(x)` computes the sine of `x` where `x` is specified in degrees. The complete list of trigonometric functions with degree variants is:

<code>sind</code>	<code>cosd</code>	<code>tand</code>	<code>cotd</code>	<code>secd</code>	<code>cscd</code>
<code>asind</code>	<code>acosd</code>	<code>atand</code>	<code>acotd</code>	<code>asecd</code>	<code>acscd</code>

Special functions

Many other special mathematical functions are provided by the package `SpecialFunctions.jl`.

Chapter 6

Complex and Rational Numbers

Julia includes predefined types for both complex and rational numbers, and supports all the standard [Mathematical Operations and Elementary Functions](#) on them. [Conversion and Promotion](#) are defined so that operations on any combination of predefined numeric types, whether primitive or composite, behave as expected.

6.1 Complex Numbers

The global constant `im` is bound to the complex number i , representing the principal square root of -1 . (Using mathematicians' i or engineers' j for this global constant was rejected since they are such popular index variable names.) Since Julia allows numeric literals to be [juxtaposed with identifiers as coefficients](#), this binding suffices to provide convenient syntax for complex numbers, similar to the traditional mathematical notation:

```
julia> 1+2im
1 + 2im
```

You can perform all the standard arithmetic operations with complex numbers:

```
julia> (1 + 2im)*(2 - 3im)
8 + 1im

julia> (1 + 2im)/(1 - 2im)
-0.6 + 0.8im

julia> (1 + 2im) + (1 - 2im)
2 + 0im

julia> (-3 + 2im) - (5 - 1im)
-8 + 3im

julia> (-1 + 2im)^2
-3 - 4im

julia> (-1 + 2im)^2.5
2.729624464784009 - 6.9606644595719im
```

```
julia> (-1 + 2im)^(1 + 1im)
-0.27910381075826657 + 0.08708053414102428im

julia> 3(2 - 5im)
6 - 15im

julia> 3(2 - 5im)^2
-63 - 60im

julia> 3(2 - 5im)^-1.0
0.20689655172413793 + 0.5172413793103449im
```

The promotion mechanism ensures that combinations of operands of different types just work:

```
julia> 2(1 - 1im)
2 - 2im

julia> (2 + 3im) - 1
1 + 3im

julia> (1 + 2im) + 0.5
1.5 + 2.0im

julia> (2 + 3im) - 0.5im
2.0 + 2.5im

julia> 0.75(1 + 2im)
0.75 + 1.5im

julia> (2 + 3im) / 2
1.0 + 1.5im

julia> (1 - 3im) / (2 + 2im)
-0.5 - 1.0im

julia> 2im^2
-2 + 0im

julia> 1 + 3/4im
1.0 - 0.75im
```

Note that $3/4im == 3/(4*im) == -(3/4*im)$, since a literal coefficient binds more tightly than division.

Standard functions to manipulate complex values are provided:

```
julia> z = 1 + 2im
1 + 2im

julia> real(1 + 2im) # real part of z
1
```

```
julia> imag(1 + 2im) # imaginary part of z
2

julia> conj(1 + 2im) # complex conjugate of z
1 - 2im

julia> abs(1 + 2im) # absolute value of z
2.23606797749979

julia> abs2(1 + 2im) # squared absolute value
5

julia> angle(1 + 2im) # phase angle in radians
1.1071487177940904
```

As usual, the absolute value ([abs](#)) of a complex number is its distance from zero. [abs2](#) gives the square of the absolute value, and is of particular use for complex numbers since it avoids taking a square root. [angle](#) returns the phase angle in radians (also known as the argument or [arg](#) function). The full gamut of other [Elementary Functions](#) is also defined for complex numbers:

```
julia> sqrt(1im)
0.7071067811865476 + 0.7071067811865475im

julia> sqrt(1 + 2im)
1.272019649514069 + 0.7861513777574233im

julia> cos(1 + 2im)
2.0327230070196656 - 3.0518977991517997im

julia> exp(1 + 2im)
-1.1312043837568135 + 2.4717266720048188im

julia> sinh(1 + 2im)
-0.4890562590412937 + 1.4031192506220405im
```

Note that mathematical functions typically return real values when applied to real numbers and complex values when applied to complex numbers. For example, [sqrt](#) behaves differently when applied to -1 versus $-1 + 0im$ even though $-1 == -1 + 0im$:

```
julia> sqrt(-1)
ERROR: DomainError with -1.0:
sqrt was called with a negative real argument but will only return a complex result if called
↳ with a complex argument. Try sqrt(Complex(x)).
Stacktrace:
[...]

julia> sqrt(-1 + 0im)
0.0 + 1.0im
```

The [literal numeric coefficient notation](#) does not work when constructing a complex number from variables. Instead, the multiplication must be explicitly written out:

```
julia> a = 1; b = 2; a + b*im
1 + 2im
```

However, this is not recommended. Instead, use the more efficient `complex` function to construct a complex value directly from its real and imaginary parts:

```
julia> a = 1; b = 2; complex(a, b)
1 + 2im
```

This construction avoids the multiplication and addition operations.

`Inf` and `NaN` propagate through complex numbers in the real and imaginary parts of a complex number as described in the [Special floating-point values](#) section:

```
julia> 1 + Inf*im
1.0 + Inf*im

julia> 1 + NaN*im
1.0 + NaN*im
```

6.2 Rational Numbers

Julia has a rational number type to represent exact ratios of integers. Rationals are constructed using the `//` operator:

```
julia> 2//3
2//3
```

If the numerator and denominator of a rational have common factors, they are reduced to lowest terms such that the denominator is non-negative:

```
julia> 6//9
2//3

julia> -4//8
-1//2

julia> 5//-15
-1//3

julia> -4//-12
1//3
```

This normalized form for a ratio of integers is unique, so equality of rational values can be tested by checking for equality of the numerator and denominator. The standardized numerator and denominator of a rational value can be extracted using the `numerator` and `denominator` functions:

```
julia> numerator(2//3)
2
julia> denominator(2//3)
3
```

Direct comparison of the numerator and denominator is generally not necessary, since the standard arithmetic and comparison operations are defined for rational values:

```
julia> 2//3 == 6//9
true
julia> 2//3 == 9//27
false
julia> 3//7 < 1//2
true
julia> 3//4 > 2//3
true
julia> 2//4 + 1//6
2//3
julia> 5//12 - 1//4
1//6
julia> 5//8 * 3//12
5//32
julia> 6//5 / 10//7
21//25
```

Rationals can easily be converted to floating-point numbers:

```
julia> float(3//4)
0.75
```

Conversion from rational to floating-point respects the following identity for any integral values of a and b , with the exception of the two cases $b == 0$ and $a == 0 \ \&\& \ b < 0$:

```
julia> a = 1; b = 2;
julia> isequal(float(a//b), a/b)
true
```

Constructing infinite rational values is acceptable:

```
julia> 5//0
1//0

julia> x = -3//0
-1//0

julia> typeof(x)
Rational{Int64}
```

Trying to construct a NaN rational value, however, is invalid:

```
julia> 0//0
ERROR: ArgumentError: invalid rational: zero(Int64)//zero(Int64)
Stacktrace:
[...]
```

As usual, the promotion system makes interactions with other numeric types effortless:

```
julia> 3//5 + 1
8//5

julia> 3//5 - 0.5
0.09999999999999998

julia> 2//7 * (1 + 2im)
2//7 + 4//7*im

julia> 2//7 * (1.5 + 2im)
0.42857142857142855 + 0.5714285714285714im

julia> 3//2 / (1 + 2im)
3//10 - 3//5*im

julia> 1//2 + 2im
1//2 + 2//1*im

julia> 1 + 2//3im
1//1 - 2//3*im

julia> 0.5 == 1//2
true

julia> 0.33 == 1//3
false

julia> 0.33 < 1//3
true

julia> 1//3 - 0.33
0.00333333333333332993
```

Chapter 7

Strings

Strings are finite sequences of characters. Of course, the real trouble comes when one asks what a character is. The characters that English speakers are familiar with are the letters A, B, C, etc., together with numerals and common punctuation symbols. These characters are standardized together with a mapping to integer values between 0 and 127 by the [ASCII](#) standard. There are, of course, many other characters used in non-English languages, including variants of the ASCII characters with accents and other modifications, related scripts such as Cyrillic and Greek, and scripts completely unrelated to ASCII and English, including Arabic, Chinese, Hebrew, Hindi, Japanese, and Korean. The [Unicode](#) standard tackles the complexities of what exactly a character is, and is generally accepted as the definitive standard addressing this problem. Depending on your needs, you can either ignore these complexities entirely and just pretend that only ASCII characters exist, or you can write code that can handle any of the characters or encodings that one may encounter when handling non-ASCII text. Julia makes dealing with plain ASCII text simple and efficient, and handling Unicode is as simple and efficient as possible. In particular, you can write C-style string code to process ASCII strings, and they will work as expected, both in terms of performance and semantics. If such code encounters non-ASCII text, it will gracefully fail with a clear error message, rather than silently introducing corrupt results. When this happens, modifying the code to handle non-ASCII data is straightforward.

There are a few noteworthy high-level features about Julia's strings:

- The built-in concrete type used for strings (and string literals) in Julia is [String](#). This supports the full range of [Unicode](#) characters via the [UTF-8](#) encoding. (A [transcode](#) function is provided to convert to/from other Unicode encodings.)
- All string types are subtypes of the abstract type `AbstractString`, and external packages define additional `AbstractString` subtypes (e.g. for other encodings). If you define a function expecting a string argument, you should declare the type as `AbstractString` in order to accept any string type.
- Like C and Java, but unlike most dynamic languages, Julia has a first-class type for representing a single character, called [AbstractChar](#). The built-in [Char](#) subtype of `AbstractChar` is a 32-bit primitive type that can represent any Unicode character (and which is based on the UTF-8 encoding).
- As in Java, strings are immutable: the value of an `AbstractString` object cannot be changed. To construct a different string value, you construct a new string from parts of other strings.
- Conceptually, a string is a partial function from indices to characters: for some index values, no character value is returned, and instead an exception is thrown. This allows for efficient indexing

into strings by the byte index of an encoded representation rather than by a character index, which cannot be implemented both efficiently and simply for variable-width encodings of Unicode strings.

7.1 Characters

A `Char` value represents a single character: it is just a 32-bit primitive type with a special literal representation and appropriate arithmetic behaviors, and which can be converted to a numeric value representing a [Unicode code point](#). (Julia packages may define other subtypes of `AbstractChar`, e.g. to optimize operations for other [text encodings](#).) Here is how `Char` values are input and shown (note that character literals are delimited with single quotes, not double quotes):

```
julia> c = 'x'
'x': ASCII/Unicode U+0078 (category Ll: Letter, lowercase)

julia> typeof(c)
Char
```

You can easily convert a `Char` to its integer value, i.e. code point:

```
julia> c = Int('x')
120

julia> typeof(c)
Int64
```

On 32-bit architectures, `typeof(c)` will be `Int32`. You can convert an integer value back to a `Char` just as easily:

```
julia> Char(120)
'x': ASCII/Unicode U+0078 (category Ll: Letter, lowercase)
```

Not all integer values are valid Unicode code points, but for performance, the `Char` conversion does not check that every character value is valid. If you want to check that each converted value is a valid code point, use the `isvalid` function:

```
julia> Char(0x110000)
'\U110000': Unicode U+110000 (category In: Invalid, too high)

julia> isvalid(Char, 0x110000)
false
```

As of this writing, the valid Unicode code points are U+0000 through U+D7FF and U+E000 through U+10FFFF. These have not all been assigned intelligible meanings yet, nor are they necessarily interpretable by applications, but all of these values are considered to be valid Unicode characters.

You can input any Unicode character in single quotes using `\u` followed by up to four hexadecimal digits or `\U` followed by up to eight hexadecimal digits (the longest valid value only requires six):

```
julia> '\u0'
'\0': ASCII/Unicode U+0000 (category Cc: Other, control)

julia> '\u78'
'x': ASCII/Unicode U+0078 (category Ll: Letter, lowercase)

julia> '\u2200'
'∀': Unicode U+2200 (category Sm: Symbol, math)

julia> '\U10ffff'
'\U10ffff': Unicode U+10FFFF (category Cn: Other, not assigned)
```

Julia uses your system's locale and language settings to determine which characters can be printed as-is and which must be output using the generic, escaped `\u` or `\U` input forms. In addition to these Unicode escape forms, all of [C's traditional escaped input forms](#) can also be used:

```
julia> Int('\0')
0

julia> Int('\t')
9

julia> Int('\n')
10

julia> Int('\e')
27

julia> Int('\x7f')
127

julia> Int('\177')
127
```

You can do comparisons and a limited amount of arithmetic with Char values:

```
julia> 'A' < 'a'
true

julia> 'A' <= 'a' <= 'Z'
false

julia> 'A' <= 'X' <= 'Z'
true

julia> 'x' - 'a'
23

julia> 'A' + 1
'B': ASCII/Unicode U+0042 (category Lu: Letter, uppercase)
```

7.2 String Basics

String literals are delimited by double quotes or triple double quotes (not single quotes):

```
julia> str = "Hello, world.\n"
"Hello, world.\n"

julia> """Contains "quote" characters"""
"Contains \"quote\" characters"
```

Long lines in strings can be broken up by preceding the newline with a backslash (\):

```
julia> "This is a long \
      line"
"This is a long line"
```

If you want to extract a character from a string, you index into it:

```
julia> str[begin]
'H': ASCII/Unicode U+0048 (category Lu: Letter, uppercase)

julia> str[1]
'H': ASCII/Unicode U+0048 (category Lu: Letter, uppercase)

julia> str[6]
',': ASCII/Unicode U+002C (category Po: Punctuation, other)

julia> str[end]
'\n': ASCII/Unicode U+000A (category Cc: Other, control)
```

Many Julia objects, including strings, can be indexed with integers. The index of the first element (the first character of a string) is returned by `firstindex(str)`, and the index of the last element (character) with `lastindex(str)`. The keywords `begin` and `end` can be used inside an indexing operation as shorthand for the first and last indices, respectively, along the given dimension. String indexing, like most indexing in Julia, is 1-based: `firstindex` always returns 1 for any `AbstractString`. As we will see below, however, `lastindex(str)` is not in general the same as `length(str)` for a string, because some Unicode characters can occupy multiple "code units".

You can perform arithmetic and other operations with `end`, just like a normal value:

```
julia> str[end-1]
',': ASCII/Unicode U+002E (category Po: Punctuation, other)

julia> str[end+2]
' ': ASCII/Unicode U+0020 (category Zs: Separator, space)
```

Using an index less than `begin` (1) or greater than `end` raises an error:

```
julia> str[begin-1]
ERROR: BoundsError: attempt to access 14-codeunit String at index [0]
[...]

julia> str[end+1]
ERROR: BoundsError: attempt to access 14-codeunit String at index [15]
[...]
```

You can also extract a substring using range indexing:

```
julia> str[4:9]
"lo, wo"
```

Notice that the expressions `str[k]` and `str[k:k]` do not give the same result:

```
julia> str[6]
',': ASCII/Unicode U+002C (category Po: Punctuation, other)

julia> str[6:6]
","
```

The former is a single character value of type `Char`, while the latter is a string value that happens to contain only a single character. In Julia these are very different things.

Range indexing makes a copy of the selected part of the original string. Alternatively, it is possible to create a view into a string using the type `SubString`. More simply, using the `@views` macro on a block of code converts all string slices into substrings. For example:

```
julia> str = "long string"
"long string"

julia> substr = SubString(str, 1, 4)
"long"

julia> typeof(substr)
SubString{String}

julia> @views typeof(str[1:4]) # @views converts slices to SubStrings
SubString{String}
```

Several standard functions like `chop`, `chomp` or `strip` return a `SubString`.

7.3 Unicode and UTF-8

Julia fully supports Unicode characters and strings. As [discussed above](#), in character literals, Unicode code points can be represented using Unicode `\u` and `\U` escape sequences, as well as all the standard C escape sequences. These can likewise be used to write string literals:

```
julia> s = "\u2200 x \u2203 y"
"∀ x ∃ y"
```

Whether these Unicode characters are displayed as escapes or shown as special characters depends on your terminal's locale settings and its support for Unicode. String literals are encoded using the UTF-8 encoding. UTF-8 is a variable-width encoding, meaning that not all characters are encoded in the same number of bytes ("code units"). In UTF-8, ASCII characters — i.e. those with code points less than 0x80 (128) — are encoded as they are in ASCII, using a single byte, while code points 0x80 and above are encoded using multiple bytes — up to four per character.

String indices in Julia refer to code units (= bytes for UTF-8), the fixed-width building blocks that are used to encode arbitrary characters (code points). This means that not every index into a `String` is necessarily a valid index for a character. If you index into a string at such an invalid byte index, an error is thrown:

```
julia> s[1]
'∀': Unicode U+2200 (category Sm: Symbol, math)

julia> s[2]
ERROR: StringIndexError: invalid index [2], valid nearby indices [1]=>'∀', [4]=>' '
Stacktrace:
[...]

julia> s[3]
ERROR: StringIndexError: invalid index [3], valid nearby indices [1]=>'∀', [4]=>' '
Stacktrace:
[...]

julia> s[4]
' ': ASCII/Unicode U+0020 (category Zs: Separator, space)
```

In this case, the character `∀` is a three-byte character, so the indices 2 and 3 are invalid and the next character's index is 4; this next valid index can be computed by `nextind(s,1)`, and the next index after that by `nextind(s,4)` and so on.

Since `end` is always the last valid index into a collection, `end-1` references an invalid byte index if the second-to-last character is multibyte.

```
julia> s[end-1]
' ': ASCII/Unicode U+0020 (category Zs: Separator, space)

julia> s[end-2]
ERROR: StringIndexError: invalid index [9], valid nearby indices [7]=>'∃', [10]=>' '
Stacktrace:
[...]

julia> s[prevind(s, end, 2)]
'∃': Unicode U+2203 (category Sm: Symbol, math)
```

The first case works, because the last character `y` and the space are one-byte characters, whereas `end-2` indexes into the middle of the `∃` multibyte representation. The correct way for this case is using `prevind(s, lastindex(s), 2)` or, if you're using that value to index into `s` you can write `s[prevind(s, end, 2)]` and `end` expands to `lastindex(s)`.

Extraction of a substring using range indexing also expects valid byte indices or an error is thrown:

```
julia> s[1:1]
"V"

julia> s[1:2]
ERROR: StringIndexError: invalid index [2], valid nearby indices [1]=>'V', [4]=>' '
Stacktrace:
[...]

julia> s[1:4]
"V "
```

Because of variable-length encodings, the number of characters in a string (given by `length(s)`) is not always the same as the last index. If you iterate through the indices 1 through `lastindex(s)` and index into `s`, the sequence of characters returned when errors aren't thrown is the sequence of characters comprising the string `s`. Thus `length(s) <= lastindex(s)`, since each character in a string must have its own index. The following is an inefficient and verbose way to iterate through the characters of `s`:

```
julia> for i = firstindex(s):lastindex(s)
    try
        println(s[i])
    catch
        # ignore the index error
    end
end

V
x
␣
y
```

The blank lines actually have spaces on them. Fortunately, the above awkward idiom is unnecessary for iterating through the characters in a string, since you can just use the string as an iterable object, no exception handling required:

```
julia> for c in s
    println(c)
end

V
x
␣
y
```

If you need to obtain valid indices for a string, you can use the `nextind` and `prevind` functions to increment/decrement to the next/previous valid index, as mentioned above. You can also use the `eachindex` function to iterate over the valid character indices:

```
julia> collect(eachindex(s))
7-element Vector{Int64}:
 1
 4
 5
 6
 7
10
11
```

To access the raw code units (bytes for UTF-8) of the encoding, you can use the `codeunit(s,i)` function, where the index `i` runs consecutively from 1 to `ncodeunits(s)`. The `codeunits(s)` function returns an `AbstractVector{UInt8}` wrapper that lets you access these raw codeunits (bytes) as an array.

Strings in Julia can contain invalid UTF-8 code unit sequences. This convention allows to treat any byte sequence as a `String`. In such situations a rule is that when parsing a sequence of code units from left to right characters are formed by the longest sequence of 8-bit code units that matches the start of one of the following bit patterns (each `x` can be 0 or 1):

- 0xxxxxxx;
- 110xxxxx 10xxxxxx;
- 1110xxxx 10xxxxxx 10xxxxxx;
- 11110xxx 10xxxxxx 10xxxxxx 10xxxxxx;
- 10xxxxxx;
- 1111xxx.

In particular this means that overlong and too-high code unit sequences and prefixes thereof are treated as a single invalid character rather than multiple invalid characters. This rule may be best explained with an example:

```
julia> s = "\xc0\xa0\xe2\x88\xe2|"
"\xc0\xa0\xe2\x88\xe2|"

julia> foreach(display, s)
'\xc0\xa0': [overlong] ASCII/Unicode U+0020 (category Zs: Separator, space)
'\xe2\x88': Malformed UTF-8 (category Ma: Malformed, bad data)
'\xe2': Malformed UTF-8 (category Ma: Malformed, bad data)
'|': ASCII/Unicode U+007C (category Sm: Symbol, math)

julia> isvalid.(collect(s))
4-element BitArray{1}:
 0
 0
 0
 1

julia> s2 = "\xf7\xbf\xbf\xbf"
```

```
"\U1ffffff"

julia> foreach(display, s2)
'\U1ffffff': Unicode U+1FFFFFF (category In: Invalid, too high)
```

We can see that the first two code units in the string `s` form an overlong encoding of space character. It is invalid, but is accepted in a string as a single character. The next two code units form a valid start of a three-byte UTF-8 sequence. However, the fifth code unit `\xe2` is not its valid continuation. Therefore code units 3 and 4 are also interpreted as malformed characters in this string. Similarly code unit 5 forms a malformed character because `|` is not a valid continuation to it. Finally the string `s2` contains one too high code point.

Julia uses the UTF-8 encoding by default, and support for new encodings can be added by packages. For example, the [LegacyStrings.jl](#) package implements `UTF16String` and `UTF32String` types. Additional discussion of other encodings and how to implement support for them is beyond the scope of this document for the time being. For further discussion of UTF-8 encoding issues, see the section below on [byte array literals](#). The `transcode` function is provided to convert data between the various UTF-xx encodings, primarily for working with external data and libraries.

7.4 Concatenation

One of the most common and useful string operations is concatenation:

```
julia> greet = "Hello"
"Hello"

julia> whom = "world"
"world"

julia> string(greet, ", ", whom, ".\n")
"Hello, world.\n"
```

It's important to be aware of potentially dangerous situations such as concatenation of invalid UTF-8 strings. The resulting string may contain different characters than the input strings, and its number of characters may be lower than sum of numbers of characters of the concatenated strings, e.g.:

```
julia> a, b = "\xe2\x88", "\x80"
("\xe2\x88", "\x80")

julia> c = string(a, b)
"V"

julia> collect.([a, b, c])
3-element Vector{Vector{Char}}:
 ['\xe2\x88']
 ['\x80']
 ['V']

julia> length.([a, b, c])
3-element Vector{Int64}:
 2
 1
 1
```

```
| 1
| 1
| 1
```

This situation can happen only for invalid UTF-8 strings. For valid UTF-8 strings concatenation preserves all characters in strings and additivity of string lengths.

Julia also provides `*` for string concatenation:

```
| julia> greet * ", " * whom * ".\n"
| "Hello, world.\n"
```

While `*` may seem like a surprising choice to users of languages that provide `+` for string concatenation, this use of `*` has precedent in mathematics, particularly in abstract algebra.

In mathematics, `+` usually denotes a commutative operation, where the order of the operands does not matter. An example of this is matrix addition, where $A + B == B + A$ for any matrices A and B that have the same shape. In contrast, `*` typically denotes a noncommutative operation, where the order of the operands does matter. An example of this is matrix multiplication, where in general $A * B != B * A$. As with matrix multiplication, string concatenation is noncommutative: $\text{greet} * \text{whom} != \text{whom} * \text{greet}$. As such, `*` is a more natural choice for an infix string concatenation operator, consistent with common mathematical use.

More precisely, the set of all finite-length strings S together with the string concatenation operator `*` forms a [free monoid](#) $(S, *)$. The identity element of this set is the empty string, `""`. Whenever a free monoid is not commutative, the operation is typically represented as `\cdot`, `*`, or a similar symbol, rather than `+`, which as stated usually implies commutativity.

7.5 Interpolation

Constructing strings using concatenation can become a bit cumbersome, however. To reduce the need for these verbose calls to `string` or repeated multiplications, Julia allows interpolation into string literals using `$`, as in Perl:

```
| julia> greet = "Hello"; whom = "world";
|
| julia> "$greet, $whom.\n"
| "Hello, world.\n"
```

This is more readable and convenient and equivalent to the above string concatenation – the system rewrites this apparent single string literal into the call `string(greet, ", ", whom, ".\n")`.

The shortest complete expression after the `$` is taken as the expression whose value is to be interpolated into the string. Thus, you can interpolate any expression into a string using parentheses:

```
| julia> "1 + 2 = $(1 + 2)"
| "1 + 2 = 3"
```

Both concatenation and string interpolation call `string` to convert objects into string form. However, `string` actually just returns the output of `print`, so new types should add methods to `print` or `show` instead of `string`.

Most non-`AbstractString` objects are converted to strings closely corresponding to how they are entered as literal expressions:

```
julia> v = [1,2,3]
3-element Vector{Int64}:
 1
 2
 3

julia> "v: $v"
"v: [1, 2, 3]"
```

`string` is the identity for `AbstractString` and `AbstractChar` values, so these are interpolated into strings as themselves, unquoted and unescaped:

```
julia> c = 'x'
'x': ASCII/Unicode U+0078 (category Ll: Letter, lowercase)

julia> "hi, $c"
"hi, x"
```

To include a literal `$` in a string literal, escape it with a backslash:

```
julia> print("I have \$100 in my account.\n")
I have $100 in my account.
```

7.6 Triple-Quoted String Literals

When strings are created using triple-quotes (`"""..."""`) they have some special behavior that can be useful for creating longer blocks of text.

First, triple-quoted strings are also dedented to the level of the least-indented line. This is useful for defining strings within code that is indented. For example:

```
julia> str = """
        Hello,
        world.
        """
" Hello,\n world.\n"
```

In this case the final (empty) line before the closing `"""` sets the indentation level.

The dedentation level is determined as the longest common starting sequence of spaces or tabs in all lines, excluding the line following the opening `"""` and lines containing only spaces or tabs (the line containing the closing `"""` is always included). Then for all lines, excluding the text following the opening `"""`, the common starting sequence is removed (including lines containing only spaces and tabs if they start with this sequence), e.g.:

```
julia> """    This
           is
           a test"""
"    This\nis\n a test"
```

Next, if the opening `"""` is followed by a newline, the newline is stripped from the resulting string.

```
"""hello"""
```

is equivalent to

```
"""
hello"""
```

but

```
"""
hello"""
```

will contain a literal newline at the beginning.

Stripping of the newline is performed after the dedentation. For example:

```
julia> """
           Hello,
           world."""
"Hello,\nworld."
```

If the newline is removed using a backslash, dedentation will be respected as well:

```
julia> """
           Averylong\
           word"""
"Averylongword"
```

Trailing whitespace is left unaltered.

Triple-quoted string literals can contain `"` characters without escaping.

Note that line breaks in literal strings, whether single- or triple-quoted, result in a newline (LF) character `\n` in the string, even if your editor uses a carriage return `\r` (CR) or CRLF combination to end lines. To include a CR in a string, use an explicit escape `\r`; for example, you can enter the literal string "a CRLF line ending\r\n".

7.7 Common Operations

You can lexicographically compare strings using the standard comparison operators:

```
julia> "abracadabra" < "xylophone"
true

julia> "abracadabra" == "xylophone"
false

julia> "Hello, world." != "Goodbye, world."
true

julia> "1 + 2 = 3" == "1 + 2 = $(1 + 2)"
true
```

You can search for the index of a particular character using the `findfirst` and `findlast` functions:

```
julia> findfirst('o', "xylophone")
4

julia> findlast('o', "xylophone")
7

julia> findfirst('z', "xylophone")
```

You can start the search for a character at a given offset by using the functions `findnext` and `findprev`:

```
julia> findnext('o', "xylophone", 1)
4

julia> findnext('o', "xylophone", 5)
7

julia> findprev('o', "xylophone", 5)
4

julia> findnext('o', "xylophone", 8)
```

You can use the `occursin` function to check if a substring is found within a string:

```
julia> occursin("world", "Hello, world.")
true

julia> occursin("o", "Xylophon")
true

julia> occursin("a", "Xylophon")
false

julia> occursin('o', "Xylophon")
true
```

The last example shows that `occursin` can also look for a character literal.

Two other handy string functions are `repeat` and `join`:

```
julia> repeat(".:Z:.", 10)
".:Z:.:Z:.:Z:.:Z:.:Z:.:Z:.:Z:.:Z:.:Z:."

julia> join(["apples", "bananas", "pineapples"], ", ", " and ")
"apples, bananas and pineapples"
```

Some other useful functions include:

- `firstindex(str)` gives the minimal (byte) index that can be used to index into `str` (always 1 for strings, not necessarily true for other containers).
- `lastindex(str)` gives the maximal (byte) index that can be used to index into `str`.
- `length(str)` the number of characters in `str`.
- `length(str, i, j)` the number of valid character indices in `str` from `i` to `j`.
- `ncodeunits(str)` number of `code units` in a string.
- `codeunit(str, i)` gives the code unit value in the string `str` at index `i`.
- `thisind(str, i)` given an arbitrary index into a string find the first index of the character into which the index points.
- `nextind(str, i, n=1)` find the start of the `n`th character starting after index `i`.
- `prevind(str, i, n=1)` find the start of the `n`th character starting before index `i`.

7.8 Non-Standard String Literals

There are situations when you want to construct a string or use string semantics, but the behavior of the standard string construct is not quite what is needed. For these kinds of situations, Julia provides non-standard string literals. A non-standard string literal looks like a regular double-quoted string literal, but is immediately prefixed by an identifier, and may behave differently from a normal string literal.

[Regular expressions](#), [byte array literals](#), and [version number literals](#), as described below, are some examples of non-standard string literals. Users and packages may also define new non-standard string literals. Further documentation is given in the [Metaprogramming](#) section.

7.9 Regular Expressions

Sometimes you are not looking for an exact string, but a particular pattern. For example, suppose you are trying to extract a single date from a large text file. You don't know what that date is (that's why you are searching for it), but you do know it will look something like YYYY-MM-DD. Regular expressions allow you to specify these patterns and search for them.

Julia uses version 2 of Perl-compatible regular expressions (regexes), as provided by the [PCRE](#) library (see the [PCRE2 syntax description](#) for more details). Regular expressions are related to strings in two ways:

the obvious connection is that regular expressions are used to find regular patterns in strings; the other connection is that regular expressions are themselves input as strings, which are parsed into a state machine that can be used to efficiently search for patterns in strings. In Julia, regular expressions are input using non-standard string literals prefixed with various identifiers beginning with `r`. The most basic regular expression literal without any options turned on just uses `r"..."`:

```
julia> re = r"\s*(?:#|$)"
r"\s*(?:#|$)"

julia> typeof(re)
Regex
```

To check if a regex matches a string, use `occursin`:

```
julia> occursin(r"\s*(?:#|$)", "not a comment")
false

julia> occursin(r"\s*(?:#|$)", "# a comment")
true
```

As one can see here, `occursin` simply returns true or false, indicating whether a match for the given regex occurs in the string. Commonly, however, one wants to know not just whether a string matched, but also how it matched. To capture this information about a match, use the `match` function instead:

```
julia> match(r"\s*(?:#|$)", "not a comment")

julia> match(r"\s*(?:#|$)", "# a comment")
RegexMatch("#")
```

If the regular expression does not match the given string, `match` returns `nothing` – a special value that does not print anything at the interactive prompt. Other than not printing, it is a completely normal value and you can test for it programmatically:

```
m = match(r"\s*(?:#|$)", line)
if m == nothing
    println("not a comment")
else
    println("blank or comment")
end
```

If a regular expression does match, the value returned by `match` is a `RegexMatch` object. These objects record how the expression matches, including the substring that the pattern matches and any captured substrings, if there are any. This example only captures the portion of the substring that matches, but perhaps we want to capture any non-blank text after the comment character. We could do the following:

```
julia> m = match(r"\s*(?:#\s*(.*?)\s*$)", "# a comment ")
RegexMatch("# a comment ", 1="a comment")
```

When calling `match`, you have the option to specify an index at which to start the search. For example:

```
julia> m = match(r"[0-9]", "aaaa1aaaa2aaaa3", 1)
RegexMatch("1")

julia> m = match(r"[0-9]", "aaaa1aaaa2aaaa3", 6)
RegexMatch("2")

julia> m = match(r"[0-9]", "aaaa1aaaa2aaaa3", 11)
RegexMatch("3")
```

You can extract the following info from a `RegexMatch` object:

- the entire substring matched: `m.match`
- the captured substrings as an array of strings: `m.captures`
- the offset at which the whole match begins: `m.offset`
- the offsets of the captured substrings as a vector: `m.offsets`

For when a capture doesn't match, instead of a substring, `m.captures` contains nothing in that position, and `m.offsets` has a zero offset (recall that indices in Julia are 1-based, so a zero offset into a string is invalid). Here is a pair of somewhat contrived examples:

```
julia> m = match(r"(a|b)(c)?(d)", "acd")
RegexMatch("acd", 1="a", 2="c", 3="d")

julia> m.match
"acd"

julia> m.captures
3-element Vector{Union{Nothing, SubString{String}}}:
 "a"
 "c"
 "d"

julia> m.offset
1

julia> m.offsets
3-element Vector{Int64}:
 1
 2
 3

julia> m = match(r"(a|b)(c)?(d)", "ad")
RegexMatch("ad", 1="a", 2=nothing, 3="d")

julia> m.match
"ad"
```

```
julia> m.captures
3-element Vector{Union{Nothing, SubString{String}}}:
"a"
nothing
"d"

julia> m.offset
1

julia> m.offsets
3-element Vector{Int64}:
1
0
2
```

It is convenient to have captures returned as an array so that one can use destructuring syntax to bind them to local variables. As a convenience, the `RegexMatch` object implements iterator methods that pass through to the captures field, so you can destructure the match object directly:

```
julia> first, second, third = m; first
"a"
```

Captures can also be accessed by indexing the `RegexMatch` object with the number or name of the capture group:

```
julia> m=match(r"(?<hour>\d+):(?<minute>\d+)", "12:45")
RegexMatch("12:45", hour="12", minute="45")

julia> m[:minute]
"45"

julia> m[2]
"45"
```

Captures can be referenced in a substitution string when using `replace` by using `\n` to refer to the *n*th capture group and prefixing the substitution string with `s`. Capture group 0 refers to the entire match object. Named capture groups can be referenced in the substitution with `\g<groupname>`. For example:

```
julia> replace("first second", r"(\w+) (?<agroup>\w+)" => s"\g<agroup> \1")
"second first"
```

Numbered capture groups can also be referenced as `\g<n>` for disambiguation, as in:

```
julia> replace("a", r"." => s"\g<0>1")
"a1"
```

You can modify the behavior of regular expressions by some combination of the flags `i`, `m`, `s`, and `x` after the closing double quote mark. These flags have the same meaning as they do in Perl, as explained in this excerpt from the [perlre manpage](#):

- i Do case-insensitive pattern matching.

If locale matching rules are in effect, the case map is taken from the current locale for code points less than 255, and from Unicode rules for larger code points. However, matches that would cross the Unicode rules/non-Unicode rules boundary (ords 255/256) will not succeed.
- m Treat string as multiple lines. That is, change "^" and "\$" from matching the start or end of the string to matching the start or end of any line anywhere within the string.
- s Treat string as single line. That is, change "." to match any character whatsoever, even a newline, which normally it would not match.

Used together, as r"ms, they let the "." match any character whatsoever, while still allowing "^" and "\$" to match, respectively, just after and just before newlines within the string.
- x Tells the regular expression parser to ignore most whitespace that is neither backslashed nor within a character class. You can use this to break up your regular expression into (slightly) more readable parts. The '#' character is also treated as a metacharacter introducing a comment, just as in ordinary code.

For example, the following regex has all three flags turned on:

```
julia> r"a+.*b+.*?d$"ism
r"a+.*b+.*?d$"ims

julia> match(r"a+.*b+.*?d$"ism, "Goodbye,\n0h, angry,\nBad world\n")
RegexMatch("angry,\nBad world")
```

The r"... " literal is constructed without interpolation and unescaping (except for quotation mark " which still has to be escaped). Here is an example showing the difference from standard string literals:

```
julia> x = 10
10

julia> r"$x"
r"$x"

julia> "$x"
"10"

julia> r"\x"
r"\x"

julia> "\x"
ERROR: syntax: invalid escape sequence
```

Triple-quoted regex strings, of the form `r"""..."""`, are also supported (and may be convenient for regular expressions containing quotation marks or newlines).

The `Regex()` constructor may be used to create a valid regex string programmatically. This permits using the contents of string variables and other string operations when constructing the regex string. Any of the regex codes above can be used within the single string argument to `Regex()`. Here are some examples:

```
julia> using Dates

julia> d = Date(1962,7,10)
1962-07-10

julia> regex_d = Regex("Day " * string(day(d)))
r"Day 10"

julia> match(regex_d, "It happened on Day 10")
RegexMatch("Day 10")

julia> name = "Jon"
"Jon"

julia> regex_name = Regex("\\"( )\\Q$name\\E\\" )" # interpolate value of name
r"\\"( )\\QJon\\E\\" )"

julia> match(regex_name, " Jon ")
RegexMatch(" Jon ")

julia> match(regex_name, "[Jon]") == nothing
true
```

Note the use of the `\Q...E` escape sequence. All characters between the `\Q` and the `E` are interpreted as literal characters. This is convenient for matching characters that would otherwise be regex metacharacters. However, caution is needed when using this feature together with string interpolation, since the interpolated string might itself contain the `E` sequence, unexpectedly terminating literal matching. User inputs need to be sanitized before inclusion in a regex.

7.10 Byte Array Literals

Another useful non-standard string literal is the byte-array string literal: `b"..."`. This form lets you use string notation to express read only literal byte arrays – i.e. arrays of `UInt8` values. The type of those objects is `CodeUnits{UInt8, String}`. The rules for byte array literals are the following:

- ASCII characters and ASCII escapes produce a single byte.
- `\x` and octal escape sequences produce the byte corresponding to the escape value.
- Unicode escape sequences produce a sequence of bytes encoding that code point in UTF-8.

There is some overlap between these rules since the behavior of `\x` and octal escapes less than `0x80` (128) are covered by both of the first two rules, but here these rules agree. Together, these rules allow one to easily use ASCII characters, arbitrary byte values, and UTF-8 sequences to produce arrays of bytes. Here is an example using all three:

```
julia> b"DATA\xff\u2200"
8-element Base.CodeUnits{UInt8, String}:
 0x44
 0x41
 0x54
 0x41
 0xff
 0xe2
 0x88
 0x80
```

The ASCII string "DATA" corresponds to the bytes 68, 65, 84, 65. `\xff` produces the single byte 255. The Unicode escape `\u2200` is encoded in UTF-8 as the three bytes 226, 136, 128. Note that the resulting byte array does not correspond to a valid UTF-8 string:

```
julia> isvalid("DATA\xff\u2200")
false
```

As it was mentioned `CodeUnits{UInt8, String}` type behaves like read only array of `UInt8` and if you need a standard vector you can convert it using `Vector{UInt8}`:

```
julia> x = b"123"
3-element Base.CodeUnits{UInt8, String}:
 0x31
 0x32
 0x33

julia> x[1]
0x31

julia> x[1] = 0x32
ERROR: CanonicalIndexError: setindex! not defined for Base.CodeUnits{UInt8, String}
[...]

julia> Vector{UInt8}(x)
3-element Vector{UInt8}:
 0x31
 0x32
 0x33
```

Also observe the significant distinction between `\xff` and `\uff`: the former escape sequence encodes the byte 255, whereas the latter escape sequence represents the code point 255, which is encoded as two bytes in UTF-8:

```
julia> b"\xff"
1-element Base.CodeUnits{UInt8, String}:
 0xff

julia> b"\uff"
2-element Base.CodeUnits{UInt8, String}:
 0xc3
 0xbf
```

Character literals use the same behavior.

For code points less than `\u80`, it happens that the UTF-8 encoding of each code point is just the single byte produced by the corresponding `\x` escape, so the distinction can safely be ignored. For the escapes `\x80` through `\xff` as compared to `\u80` through `\uff`, however, there is a major difference: the former escapes all encode single bytes, which – unless followed by very specific continuation bytes – do not form valid UTF-8 data, whereas the latter escapes all represent Unicode code points with two-byte encodings.

If this is all extremely confusing, try reading ["The Absolute Minimum Every Software Developer Absolutely, Positively Must Know About Unicode and Character Sets"](#). It's an excellent introduction to Unicode and UTF-8, and may help alleviate some confusion regarding the matter.

7.11 Version Number Literals

Version numbers can easily be expressed with non-standard string literals of the form `v"..."`. Version number literals create `VersionNumber` objects which follow the specifications of [semantic versioning](#), and therefore are composed of major, minor and patch numeric values, followed by pre-release and build alpha-numeric annotations. For example, `v"0.2.1-rc1+win64"` is broken into major version 0, minor version 2, patch version 1, pre-release `rc1` and build `win64`. When entering a version literal, everything except the major version number is optional, therefore e.g. `v"0.2"` is equivalent to `v"0.2.0"` (with empty pre-release/build annotations), `v"2"` is equivalent to `v"2.0.0"`, and so on.

`VersionNumber` objects are mostly useful to easily and correctly compare two (or more) versions. For example, the constant `VERSION` holds Julia version number as a `VersionNumber` object, and therefore one can define some version-specific behavior using simple statements as:

```
if v"0.2" <= VERSION < v"0.3-"
    # do something specific to 0.2 release series
end
```

Note that in the above example the non-standard version number `v"0.3-"` is used, with a trailing `-`: this notation is a Julia extension of the standard, and it's used to indicate a version which is lower than any `0.3` release, including all of its pre-releases. So in the above example the code would only run with stable `0.2` versions, and exclude such versions as `v"0.3.0-rc1"`. In order to also allow for unstable (i.e. pre-release) `0.2` versions, the lower bound check should be modified like this: `v"0.2-" <= VERSION`.

Another non-standard version specification extension allows one to use a trailing `+` to express an upper limit on build versions, e.g. `VERSION > v"0.2-rc1+"` can be used to mean any version above `0.2-rc1` and any of its builds: it will return `false` for version `v"0.2-rc1+win64"` and `true` for `v"0.2-rc2"`.

It is good practice to use such special versions in comparisons (particularly, the trailing `-` should always be used on upper bounds unless there's a good reason not to), but they must not be used as the actual version number of anything, as they are invalid in the semantic versioning scheme.

Besides being used for the `VERSION` constant, `VersionNumber` objects are widely used in the `Pkg` module, to specify packages versions and their dependencies.

7.12 Raw String Literals

Raw strings without interpolation or unescaping can be expressed with non-standard string literals of the form `raw"..."`. Raw string literals create ordinary `String` objects which contain the enclosed contents

exactly as entered with no interpolation or unescaping. This is useful for strings which contain code or markup in other languages which use \$ or \ as special characters.

The exception is that quotation marks still must be escaped, e.g. `raw\""` is equivalent to `"\""`. To make it possible to express all strings, backslashes then also must be escaped, but only when appearing right before a quote character:

```
julia> println(raw"\\ \\"")  
\\ \"
```

Notice that the first two backslashes appear verbatim in the output, since they do not precede a quote character. However, the next backslash character escapes the backslash that follows it, and the last backslash escapes a quote, since these backslashes appear before a quote.

Chapter 8

Functions

In Julia, a function is an object that maps a tuple of argument values to a return value. Julia functions are not pure mathematical functions, because they can alter and be affected by the global state of the program. The basic syntax for defining functions in Julia is:

```
julia> function f(x,y)
           x + y
       end
f (generic function with 1 method)
```

This function accepts two arguments x and y and returns the value of the last expression evaluated, which is $x + y$.

There is a second, more terse syntax for defining a function in Julia. The traditional function declaration syntax demonstrated above is equivalent to the following compact "assignment form":

```
julia> f(x,y) = x + y
f (generic function with 1 method)
```

In the assignment form, the body of the function must be a single expression, although it can be a compound expression (see [Compound Expressions](#)). Short, simple function definitions are common in Julia. The short function syntax is accordingly quite idiomatic, considerably reducing both typing and visual noise.

A function is called using the traditional parenthesis syntax:

```
julia> f(2,3)
5
```

Without parentheses, the expression f refers to the function object, and can be passed around like any other value:

```
julia> g = f;
julia> g(2,3)
5
```

As with variables, Unicode can also be used for function names:

```
julia> Σ(x,y) = x + y
Σ (generic function with 1 method)

julia> Σ(2, 3)
5
```

8.1 Argument Passing Behavior

Julia function arguments follow a convention sometimes called "pass-by-sharing", which means that values are not copied when they are passed to functions. Function arguments themselves act as new variable bindings (new "names" that can refer to values), much like [assignments](#) `argument_name = argument_value`, so that the objects they refer to are identical to the passed values. Modifications to mutable values (such as Arrays) made within a function will be visible to the caller. (This is the same behavior found in Scheme, most Lisps, Python, Ruby and Perl, among other dynamic languages.)

For example, in the function

```
function f(x, y)
    x[1] = 42    # mutates x
    y = 7 + y    # new binding for y, no mutation
    return y
end
```

The statement `x[1] = 42` mutates the object `x`, and hence this change will be visible in the array passed by the caller for this argument. On the other hand, the assignment `y = 7 + y` changes the binding ("name") `y` to refer to a new value `7 + y`, rather than mutating the original object referred to by `y`, and hence does not change the corresponding argument passed by the caller. This can be seen if we call `f(x, y)`:

```
julia> a = [4,5,6]
3-element Vector{Int64}:
 4
 5
 6

julia> b = 3
3

julia> f(a, b) # returns 7 + b == 10
10

julia> a # a[1] is changed to 42 by f
3-element Vector{Int64}:
42
 5
 6

julia> b # not changed
3
```

As a common convention in Julia (not a syntactic requirement), such a function would [typically be named](#) `f!(x, y)` rather than `f(x, y)`, as a visual reminder at the call site that at least one of the arguments (often the first one) is being mutated.

Shared memory between arguments

The behavior of a mutating function can be unexpected when a mutated argument shares memory with another argument, a situation known as aliasing (e.g. when one is a view of the other). Unless the function docstring explicitly indicates that aliasing produces the expected result, it is the responsibility of the caller to ensure proper behavior on such inputs.

8.2 Argument-type declarations

You can declare the types of function arguments by appending `::TypeName` to the argument name, as usual for [Type Declarations](#) in Julia. For example, the following function computes [Fibonacci numbers](#) recursively:

```
| fib(n::Integer) = n ≤ 2 ? one(n) : fib(n-1) + fib(n-2)
```

and the `::Integer` specification means that it will only be callable when `n` is a subtype of the [abstract Integer](#) type.

Argument-type declarations **normally have no impact on performance**: regardless of what argument types (if any) are declared, Julia compiles a specialized version of the function for the actual argument types passed by the caller. For example, calling `fib(1)` will trigger the compilation of specialized version of `fib` optimized specifically for `Int` arguments, which is then re-used if `fib(7)` or `fib(15)` are called. (There are rare exceptions when an argument-type declaration can trigger additional compiler specializations; see: [Be aware of when Julia avoids specializing.](#)) The most common reasons to declare argument types in Julia are, instead:

- **Dispatch:** As explained in [Methods](#), you can have different versions ("methods") of a function for different argument types, in which case the argument types are used to determine which implementation is called for which arguments. For example, you might implement a completely different algorithm `fib(x::Number) = ...` that works for any `Number` type by using [Binet's formula](#) to extend it to non-integer values.
- **Correctness:** Type declarations can be useful if your function only returns correct results for certain argument types. For example, if we omitted argument types and wrote `fib(n) = n ≤ 2 ? one(n) : fib(n-1) + fib(n-2)`, then `fib(1.5)` would silently give us the nonsensical answer `1.0`.
- **Clarity:** Type declarations can serve as a form of documentation about the expected arguments.

However, it is a **common mistake to overly restrict the argument types**, which can unnecessarily limit the applicability of the function and prevent it from being re-used in circumstances you did not anticipate. For example, the `fib(n::Integer)` function above works equally well for `Int` arguments (machine integers) and `BigInt` arbitrary-precision integers (see [BigFloats and BigInts](#)), which is especially useful because Fibonacci numbers grow exponentially rapidly and will quickly overflow any fixed-precision type like `Int` (see [Overflow behavior](#)). If we had declared our function as `fib(n::Int)`, however, the application to `BigInt` would have been prevented for no reason. In general, you should use the most general applicable abstract types for arguments, and **when in doubt, omit the argument types**. You can always add argument-type specifications later if they become necessary, and you don't sacrifice performance or functionality by omitting them.

8.3 The return Keyword

The value returned by a function is the value of the last expression evaluated, which, by default, is the last expression in the body of the function definition. In the example function, `f`, from the previous section this is the value of the expression `x + y`. As an alternative, as in many other languages, the `return` keyword causes a function to return immediately, providing an expression whose value is returned:

```
function g(x,y)
    return x * y
    x + y
end
```

Since function definitions can be entered into interactive sessions, it is easy to compare these definitions:

```
julia> f(x,y) = x + y
f (generic function with 1 method)

julia> function g(x,y)
    return x * y
    x + y
end
g (generic function with 1 method)

julia> f(2,3)
5

julia> g(2,3)
6
```

Of course, in a purely linear function body like `g`, the usage of `return` is pointless since the expression `x + y` is never evaluated and we could simply make `x * y` the last expression in the function and omit the `return`. In conjunction with other control flow, however, `return` is of real use. Here, for example, is a function that computes the hypotenuse length of a right triangle with sides of length `x` and `y`, avoiding overflow:

```
julia> function hypot(x,y)
    x = abs(x)
    y = abs(y)
    if x > y
        r = y/x
        return x*sqrt(1+r*r)
    end
    if y == 0
        return zero(x)
    end
    r = x/y
    return y*sqrt(1+r*r)
end
hypot (generic function with 1 method)

julia> hypot(3, 4)
5.0
```

There are three possible points of return from this function, returning the values of three different expressions, depending on the values of `x` and `y`. The `return` on the last line could be omitted since it is the last expression.

Return type

A return type can be specified in the function declaration using the `::` operator. This converts the return value to the specified type.

```
julia> function g(x, y)::Int8
           return x * y
       end;

julia> typeof(g(1, 2))
Int8
```

This function will always return an `Int8` regardless of the types of `x` and `y`. See [Type Declarations](#) for more on return types.

Return type declarations are **rarely used** in Julia: in general, you should instead write "type-stable" functions in which Julia's compiler can automatically infer the return type. For more information, see the [Performance Tips](#) chapter.

Returning nothing

For functions that do not need to return a value (functions used only for some side effects), the Julia convention is to return the value `nothing`:

```
function printx(x)
    println("x = $x")
    return nothing
end
```

This is a convention in the sense that `nothing` is not a Julia keyword but only a singleton object of type `Nothing`. Also, you may notice that the `printx` function example above is contrived, because `println` already returns `nothing`, so that the `return` line is redundant.

There are two possible shortened forms for the `return nothing` expression. On the one hand, the `return` keyword implicitly returns `nothing`, so it can be used alone. On the other hand, since functions implicitly return their last expression evaluated, `nothing` can be used alone when it's the last expression. The preference for the expression `return nothing` as opposed to `return` or `nothing` alone is a matter of coding style.

8.4 Operators Are Functions

In Julia, most operators are just functions with support for special syntax. (The exceptions are operators with special evaluation semantics like `&&` and `||`. These operators cannot be functions since [Short-Circuit Evaluation](#) requires that their operands are not evaluated before evaluation of the operator.) Accordingly, you can also apply them using parenthesized argument lists, just as you would any other function:

```
julia> 1 + 2 + 3
6

julia> +(1,2,3)
6
```

The infix form is exactly equivalent to the function application form – in fact the former is parsed to produce the function call internally. This also means that you can assign and pass around operators such as `+` and `*` just like you would with other function values:

```
julia> f = +;

julia> f(1,2,3)
6
```

Under the name `f`, the function does not support infix notation, however.

8.5 Operators With Special Names

A few special expressions correspond to calls to functions with non-obvious names. These are:

Expression	Calls
<code>[A B C ...]</code>	<code>hcat</code>
<code>[A; B; C; ...]</code>	<code>vcat</code>
<code>[A B; C D; ...]</code>	<code>hvcat</code>
<code>[A; B;; C; D;; ...]</code>	<code>hvncat</code>
<code>A'</code>	<code>adjoint</code>
<code>A[i]</code>	<code>getindex</code>
<code>A[i] = x</code>	<code>setindex!</code>
<code>A.n</code>	<code>getproperty</code>
<code>A.n = x</code>	<code>setproperty!</code>

Note that expressions similar to `[A; B;; C; D;; ...]` but with more than two consecutive `;` also correspond to `hvncat` calls.

8.6 Anonymous Functions

Functions in Julia are *first-class objects*: they can be assigned to variables, and called using the standard function call syntax from the variable they have been assigned to. They can be used as arguments, and they can be returned as values. They can also be created anonymously, without being given a name, using either of these syntaxes:

```
julia> x -> x^2 + 2x - 1
#1 (generic function with 1 method)

julia> function (x)
    x^2 + 2x - 1
end
#3 (generic function with 1 method)
```

This creates a function taking one argument x and returning the value of the polynomial $x^2 + 2x - 1$ at that value. Notice that the result is a generic function, but with a compiler-generated name based on consecutive numbering.

The primary use for anonymous functions is passing them to functions which take other functions as arguments. A classic example is `map`, which applies a function to each value of an array and returns a new array containing the resulting values:

```
julia> map(round, [1.2, 3.5, 1.7])
3-element Vector{Float64}:
 1.0
 4.0
 2.0
```

This is fine if a named function effecting the transform already exists to pass as the first argument to `map`. Often, however, a ready-to-use, named function does not exist. In these situations, the anonymous function construct allows easy creation of a single-use function object without needing a name:

```
julia> map(x -> x^2 + 2x - 1, [1, 3, -1])
3-element Vector{Int64}:
 2
14
-2
```

An anonymous function accepting multiple arguments can be written using the syntax $(x, y, z) \rightarrow 2x + y - z$. A zero-argument anonymous function is written as $() \rightarrow 3$. The idea of a function with no arguments may seem strange, but is useful for "delaying" a computation. In this usage, a block of code is wrapped in a zero-argument function, which is later invoked by calling it as `f`.

As an example, consider this call to `get`:

```
get(dict, key) do
    # default value calculated here
    time()
end
```

The code above is equivalent to calling `get` with an anonymous function containing the code enclosed between `do` and `end`, like so:

```
get(()->time(), dict, key)
```

The call to `time` is delayed by wrapping it in a 0-argument anonymous function that is called only if the requested key is absent from `dict`.

8.7 Tuples

Julia has a built-in data structure called a tuple that is closely related to function arguments and return values. A tuple is a fixed-length container that can hold any values, but cannot be modified (it is immutable). Tuples are constructed with commas and parentheses, and can be accessed via indexing:

```
julia> (1, 1+1)
(1, 2)

julia> (1,)
(1,)

julia> x = (0.0, "hello", 6*7)
(0.0, "hello", 42)

julia> x[2]
"hello"
```

Notice that a length-1 tuple must be written with a comma, `(1,)`, since `(1)` would just be a parenthesized value. `()` represents the empty (length-0) tuple.

8.8 Named Tuples

The components of tuples can optionally be named, in which case a named tuple is constructed:

```
julia> x = (a=2, b=1+2)
(a = 2, b = 3)

julia> x[1]
2

julia> x.a
2
```

The fields of named tuples can be accessed by name using dot syntax `x.a` in addition to the regular indexing syntax `x[1]` or `x[:a]`.

8.9 Destructuring Assignment and Multiple Return Values

A comma-separated list of variables (optionally wrapped in parentheses) can appear on the left side of an assignment: the value on the right side is destructured by iterating over and assigning to each variable in turn:

```
julia> (a,b,c) = 1:3
1:3

julia> b
2
```

The value on the right should be an iterator (see [Iteration interface](#)) at least as long as the number of variables on the left (any excess elements of the iterator are ignored).

This can be used to return multiple values from functions by returning a tuple or other iterable value. For example, the following function returns two values:

```
julia> function foo(a,b)
           a+b, a*b
       end
foo (generic function with 1 method)
```

If you call it in an interactive session without assigning the return value anywhere, you will see the tuple returned:

```
julia> foo(2,3)
(5, 6)
```

Destructuring assignment extracts each value into a variable:

```
julia> x, y = foo(2,3)
(5, 6)

julia> x
5

julia> y
6
```

Another common use is for swapping variables:

```
julia> y, x = x, y
(5, 6)

julia> x
6

julia> y
5
```

If only a subset of the elements of the iterator are required, a common convention is to assign ignored elements to a variable consisting of only underscores `_` (which is an otherwise invalid variable name, see [Allowed Variable Names](#)):

```
julia> _, _, _, d = 1:10
1:10

julia> d
4
```

Other valid left-hand side expressions can be used as elements of the assignment list, which will call [setindex!](#) or [setproperty!](#), or recursively destructure individual elements of the iterator:

```
julia> X = zeros(3);

julia> X[1], (a,b) = (1, (2, 3))
(1, (2, 3))

julia> X
3-element Vector{Float64}:
 1.0
 0.0
 0.0

julia> a
2

julia> b
3
```

Julia 1.6

... with assignment requires Julia 1.6

If the last symbol in the assignment list is suffixed by ... (known as slurping), then it will be assigned a collection or lazy iterator of the remaining elements of the right-hand side iterator:

```
julia> a, b... = "hello"
"hello"

julia> a
'h': ASCII/Unicode U+0068 (category Ll: Letter, lowercase)

julia> b
"ello"

julia> a, b... = Iterators.map(abs2, 1:4)
Base.Generator{UnitRange{Int64}, typeof(abs2)}(abs2, 1:4)

julia> a
1

julia> b
Base.Iterators.Rest{Base.Generator{UnitRange{Int64}, typeof(abs2)},
  ↳ Int64}(Base.Generator{UnitRange{Int64}, typeof(abs2)}(abs2, 1:4), 1)
```

See [Base.rest](#) for details on the precise handling and customization for specific iterators.

Julia 1.9

... in non-final position of an assignment requires Julia 1.9

Slurping in assignments can also occur in any other position. As opposed to slurping the end of a collection however, this will always be eager.

```
julia> a, b..., c = 1:5
1:5

julia> a
1

julia> b
3-element Vector{Int64}:
 2
 3
 4

julia> c
5

julia> front..., tail = "Hi!"
"Hi!"

julia> front
"Hi"

julia> tail
'!': ASCII/Unicode U+0021 (category Po: Punctuation, other)
```

This is implemented in terms of the function `Base.split_rest`.

Note that for variadic function definitions, slurping is still only allowed in final position. This does not apply to [single argument destructuring](#) though, as that does not affect method dispatch:

```
julia> f(x..., y) = x
ERROR: syntax: invalid "..." on non-final argument
Stacktrace:
[...]

julia> f((x..., y)) = x
f (generic function with 1 method)

julia> f((1, 2, 3))
(1, 2)
```

8.10 Property destructuring

Instead of destructuring based on iteration, the right side of assignments can also be destructured using property names. This follows the syntax for `NamedTuples`, and works by assigning to each variable on the left a property of the right side of the assignment with the same name using `getproperty`:

```
julia> (; b, a) = (a=1, b=2, c=3)
(a = 1, b = 2, c = 3)
```

```
julia> a
1

julia> b
2
```

8.11 Argument destructuring

The destructuring feature can also be used within a function argument. If a function argument name is written as a tuple (e.g. `(x, y)`) instead of just a symbol, then an assignment `(x, y) = argument` will be inserted for you:

```
julia> minmax(x, y) = (y < x) ? (y, x) : (x, y)

julia> gap((min, max)) = max - min

julia> gap(minmax(10, 2))
8
```

Notice the extra set of parentheses in the definition of `gap`. Without those, `gap` would be a two-argument function, and this example would not work.

Similarly, property destructuring can also be used for function arguments:

```
julia> foo(; x, y) = x + y
foo (generic function with 1 method)

julia> foo((x=1, y=2))
3

julia> struct A
           x
           y
       end

julia> foo(A(3, 4))
7
```

For anonymous functions, destructuring a single argument requires an extra comma:

```
julia> map((x,y,) -> x + y, [(1,2), (3,4)])
2-element Array{Int64,1}:
 3
 7
```

8.12 Varargs Functions

It is often convenient to be able to write functions taking an arbitrary number of arguments. Such functions are traditionally known as "varargs" functions, which is short for "variable number of arguments". You can define a varargs function by following the last positional argument with an ellipsis:

```
julia> bar(a,b,x...) = (a,b,x)
bar (generic function with 1 method)
```

The variables `a` and `b` are bound to the first two argument values as usual, and the variable `x` is bound to an iterable collection of the zero or more values passed to `bar` after its first two arguments:

```
julia> bar(1,2)
(1, 2, ())

julia> bar(1,2,3)
(1, 2, (3,))

julia> bar(1, 2, 3, 4)
(1, 2, (3, 4))

julia> bar(1,2,3,4,5,6)
(1, 2, (3, 4, 5, 6))
```

In all these cases, `x` is bound to a tuple of the trailing values passed to `bar`.

It is possible to constrain the number of values passed as a variable argument; this will be discussed later in [Parametrically-constrained Varargs methods](#).

On the flip side, it is often handy to "splat" the values contained in an iterable collection into a function call as individual arguments. To do this, one also uses `...` but in the function call instead:

```
julia> x = (3, 4)
(3, 4)

julia> bar(1,2,x...)
(1, 2, (3, 4))
```

In this case a tuple of values is spliced into a varargs call precisely where the variable number of arguments go. This need not be the case, however:

```
julia> x = (2, 3, 4)
(2, 3, 4)

julia> bar(1,x...)
(1, 2, (3, 4))

julia> x = (1, 2, 3, 4)
(1, 2, 3, 4)

julia> bar(x...)
(1, 2, (3, 4))
```

Furthermore, the iterable object splatted into a function call need not be a tuple:

```

julia> x = [3,4]
2-element Vector{Int64}:
 3
 4

julia> bar(1,2,x...)
(1, 2, (3, 4))

julia> x = [1,2,3,4]
4-element Vector{Int64}:
 1
 2
 3
 4

julia> bar(x...)
(1, 2, (3, 4))

```

Also, the function that arguments are splatted into need not be a varargs function (although it often is):

```

julia> baz(a,b) = a + b;

julia> args = [1,2]
2-element Vector{Int64}:
 1
 2

julia> baz(args...)
3

julia> args = [1,2,3]
3-element Vector{Int64}:
 1
 2
 3

julia> baz(args...)
ERROR: MethodError: no method matching baz(::Int64, ::Int64, ::Int64)

Closest candidates are:
  baz(::Any, ::Any)
    @ Main none:1

Stacktrace:
[...]

```

As you can see, if the wrong number of elements are in the splatted container, then the function call will fail, just as it would if too many arguments were given explicitly.

8.13 Optional Arguments

It is often possible to provide sensible default values for function arguments. This can save users from having to pass every argument on every call. For example, the function `Date(y, [m, d])` from `Dates` module constructs a `Date` type for a given year `y`, month `m` and day `d`. However, `m` and `d` arguments are optional and their default value is 1. This behavior can be expressed concisely as:

```
julia> using Dates

julia> function date(y::Int64, m::Int64=1, d::Int64=1)
    err = Dates.validargs(Date, y, m, d)
    err == nothing || throw(err)
    return Date(Dates.UTD(Dates.totaldays(y, m, d)))
end

date (generic function with 3 methods)
```

Observe, that this definition calls another method of the `Date` function that takes one argument of type `UTInstant{Day}`.

With this definition, the function can be called with either one, two or three arguments, and 1 is automatically passed when only one or two of the arguments are specified:

```
julia> date(2000, 12, 12)
2000-12-12

julia> date(2000, 12)
2000-12-01

julia> date(2000)
2000-01-01
```

Optional arguments are actually just a convenient syntax for writing multiple method definitions with different numbers of arguments (see [Note on Optional and keyword Arguments](#)). This can be checked for our `date` function example by calling the `methods` function:

```
julia> methods(date)
# 3 methods for generic function "date":
[1] date(y::Int64) in Main at REPL[1]:1
[2] date(y::Int64, m::Int64) in Main at REPL[1]:1
[3] date(y::Int64, m::Int64, d::Int64) in Main at REPL[1]:1
```

8.14 Keyword Arguments

Some functions need a large number of arguments, or have a large number of behaviors. Remembering how to call such functions can be difficult. Keyword arguments can make these complex interfaces easier to use and extend by allowing arguments to be identified by name instead of only by position.

For example, consider a function `plot` that plots a line. This function might have many options, for controlling line style, width, color, and so on. If it accepts keyword arguments, a possible call might look like

`plot(x, y, width=2)`, where we have chosen to specify only line width. Notice that this serves two purposes. The call is easier to read, since we can label an argument with its meaning. It also becomes possible to pass any subset of a large number of arguments, in any order.

Functions with keyword arguments are defined using a semicolon in the signature:

```
function plot(x, y; style="solid", width=1, color="black")
    ###
end
```

When the function is called, the semicolon is optional: one can either call `plot(x, y, width=2)` or `plot(x, y; width=2)`, but the former style is more common. An explicit semicolon is required only for passing varargs or computed keywords as described below.

Keyword argument default values are evaluated only when necessary (when a corresponding keyword argument is not passed), and in left-to-right order. Therefore default expressions may refer to prior keyword arguments.

The types of keyword arguments can be made explicit as follows:

```
function f(;x::Int=1)
    ###
end
```

Keyword arguments can also be used in varargs functions:

```
function plot(x...; style="solid")
    ###
end
```

Extra keyword arguments can be collected using `...`, as in varargs functions:

```
function f(x; y=0, kwargs...)
    ###
end
```

Inside `f`, `kwargs` will be an immutable key-value iterator over a named tuple. Named tuples (as well as dictionaries with keys of `Symbol`, and other iterators yielding two-value collections with symbol as first values) can be passed as keyword arguments using a semicolon in a call, e.g. `f(x, z=1; kwargs...)`.

If a keyword argument is not assigned a default value in the method definition, then it is required: an `UndefKeywordError` exception will be thrown if the caller does not assign it a value:

```
function f(x; y)
    ###
end
f(3, y=5) # ok, y is assigned
f(3)      # throws UndefKeywordError(:y)
```

One can also pass `key => value` expressions after a semicolon. For example, `plot(x, y; :width => 2)` is equivalent to `plot(x, y, width=2)`. This is useful in situations where the keyword name is computed at runtime.

When a bare identifier or dot expression occurs after a semicolon, the keyword argument name is implied by the identifier or field name. For example `plot(x, y; width)` is equivalent to `plot(x, y; width=width)` and `plot(x, y; options.width)` is equivalent to `plot(x, y; width=options.width)`.

The nature of keyword arguments makes it possible to specify the same argument more than once. For example, in the call `plot(x, y; options..., width=2)` it is possible that the `options` structure also contains a value for `width`. In such a case the rightmost occurrence takes precedence; in this example, `width` is certain to have the value 2. However, explicitly specifying the same keyword argument multiple times, for example `plot(x, y, width=2, width=3)`, is not allowed and results in a syntax error.

8.15 Evaluation Scope of Default Values

When optional and keyword argument default expressions are evaluated, only previous arguments are in scope. For example, given this definition:

```
function f(x, a=b, b=1)
    ###
end
```

the `b` in `a=b` refers to a `b` in an outer scope, not the subsequent argument `b`.

8.16 Do-Block Syntax for Function Arguments

Passing functions as arguments to other functions is a powerful technique, but the syntax for it is not always convenient. Such calls are especially awkward to write when the function argument requires multiple lines. As an example, consider calling `map` on a function with several cases:

```
map(x->begin
    if x < 0 && iseven(x)
        return 0
    elseif x == 0
        return 1
    else
        return x
    end
end,
[A, B, C])
```

Julia provides a reserved word `do` for rewriting this code more clearly:

```
map([A, B, C]) do x
    if x < 0 && iseven(x)
        return 0
    elseif x == 0
        return 1
    else
        return x
    end
end
```

```

        return x
    end
end

```

The `do x` syntax creates an anonymous function with argument `x` and passes it as the first argument to `map`. Similarly, `do a,b` would create a two-argument anonymous function. Note that `do (a,b)` would create a one-argument anonymous function, whose argument is a tuple to be deconstructed. A plain `do` would declare that what follows is an anonymous function of the form `() -> ...`.

How these arguments are initialized depends on the "outer" function; here, `map` will sequentially set `x` to `A`, `B`, `C`, calling the anonymous function on each, just as would happen in the syntax `map(func, [A, B, C])`.

This syntax makes it easier to use functions to effectively extend the language, since calls look like normal code blocks. There are many possible uses quite different from `map`, such as managing system state. For example, there is a version of `open` that runs code ensuring that the opened file is eventually closed:

```

open("outfile", "w") do io
    write(io, data)
end

```

This is accomplished by the following definition:

```

function open(f::Function, args...)
    io = open(args...)
    try
        f(io)
    finally
        close(io)
    end
end

```

Here, `open` first opens the file for writing and then passes the resulting output stream to the anonymous function you defined in the `do ... end` block. After your function exits, `open` will make sure that the stream is properly closed, regardless of whether your function exited normally or threw an exception. (The `try/finally` construct will be described in [Control Flow](#).)

With the `do` block syntax, it helps to check the documentation or implementation to know how the arguments of the user function are initialized.

A `do` block, like any other inner function, can "capture" variables from its enclosing scope. For example, the variable `data` in the above example of `open...do` is captured from the outer scope. Captured variables can create performance challenges as discussed in [performance tips](#).

8.17 Function composition and piping

Functions in Julia can be combined by composing or piping (chaining) them together.

Function composition is when you combine functions together and apply the resulting composition to arguments. You use the function composition operator (`∘`) to compose the functions, so `(f ∘ g)(args...)` is the same as `f(g(args...))`.

You can type the composition operator at the REPL and suitably-configured editors using `\circ<tab>`.

For example, the `sqrt` and `+` functions can be composed like this:

```
julia> (sqrt ∘ +)(3, 6)
3.0
```

This adds the numbers first, then finds the square root of the result.

The next example composes three functions and maps the result over an array of strings:

```
julia> map(first ∘ reverse ∘ uppercase, split("you can compose functions like this"))
6-element Vector{Char}:
 'U': ASCII/Unicode U+0055 (category Lu: Letter, uppercase)
 'N': ASCII/Unicode U+004E (category Lu: Letter, uppercase)
 'E': ASCII/Unicode U+0045 (category Lu: Letter, uppercase)
 'S': ASCII/Unicode U+0053 (category Lu: Letter, uppercase)
 'E': ASCII/Unicode U+0045 (category Lu: Letter, uppercase)
 'S': ASCII/Unicode U+0053 (category Lu: Letter, uppercase)
```

Function chaining (sometimes called "piping" or "using a pipe" to send data to a subsequent function) is when you apply a function to the previous function's output:

```
julia> 1:10 |> sum |> sqrt
7.416198487095663
```

Here, the total produced by `sum` is passed to the `sqrt` function. The equivalent composition would be:

```
julia> (sqrt ∘ sum)(1:10)
7.416198487095663
```

The pipe operator can also be used with broadcasting, as `.|>`, to provide a useful combination of the chaining/piping and dot vectorization syntax (described below).

```
julia> ["a", "list", "of", "strings"] .|> [uppercase, reverse, titlecase, length]
4-element Vector{Any}:
 "A"
 "tsil"
 "Of"
 7
```

When combining pipes with anonymous functions, parentheses must be used if subsequent pipes are not to be parsed as part of the anonymous function's body. Compare:

```
julia> 1:3 .|> (x -> x^2) |> sum |> sqrt
3.7416573867739413

julia> 1:3 .|> x -> x^2 |> sum |> sqrt
3-element Vector{Float64}:
 1.0
 2.0
 3.0
```

8.18 Dot Syntax for Vectorizing Functions

In technical-computing languages, it is common to have "vectorized" versions of functions, which simply apply a given function $f(x)$ to each element of an array A to yield a new array via $f(A)$. This kind of syntax is convenient for data processing, but in other languages vectorization is also often required for performance: if loops are slow, the "vectorized" version of a function can call fast library code written in a low-level language. In Julia, vectorized functions are not required for performance, and indeed it is often beneficial to write your own loops (see [Performance Tips](#)), but they can still be convenient. Therefore, any Julia function f can be applied elementwise to any array (or other collection) with the syntax $f.(A)$. For example, `sin` can be applied to all elements in the vector A like so:

```
julia> A = [1.0, 2.0, 3.0]
3-element Vector{Float64}:
 1.0
 2.0
 3.0

julia> sin.(A)
3-element Vector{Float64}:
 0.8414709848078965
 0.9092974268256817
 0.1411200080598672
```

Of course, you can omit the dot if you write a specialized "vector" method of f , e.g. via $f(A::AbstractArray) = \text{map}(f, A)$, and this is just as efficient as $f.(A)$. The advantage of the $f.(A)$ syntax is that which functions are vectorizable need not be decided upon in advance by the library writer.

More generally, $f.(args...)$ is actually equivalent to `broadcast(f, args...)`, which allows you to operate on multiple arrays (even of different shapes), or a mix of arrays and scalars (see [Broadcasting](#)). For example, if you have $f(x, y) = 3x + 4y$, then $f.(pi, A)$ will return a new array consisting of $f(pi, a)$ for each a in A , and $f.(vector1, vector2)$ will return a new vector consisting of $f(vector1[i], vector2[i])$ for each index i (throwing an exception if the vectors have different length).

```
julia> f(x,y) = 3x + 4y;

julia> A = [1.0, 2.0, 3.0];

julia> B = [4.0, 5.0, 6.0];

julia> f.(pi, A)
3-element Vector{Float64}:
13.42477796076938
17.42477796076938
21.42477796076938

julia> f.(A, B)
3-element Vector{Float64}:
19.0
26.0
33.0
```

Keyword arguments are not broadcasted over, but are simply passed through to each call of the function. For example, `round(x, digits=3)` is equivalent to `broadcast(x -> round(x, digits=3), x)`.

Moreover, nested `f.(args...)` calls are fused into a single broadcast loop. For example, `sin.(cos.(X))` is equivalent to `broadcast(x -> sin(cos(x)), X)`, similar to `[sin(cos(x)) for x in X]`: there is only a single loop over `X`, and a single array is allocated for the result. [In contrast, `sin(cos(X))` in a typical "vectorized" language would first allocate one temporary array for `tmp=cos(X)`, and then compute `sin(tmp)` in a separate loop, allocating a second array.] This loop fusion is not a compiler optimization that may or may not occur, it is a syntactic guarantee whenever nested `f.(args...)` calls are encountered. Technically, the fusion stops as soon as a "non-dot" function call is encountered; for example, in `sin.(sort(cos.(X)))` the `sin` and `cos` loops cannot be merged because of the intervening `sort` function.

Finally, the maximum efficiency is typically achieved when the output array of a vectorized operation is pre-allocated, so that repeated calls do not allocate new arrays over and over again for the results (see [Pre-allocating outputs](#)). A convenient syntax for this is `X .= ...`, which is equivalent to `broadcast!(identity, X, ...)` except that, as above, the `broadcast!` loop is fused with any nested "dot" calls. For example, `X .= sin.(Y)` is equivalent to `broadcast!(sin, X, Y)`, overwriting `X` with `sin.(Y)` in-place. If the left-hand side is an array-indexing expression, e.g. `X[begin+1:end] .= sin.(Y)`, then it translates to `broadcast!` on a view, e.g. `broadcast!(sin, view(X, firstindex(X)+1:lastindex(X)), Y)`, so that the left-hand side is updated in-place.

Since adding dots to many operations and function calls in an expression can be tedious and lead to code that is difficult to read, the macro `@.` is provided to convert every function call, operation, and assignment in an expression into the "dotted" version.

```
julia> Y = [1.0, 2.0, 3.0, 4.0];

julia> X = similar(Y); # pre-allocate output array

julia> @. X = sin(cos(Y)) # equivalent to X .= sin.(cos.(Y))
4-element Vector{Float64}:
 0.5143952585235492
-0.4042391538522658
-0.8360218615377305
-0.6080830096407656
```

Binary (or unary) operators like `.+` are handled with the same mechanism: they are equivalent to broadcast calls and are fused with other nested "dot" calls. `X .+= Y` etcetera is equivalent to `X .= X .+ Y` and results in a fused in-place assignment; see also [dot operators](#).

You can also combine dot operations with function chaining using `|>`, as in this example:

```
julia> 1:5 .|> [x->x^2, inv, x->2*x, -, isodd]
5-element Vector{Real}:
 1
 0.5
 6
 -4
 true
```

8.19 Further Reading

We should mention here that this is far from a complete picture of defining functions. Julia has a sophisticated type system and allows multiple dispatch on argument types. None of the examples given here provide any type annotations on their arguments, meaning that they are applicable to all types of arguments. The type system is described in [Types](#) and defining a function in terms of methods chosen by multiple dispatch on run-time argument types is described in [Methods](#).

Chapter 9

Control Flow

Julia provides a variety of control flow constructs:

- **Compound Expressions:** `begin` and `;`.
- **Conditional Evaluation:** `if-elseif-else` and `?:` (ternary operator).
- **Short-Circuit Evaluation:** logical operators `&&` (“and”) and `||` (“or”), and also chained comparisons.
- **Repeated Evaluation:** **Loops:** `while` and `for`.
- **Exception Handling:** `try-catch`, `error` and `throw`.
- **Tasks (aka Coroutines):** `yieldto`.

The first five control flow mechanisms are standard to high-level programming languages. **Tasks** are not so standard: they provide non-local control flow, making it possible to switch between temporarily-suspended computations. This is a powerful construct: both exception handling and cooperative multitasking are implemented in Julia using tasks. Everyday programming requires no direct usage of tasks, but certain problems can be solved much more easily by using tasks.

9.1 Compound Expressions

Sometimes it is convenient to have a single expression which evaluates several subexpressions in order, returning the value of the last subexpression as its value. There are two Julia constructs that accomplish this: `begin` blocks and `;` chains. The value of both compound expression constructs is that of the last subexpression. Here's an example of a `begin` block:

```
julia> z = begin
           x = 1
           y = 2
           x + y
       end
3
```

Since these are fairly small, simple expressions, they could easily be placed onto a single line, which is where the `;` chain syntax comes in handy:

```
julia> z = (x = 1; y = 2; x + y)
3
```

This syntax is particularly useful with the terse single-line function definition form introduced in [Functions](#). Although it is typical, there is no requirement that begin blocks be multiline or that ; chains be single-line:

```
julia> begin x = 1; y = 2; x + y end
3

julia> (x = 1;
        y = 2;
        x + y)
3
```

9.2 Conditional Evaluation

Conditional evaluation allows portions of code to be evaluated or not evaluated depending on the value of a boolean expression. Here is the anatomy of the if-elseif-else conditional syntax:

```
if x < y
    println("x is less than y")
elseif x > y
    println("x is greater than y")
else
    println("x is equal to y")
end
```

If the condition expression $x < y$ is true, then the corresponding block is evaluated; otherwise the condition expression $x > y$ is evaluated, and if it is true, the corresponding block is evaluated; if neither expression is true, the else block is evaluated. Here it is in action:

```
julia> function test(x, y)
    if x < y
        println("x is less than y")
    elseif x > y
        println("x is greater than y")
    else
        println("x is equal to y")
    end
end

test (generic function with 1 method)

julia> test(1, 2)
x is less than y

julia> test(2, 1)
x is greater than y

julia> test(1, 1)
x is equal to y
```

The `elseif` and `else` blocks are optional, and as many `elseif` blocks as desired can be used. The condition expressions in the `if-elseif-else` construct are evaluated until the first one evaluates to `true`, after which the associated block is evaluated, and no further condition expressions or blocks are evaluated.

`if` blocks are "leaky", i.e. they do not introduce a local scope. This means that new variables defined inside the `if` clauses can be used after the `if` block, even if they weren't defined before. So, we could have defined the test function above as

```
julia> function test(x,y)
    if x < y
        relation = "less than"
    elseif x == y
        relation = "equal to"
    else
        relation = "greater than"
    end
    println("x is ", relation, " y.")
end
test (generic function with 1 method)

julia> test(2, 1)
x is greater than y.
```

The variable `relation` is declared inside the `if` block, but used outside. However, when depending on this behavior, make sure all possible code paths define a value for the variable. The following change to the above function results in a runtime error

```
julia> function test(x,y)
    if x < y
        relation = "less than"
    elseif x == y
        relation = "equal to"
    end
    println("x is ", relation, " y.")
end
test (generic function with 1 method)

julia> test(1,2)
x is less than y.

julia> test(2,1)
ERROR: UndefVarError: `relation` not defined
Stacktrace:
 [1] test(::Int64, ::Int64) at ./none:7
```

`if` blocks also return a value, which may seem unintuitive to users coming from many other languages. This value is simply the return value of the last executed statement in the branch that was chosen, so

```
julia> x = 3
3
```

```
julia> if x > 0
    "positive!"
else
    "negative..."
end
"positive!"
```

Note that very short conditional statements (one-liners) are frequently expressed using Short-Circuit Evaluation in Julia, as outlined in the next section.

Unlike C, MATLAB, Perl, Python, and Ruby – but like Java, and a few other stricter, typed languages – it is an error if the value of a conditional expression is anything but true or false:

```
julia> if 1
    println("true")
end
ERROR: TypeError: non-boolean (Int64) used in boolean context
```

This error indicates that the conditional was of the wrong type: `Int64` rather than the required `Bool`.

The so-called "ternary operator", `?:`, is closely related to the `if-elseif-else` syntax, but is used where a conditional choice between single expression values is required, as opposed to conditional execution of longer blocks of code. It gets its name from being the only operator in most languages taking three operands:

```
a ? b : c
```

The expression `a`, before the `?`, is a condition expression, and the ternary operation evaluates the expression `b`, before the `:`, if the condition `a` is true or the expression `c`, after the `:`, if it is false. Note that the spaces around `?` and `:` are mandatory: an expression like `a?b:c` is not a valid ternary expression (but a newline is acceptable after both the `?` and the `:`).

The easiest way to understand this behavior is to see an example. In the previous example, the `println` call is shared by all three branches: the only real choice is which literal string to print. This could be written more concisely using the ternary operator. For the sake of clarity, let's try a two-way version first:

```
julia> x = 1; y = 2;

julia> println(x < y ? "less than" : "not less than")
less than

julia> x = 1; y = 0;

julia> println(x < y ? "less than" : "not less than")
not less than
```

If the expression `x < y` is true, the entire ternary operator expression evaluates to the string `"less than"` and otherwise it evaluates to the string `"not less than"`. The original three-way example requires chaining multiple uses of the ternary operator together:

```
julia> test(x, y) = println(x < y ? "x is less than y" :
                        x > y ? "x is greater than y" : "x is equal to y")
test (generic function with 1 method)

julia> test(1, 2)
x is less than y

julia> test(2, 1)
x is greater than y

julia> test(1, 1)
x is equal to y
```

To facilitate chaining, the operator associates from right to left.

It is significant that like `if-elseif-else`, the expressions before and after the `:` are only evaluated if the condition expression evaluates to `true` or `false`, respectively:

```
julia> v(x) = (println(x); x)
v (generic function with 1 method)

julia> 1 < 2 ? v("yes") : v("no")
yes
"yes"

julia> 1 > 2 ? v("yes") : v("no")
no
"no"
```

9.3 Short-Circuit Evaluation

The `&&` and `||` operators in Julia correspond to logical “and” and “or” operations, respectively, and are typically used for this purpose. However, they have an additional property of short-circuit evaluation: they don't necessarily evaluate their second argument, as explained below. (There are also bitwise `&` and `|` operators that can be used as logical “and” and “or” without short-circuit behavior, but beware that `&` and `|` have higher precedence than `&&` and `||` for evaluation order.)

Short-circuit evaluation is quite similar to conditional evaluation. The behavior is found in most imperative programming languages having the `&&` and `||` boolean operators: in a series of boolean expressions connected by these operators, only the minimum number of expressions are evaluated as are necessary to determine the final boolean value of the entire chain. Some languages (like Python) refer to them as `and` (`&&`) and `or` (`||`). Explicitly, this means that:

- In the expression `a && b`, the subexpression `b` is only evaluated if `a` evaluates to `true`.
- In the expression `a || b`, the subexpression `b` is only evaluated if `a` evaluates to `false`.

The reasoning is that `a && b` must be `false` if `a` is `false`, regardless of the value of `b`, and likewise, the value of `a || b` must be `true` if `a` is `true`, regardless of the value of `b`. Both `&&` and `||` associate to the right, but `&&` has higher precedence than `||` does. It's easy to experiment with this behavior:

```
julia> t(x) = (println(x); true)
t (generic function with 1 method)

julia> f(x) = (println(x); false)
f (generic function with 1 method)

julia> t(1) && t(2)
1
2
true

julia> t(1) && f(2)
1
2
false

julia> f(1) && t(2)
1
false

julia> f(1) && f(2)
1
false

julia> t(1) || t(2)
1
true

julia> t(1) || f(2)
1
true

julia> f(1) || t(2)
1
2
true

julia> f(1) || f(2)
1
2
false
```

You can easily experiment in the same way with the associativity and precedence of various combinations of `&&` and `||` operators.

This behavior is frequently used in Julia to form an alternative to very short `if` statements. Instead of `if <cond> <statement> end`, one can write `<cond> && <statement>` (which could be read as: `<cond>` and then `<statement>`). Similarly, instead of `if ! <cond> <statement> end`, one can write `<cond> || <statement>` (which could be read as: `<cond>` or else `<statement>`).

For example, a recursive factorial routine could be defined like this:

```
julia> function fact(n::Int)
    n >= 0 || error("n must be non-negative")
```

```

        n == 0 && return 1
        n * fact(n-1)
    end
fact (generic function with 1 method)

julia> fact(5)
120

julia> fact(0)
1

julia> fact(-1)
ERROR: n must be non-negative
Stacktrace:
 [1] error at ./error.jl:33 [inlined]
 [2] fact(::Int64) at ./none:2
 [3] top-level scope

```

Boolean operations without short-circuit evaluation can be done with the bitwise boolean operators introduced in [Mathematical Operations and Elementary Functions](#): `&` and `|`. These are normal functions, which happen to support infix operator syntax, but always evaluate their arguments:

```

julia> f(1) & t(2)
1
2
false

julia> t(1) | t(2)
1
2
true

```

Just like condition expressions used in `if`, `elseif` or the ternary operator, the operands of `&&` or `||` must be boolean values (`true` or `false`). Using a non-boolean value anywhere except for the last entry in a conditional chain is an error:

```

julia> 1 && true
ERROR: TypeError: non-boolean (Int64) used in boolean context

```

On the other hand, any type of expression can be used at the end of a conditional chain. It will be evaluated and returned depending on the preceding conditionals:

```

julia> true && (x = (1, 2, 3))
(1, 2, 3)

julia> false && (x = (1, 2, 3))
false

```

9.4 Repeated Evaluation: Loops

There are two constructs for repeated evaluation of expressions: the `while` loop and the `for` loop. Here is an example of a `while` loop:

```
julia> i = 1;

julia> while i <= 3
    println(i)
    global i += 1
end

1
2
3
```

The `while` loop evaluates the condition expression (`i <= 5` in this case), and as long it remains `true`, keeps also evaluating the body of the `while` loop. If the condition expression is `false` when the `while` loop is first reached, the body is never evaluated.

The `for` loop makes common repeated evaluation idioms easier to write. Since counting up and down like the above `while` loop does is so common, it can be expressed more concisely with a `for` loop:

```
julia> for i = 1:3
    println(i)
end

1
2
3
```

Here the `1:3` is a range object, representing the sequence of numbers 1, 2, 3. The `for` loop iterates through these values, assigning each one in turn to the variable `i`. One rather important distinction between the previous `while` loop form and the `for` loop form is the scope during which the variable is visible. A `for` loop always introduces a new iteration variable in its body, regardless of whether a variable of the same name exists in the enclosing scope. This implies that on the one hand `i` need not be declared before the loop. On the other hand it will not be visible outside the loop, nor will an outside variable of the same name be affected. You'll either need a new interactive session instance or a different variable name to test this:

```
julia> for j = 1:3
    println(j)
end

1
2
3

julia> j
ERROR: UndefVarError: `j` not defined

julia> j = 0;

julia> for j = 1:3
```

```

        println(j)
    end
1
2
3

julia> j
0

```

Use `for outer` to modify the latter behavior and reuse an existing local variable.

See [Scope of Variables](#) for a detailed explanation of variable scope, `outer`, and how it works in Julia.

In general, the `for` loop construct can iterate over any container. In these cases, the alternative (but fully equivalent) keyword `in` or `∈` is typically used instead of `=`, since it makes the code read more clearly:

```

julia> for i in [1,4,0]
    println(i)
end
1
4
0

julia> for s ∈ ["foo", "bar", "baz"]
    println(s)
end
foo
bar
baz

```

Various types of iterable containers will be introduced and discussed in later sections of the manual (see, e.g., [Multi-dimensional Arrays](#)).

It is sometimes convenient to terminate the repetition of a `while` before the test condition is falsified or stop iterating in a `for` loop before the end of the iterable object is reached. This can be accomplished with the `break` keyword:

```

julia> i = 1;

julia> while true
    println(i)
    if i >= 3
        break
    end
    global i += 1
end
1
2
3

julia> for j = 1:1000
    println(j)
end

```

```

        if j >= 3
            break
        end
    end
1
2
3

```

Without the `break` keyword, the above `while` loop would never terminate on its own, and the `for` loop would iterate up to 1000. These loops are both exited early by using `break`.

In other circumstances, it is handy to be able to stop an iteration and move on to the next one immediately. The `continue` keyword accomplishes this:

```

julia> for i = 1:10
        if i % 3 != 0
            continue
        end
        println(i)
    end
3
6
9

```

This is a somewhat contrived example since we could produce the same behavior more clearly by negating the condition and placing the `println` call inside the `if` block. In realistic usage there is more code to be evaluated after the `continue`, and often there are multiple points from which one calls `continue`.

Multiple nested `for` loops can be combined into a single outer loop, forming the cartesian product of its iterables:

```

julia> for i = 1:2, j = 3:4
        println((i, j))
    end
(1, 3)
(1, 4)
(2, 3)
(2, 4)

```

With this syntax, iterables may still refer to outer loop variables; e.g. `for i = 1:n, j = 1:i` is valid. However a `break` statement inside such a loop exits the entire nest of loops, not just the inner one. Both variables (`i` and `j`) are set to their current iteration values each time the inner loop runs. Therefore, assignments to `i` will not be visible to subsequent iterations:

```

julia> for i = 1:2, j = 3:4
        println((i, j))
        i = 0
    end
(1, 3)
(1, 4)
(2, 3)
(2, 4)

```

If this example were rewritten to use a `for` keyword for each variable, then the output would be different: the second and fourth values would contain 0.

Multiple containers can be iterated over at the same time in a single `for` loop using `zip`:

```
julia> for (j, k) in zip([1 2 3], [4 5 6 7])
    println((j,k))
end
(1, 4)
(2, 5)
(3, 6)
```

Using `zip` will create an iterator that is a tuple containing the subiterators for the containers passed to it. The `zip` iterator will iterate over all subiterators in order, choosing the i th element of each subiterator in the i th iteration of the `for` loop. Once any of the subiterators run out, the `for` loop will stop.

9.5 Exception Handling

When an unexpected condition occurs, a function may be unable to return a reasonable value to its caller. In such cases, it may be best for the exceptional condition to either terminate the program while printing a diagnostic error message, or if the programmer has provided code to handle such exceptional circumstances then allow that code to take the appropriate action.

Built-in Exceptions

Exceptions are thrown when an unexpected condition has occurred. The built-in Exceptions listed below all interrupt the normal flow of control.

For example, the `sqrt` function throws a `DomainError` if applied to a negative real value:

```
julia> sqrt(-1)
ERROR: DomainError with -1.0:
sqrt was called with a negative real argument but will only return a complex result if called
↳ with a complex argument. Try sqrt(Complex(x)).
Stacktrace:
[...]
```

You may define your own exceptions in the following way:

```
julia> struct MyCustomException <: Exception end
```

The `throw` function

Exceptions can be created explicitly with `throw`. For example, a function defined only for nonnegative numbers could be written to `throw` a `DomainError` if the argument is negative:

```
julia> f(x) = x>=0 ? exp(-x) : throw(DomainError(x, "argument must be nonnegative"))
f (generic function with 1 method)

julia> f(1)
```

Exception
ArgumentError
BoundsError
CompositeException
DimensionMismatch
DivideError
DomainError
EOFError
ErrorException
InexactError
InitError
InterruptException
InvalidStateException
KeyError
LoadError
OutOfMemoryError
ReadOnlyMemoryError
RemoteException
MethodError
OverflowError
Meta.ParseError
SystemError
TypeError
UndefRefError
UndefVarError
StringIndexError

```
0.36787944117144233

julia> f(-1)
ERROR: DomainError with -1:
argument must be nonnegative
Stacktrace:
 [1] f(::Int64) at ./none:1
```

Note that `DomainError` without parentheses is not an exception, but a type of exception. It needs to be called to obtain an Exception object:

```
julia> typeof(DomainError(nothing)) <: Exception
true

julia> typeof(DomainError) <: Exception
false
```

Additionally, some exception types take one or more arguments that are used for error reporting:

```
julia> throw(UndefVarError(:x))
ERROR: UndefVarError: `x` not defined
```

This mechanism can be implemented easily by custom exception types following the way `UndefVarError` is written:

```
julia> struct MyUndefVarError <: Exception
    var::Symbol
end

julia> Base.showerror(io::IO, e::MyUndefVarError) = print(io, e.var, " not defined")
```

Note

When writing an error message, it is preferred to make the first word lowercase. For example, `size(A) == size(B) || throw(DimensionMismatch("size of A not equal to size of B"))` is preferred over `size(A) == size(B) || throw(DimensionMismatch("Size of A not equal to size of B"))`. However, sometimes it makes sense to keep the uppercase first letter, for instance if an argument to a function is a capital letter: `size(A,1) == size(B,2) || throw(DimensionMismatch("A has first dimension..."))`.

Errors

The `error` function is used to produce an `ErrorException` that interrupts the normal flow of control.

Suppose we want to stop execution immediately if the square root of a negative number is taken. To do this, we can define a fussy version of the `sqrt` function that raises an error if its argument is negative:

```
julia> fussy_sqrt(x) = x >= 0 ? sqrt(x) : error("negative x not allowed")
fussy_sqrt (generic function with 1 method)

julia> fussy_sqrt(2)
1.4142135623730951

julia> fussy_sqrt(-1)
ERROR: negative x not allowed
Stacktrace:
 [1] error at ./error.jl:33 [inlined]
 [2] fussy_sqrt(::Int64) at ./none:1
 [3] top-level scope
```

If `fussy_sqrt` is called with a negative value from another function, instead of trying to continue execution of the calling function, it returns immediately, displaying the error message in the interactive session:

```
julia> function verbose_fussy_sqrt(x)
    println("before fussy_sqrt")
    r = fussy_sqrt(x)
    println("after fussy_sqrt")
    return r
end
verbose_fussy_sqrt (generic function with 1 method)
```

```
julia> verbose_fussy_sqrt(2)
before fussy_sqrt
after fussy_sqrt
1.4142135623730951

julia> verbose_fussy_sqrt(-1)
before fussy_sqrt
ERROR: negative x not allowed
Stacktrace:
 [1] error at ./error.jl:33 [inlined]
 [2] fussy_sqrt at ./none:1 [inlined]
 [3] verbose_fussy_sqrt(::Int64) at ./none:3
 [4] top-level scope
```

The try/catch statement

The try/catch statement allows for Exceptions to be tested for, and for the graceful handling of things that may ordinarily break your application. For example, in the below code the function for square root would normally throw an exception. By placing a try/catch block around it we can mitigate that here. You may choose how you wish to handle this exception, whether logging it, return a placeholder value or as in the case below where we just printed out a statement. One thing to think about when deciding how to handle unexpected situations is that using a try/catch block is much slower than using conditional branching to handle those situations. Below there are more examples of handling exceptions with a try/catch block:

```
julia> try
    sqrt("ten")
catch e
    println("You should have entered a numeric value")
end
You should have entered a numeric value
```

try/catch statements also allow the Exception to be saved in a variable. The following contrived example calculates the square root of the second element of x if x is indexable, otherwise assumes x is a real number and returns its square root:

```
julia> sqrt_second(x) = try
    sqrt(x[2])
catch y
    if isa(y, DomainError)
        sqrt(complex(x[2], 0))
    elseif isa(y, BoundsError)
        sqrt(x)
    end
end
sqrt_second (generic function with 1 method)

julia> sqrt_second([1 4])
2.0

julia> sqrt_second([1 -4])
```

```
0.0 + 2.0im

julia> sqrt_second(9)
3.0

julia> sqrt_second(-9)
ERROR: DomainError with -9.0:
sqrt was called with a negative real argument but will only return a complex result if called
↳ with a complex argument. Try sqrt(Complex(x)).
Stacktrace:
[...]
```

Note that the symbol following `catch` will always be interpreted as a name for the exception, so care is needed when writing `try/catch` expressions on a single line. The following code will not work to return the value of `x` in case of an error:

```
try bad() catch x end
```

Instead, use a semicolon or insert a line break after `catch`:

```
try bad() catch; x end

try bad()
catch
    x
end
```

The power of the `try/catch` construct lies in the ability to unwind a deeply nested computation immediately to a much higher level in the stack of calling functions. There are situations where no error has occurred, but the ability to unwind the stack and pass a value to a higher level is desirable. Julia provides the [rethrow](#), [backtrace](#), [catch_backtrace](#) and [current_exceptions](#) functions for more advanced error handling.

else Clauses

Julia 1.8

This functionality requires at least Julia 1.8.

In some cases, one may not only want to appropriately handle the error case, but also want to run some code only if the `try` block succeeds. For this, an `else` clause can be specified after the `catch` block that is run whenever no error was thrown previously. The advantage over including this code in the `try` block instead is that any further errors don't get silently caught by the `catch` clause.

```
local x
try
    x = read("file", String)
catch
    # handle read errors
else
    # do something with x
end
```

Note

The `try`, `catch`, `else`, and `finally` clauses each introduce their own scope blocks, so if a variable is only defined in the `try` block, it can not be accessed by the `else` or `finally` clause:

```
julia> try
    foo = 1
catch
else
    foo
end
ERROR: UndefVarError: `foo` not defined
```

Use the `local` keyword outside the `try` block to make the variable accessible from anywhere within the outer scope.

finally Clauses

In code that performs state changes or uses resources like files, there is typically clean-up work (such as closing files) that needs to be done when the code is finished. Exceptions potentially complicate this task, since they can cause a block of code to exit before reaching its normal end. The `finally` keyword provides a way to run some code when a given block of code exits, regardless of how it exits.

For example, here is how we can guarantee that an opened file is closed:

```
f = open("file")
try
    # operate on file f
finally
    close(f)
end
```

When control leaves the `try` block (for example due to a return, or just finishing normally), `close(f)` will be executed. If the `try` block exits due to an exception, the exception will continue propagating. A `catch` block may be combined with `try` and `finally` as well. In this case the `finally` block will run after `catch` has handled the error.

9.6 Tasks (aka Coroutines)

Tasks are a control flow feature that allows computations to be suspended and resumed in a flexible manner. We mention them here only for completeness; for a full discussion see [Asynchronous Programming](#).

Chapter 10

Scope of Variables

The scope of a variable is the region of code within which a variable is accessible. Variable scoping helps avoid variable naming conflicts. The concept is intuitive: two functions can both have arguments called `x` without the two `x`'s referring to the same thing. Similarly, there are many other cases where different blocks of code can use the same name without referring to the same thing. The rules for when the same variable name does or doesn't refer to the same thing are called scope rules; this section spells them out in detail.

Certain constructs in the language introduce scope blocks, which are regions of code that are eligible to be the scope of some set of variables. The scope of a variable cannot be an arbitrary set of source lines; instead, it will always line up with one of these blocks. There are two main types of scopes in Julia, global scope and local scope. The latter can be nested. There is also a distinction in Julia between constructs which introduce a "hard scope" and those which only introduce a "soft scope", which affects whether [shadowing](#) a global variable by the same name is allowed or not.

Scope constructs

The constructs introducing scope blocks are:

Construct	Scope type	Allowed within
<code>module</code> , <code>baremodule</code>	global	global
<code>struct</code>	local (soft)	global
<code>for</code> , <code>while</code> , <code>try</code>	local (soft)	global, local
<code>macro</code>	local (hard)	global
functions, <code>do</code> blocks, <code>let</code> blocks, comprehensions, generators	local (hard)	global, local

Notably missing from this table are `begin blocks` and `if blocks` which do not introduce new scopes. The three types of scopes follow somewhat different rules which will be explained below.

Julia uses [lexical scoping](#), meaning that a function's scope does not inherit from its caller's scope, but from the scope in which the function was defined. For example, in the following code the `x` inside `foo` refers to the `x` in the global scope of its module `Bar`:

```
julia> module Bar
    x = 1
    foo() = x
end;
```

and not a `x` in the scope where `foo` is used:

```
julia> import .Bar

julia> x = -1;

julia> Bar.foo()
1
```

Thus lexical scope means that what a variable in a particular piece of code refers to can be deduced from the code in which it appears alone and does not depend on how the program executes. A scope nested inside another scope can "see" variables in all the outer scopes in which it is contained. Outer scopes, on the other hand, cannot see variables in inner scopes.

10.1 Global Scope

Each module introduces a new global scope, separate from the global scope of all other modules—there is no all-encompassing global scope. Modules can introduce variables of other modules into their scope through the `using` or `import` statements or through qualified access using the dot-notation, i.e. each module is a so-called namespace as well as a first-class data structure associating names with values.

If a top-level expression contains a variable declaration with keyword `local`, then that variable is not accessible outside that expression. The variable inside the expression does not affect global variables of the same name. An example is to declare `local x` in a `begin` or `if` block at the top-level:

```
julia> x = 1
      begin
          local x = 0
          @show x
      end
      @show x;

x = 0
x = 1
```

Note that the interactive prompt (aka REPL) is in the global scope of the module `Main`.

10.2 Local Scope

A new local scope is introduced by most code blocks (see above [table](#) for a complete list). If such a block is syntactically nested inside of another local scope, the scope it creates is nested inside of all the local scopes that it appears within, which are all ultimately nested inside of the global scope of the module in which the code is evaluated. Variables in outer scopes are visible from any scope they contain — meaning that they can be read and written in inner scopes — unless there is a local variable with the same name that "shadows" the outer variable of the same name. This is true even if the outer local is declared after (in the sense of textually below) an inner block. When we say that a variable "exists" in a given scope, this means that a variable by that name exists in any of the scopes that the current scope is nested inside of, including the current one.

Some programming languages require explicitly declaring new variables before using them. Explicit declaration works in Julia too: in any local scope, writing `local x` declares a new local variable in that scope,

regardless of whether there is already a variable named `x` in an outer scope or not. Declaring each new variable like this is somewhat verbose and tedious, however, so Julia, like many other languages, considers assignment to a variable name that doesn't already exist to implicitly declare that variable. If the current scope is global, the new variable is global; if the current scope is local, the new variable is local to the innermost local scope and will be visible inside of that scope but not outside of it. If you assign to an existing local, it always updates that existing local: you can only shadow a local by explicitly declaring a new local in a nested scope with the `local` keyword. In particular, this applies to variables assigned in inner functions, which may surprise users coming from Python where assignment in an inner function creates a new local unless the variable is explicitly declared to be non-local.

Mostly this is pretty intuitive, but as with many things that behave intuitively, the details are more subtle than one might naïvely imagine.

When `x = <value>` occurs in a local scope, Julia applies the following rules to decide what the expression means based on where the assignment expression occurs and what `x` already refers to at that location:

1. **Existing local:** If `x` is already a local variable, then the existing local `x` is assigned;
2. **Hard scope:** If `x` is not already a local variable and assignment occurs inside of any hard scope construct (i.e. within a `let` block, function or macro body, comprehension, or generator), a new local named `x` is created in the scope of the assignment;
3. **Soft scope:** If `x` is not already a local variable and all of the scope constructs containing the assignment are soft scopes (loops, `try/catch` blocks, or `struct` blocks), the behavior depends on whether the global variable `x` is defined:
 - if global `x` is undefined, a new local named `x` is created in the scope of the assignment;
 - if global `x` is defined, the assignment is considered ambiguous:
 - * in non-interactive contexts (files, `eval`), an ambiguity warning is printed and a new local is created;
 - * in interactive contexts (REPL, notebooks), the global variable `x` is assigned.

You may note that in non-interactive contexts the hard and soft scope behaviors are identical except that a warning is printed when an implicitly local variable (i.e. not declared with `local x`) shadows a global. In interactive contexts, the rules follow a more complex heuristic for the sake of convenience. This is covered in depth in examples that follow.

Now that you know the rules, let's look at some examples. Each example is assumed to be evaluated in a fresh REPL session so that the only globals in each snippet are the ones that are assigned in that block of code.

We'll begin with a nice and clear-cut situation—assignment inside of a hard scope, in this case a function body, when no local variable by that name already exists:

```
julia> function greet()
           x = "hello" # new local
           println(x)
       end
greet (generic function with 1 method)

julia> greet()
```

```
hello

julia> x # global
ERROR: UndefVarError: `x` not defined
```

Inside of the `greet` function, the assignment `x = "hello"` causes `x` to be a new local variable in the function's scope. There are two relevant facts: the assignment occurs in local scope and there is no existing local `x` variable. Since `x` is local, it doesn't matter if there is a global named `x` or not. Here for example we define `x = 123` before defining and calling `greet`:

```
julia> x = 123 # global
123

julia> function greet()
    x = "hello" # new local
    println(x)
end
greet (generic function with 1 method)

julia> greet()
hello

julia> x # global
123
```

Since the `x` in `greet` is local, the value (or lack thereof) of the global `x` is unaffected by calling `greet`. The hard scope rule doesn't care whether a global named `x` exists or not: assignment to `x` in a hard scope is local (unless `x` is declared global).

The next clear cut situation we'll consider is when there is already a local variable named `x`, in which case `x = <value>` always assigns to this existing local `x`. This is true whether the assignment occurs in the same local scope, an inner local scope in the same function body, or in the body of a function nested inside of another function, also known as a [closure](#).

We'll use the `sum_to` function, which computes the sum of integers from one up to `n`, as an example:

```
function sum_to(n)
    s = 0 # new local
    for i = 1:n
        s = s + i # assign existing local
    end
    return s # same local
end
```

As in the previous example, the first assignment to `s` at the top of `sum_to` causes `s` to be a new local variable in the body of the function. The `for` loop has its own inner local scope within the function scope. At the point where `s = s + i` occurs, `s` is already a local variable, so the assignment updates the existing `s` instead of creating a new local. We can test this out by calling `sum_to` in the REPL:

```
julia> function sum_to(n)
    s = 0 # new local
```

```

        for i = 1:n
            s = s + i # assign existing local
        end
        return s # same local
    end
sum_to (generic function with 1 method)

julia> sum_to(10)
55

julia> s # global
ERROR: UndefVarError: `s` not defined

```

Since `s` is local to the function `sum_to`, calling the function has no effect on the global variable `s`. We can also see that the update `s = s + i` in the `for` loop must have updated the same `s` created by the initialization `s = 0` since we get the correct sum of 55 for the integers 1 through 10.

Let's dig into the fact that the `for` loop body has its own scope for a second by writing a slightly more verbose variation which we'll call `sum_to_def`, in which we save the sum `s + i` in a variable `t` before updating `s`:

```

julia> function sum_to_def(n)
    s = 0 # new local
    for i = 1:n
        t = s + i # new local `t`
        s = t # assign existing local `s`
    end
    return s, @isdefined(t)
end
sum_to_def (generic function with 1 method)

julia> sum_to_def(10)
(55, false)

```

This version returns `s` as before but it also uses the `@isdefined` macro to return a boolean indicating whether there is a local variable named `t` defined in the function's outermost local scope. As you can see, there is no `t` defined outside of the `for` loop body. This is because of the hard scope rule again: since the assignment to `t` occurs inside of a function, which introduces a hard scope, the assignment causes `t` to become a new local variable in the local scope where it appears, i.e. inside of the loop body. Even if there were a global named `t`, it would make no difference—the hard scope rule isn't affected by anything in global scope.

Note that the local scope of a `for` loop body is no different from the local scope of an inner function. This means that we could rewrite this example so that the loop body is implemented as a call to an inner helper function and it behaves the same way:

```

julia> function sum_to_def_closure(n)
    function loop_body(i)
        t = s + i # new local `t`
        s = t # assign same local `s` as below
    end

```

```

        s = 0 # new local
        for i = 1:n
            loop_body(i)
        end
        return s, @isdefined(t)
    end
sum_to_def_closure (generic function with 1 method)

julia> sum_to_def_closure(10)
(55, false)

```

This example illustrates a couple of key points:

1. Inner function scopes are just like any other nested local scope. In particular, if a variable is already a local outside of an inner function and you assign to it in the inner function, the outer local variable is updated.
2. It doesn't matter if the definition of an outer local happens below where it is updated, the rule remains the same. The entire enclosing local scope is parsed and its locals determined before inner local meanings are resolved.

This design means that you can generally move code in or out of an inner function without changing its meaning, which facilitates a number of common idioms in the language using closures (see [do blocks](#)).

Let's move onto some more ambiguous cases covered by the soft scope rule. We'll explore this by extracting the bodies of the `greet` and `sum_to_def` functions into soft scope contexts. First, let's put the body of `greet` in a `for` loop—which is soft, rather than hard—and evaluate it in the REPL:

```

julia> for i = 1:3
        x = "hello" # new local
        println(x)
    end
hello
hello
hello

julia> x
ERROR: UndefVarError: `x` not defined

```

Since the global `x` is not defined when the `for` loop is evaluated, the first clause of the soft scope rule applies and `x` is created as local to the `for` loop and therefore global `x` remains undefined after the loop executes. Next, let's consider the body of `sum_to_def` extracted into global scope, fixing its argument to `n = 10`

```

s = 0
for i = 1:10
    t = s + i
    s = t
end
s
@isdefined(t)

```

What does this code do? Hint: it's a trick question. The answer is "it depends." If this code is entered interactively, it behaves the same way it does in a function body. But if the code appears in a file, it prints an ambiguity warning and throws an undefined variable error. Let's see it working in the REPL first:

```
julia> s = 0 # global
0

julia> for i = 1:10
    t = s + i # new local `t`
    s = t # assign global `s`
end

julia> s # global
55

julia> @isdefined(t) # global
false
```

The REPL approximates being in the body of a function by deciding whether assignment inside the loop assigns to a global or creates new local based on whether a global variable by that name is defined or not. If a global by the name exists, then the assignment updates it. If no global exists, then the assignment creates a new local variable. In this example we see both cases in action:

- There is no global named `t`, so `t = s + i` creates a new `t` that is local to the for loop;
- There is a global named `s`, so `s = t` assigns to it.

The second fact is why execution of the loop changes the global value of `s` and the first fact is why `t` is still undefined after the loop executes. Now, let's try evaluating this same code as though it were in a file instead:

```
julia> code = """
    s = 0 # global
    for i = 1:10
        t = s + i # new local `t`
        s = t # new local `s` with warning
    end
    s, # global
    @isdefined(t) # global
    """;

julia> include_string(Main, code)
└─ Warning: Assignment to `s` in soft scope is ambiguous because a global variable by the same
↳ name exists: `s` will be treated as a new local. Disambiguate by using `local s` to suppress
↳ this warning or `global s` to assign to the existing global variable.
└─ @ string:4
ERROR: LoadError: UndefVarError: `s` not defined
```

Here we use `include_string`, to evaluate code as though it were the contents of a file. We could also save code to a file and then call `include` on that file—the result would be the same. As you can see, this behaves quite different from evaluating the same code in the REPL. Let's break down what's happening here:

- global `s` is defined with the value `0` before the loop is evaluated
- the assignment `s = t` occurs in a soft scope—a `for` loop outside of any function body or other hard scope construct
- therefore the second clause of the soft scope rule applies, and the assignment is ambiguous so a warning is emitted
- execution continues, making `s` local to the `for` loop body
- since `s` is local to the `for` loop, it is undefined when `t = s + i` is evaluated, causing an error
- evaluation stops there, but if it got to `s` and `@isdefined(t)`, it would return `0` and `false`.

This demonstrates some important aspects of scope: in a scope, each variable can only have one meaning, and that meaning is determined regardless of the order of expressions. The presence of the expression `s = t` in the loop causes `s` to be local to the loop, which means that it is also local when it appears on the right hand side of `t = s + i`, even though that expression appears first and is evaluated first. One might imagine that the `s` on the first line of the loop could be global while the `s` on the second line of the loop is local, but that's not possible since the two lines are in the same scope block and each variable can only mean one thing in a given scope.

On Soft Scope

We have now covered all the local scope rules, but before wrapping up this section, perhaps a few words should be said about why the ambiguous soft scope case is handled differently in interactive and non-interactive contexts. There are two obvious questions one could ask:

1. Why doesn't it just work like the REPL everywhere?
2. Why doesn't it just work like in files everywhere? And maybe skip the warning?

In Julia ≤ 0.6 , all global scopes did work like the current REPL: when `x = <value>` occurred in a loop (or `try/catch`, or `struct` body) but outside of a function body (or `let` block or comprehension), it was decided based on whether a global named `x` was defined or not whether `x` should be local to the loop. This behavior has the advantage of being intuitive and convenient since it approximates the behavior inside of a function body as closely as possible. In particular, it makes it easy to move code back and forth between a function body and the REPL when trying to debug the behavior of a function. However, it has some downsides. First, it's quite a complex behavior: many people over the years were confused about this behavior and complained that it was complicated and hard both to explain and understand. Fair point. Second, and arguably worse, is that it's bad for programming "at scale." When you see a small piece of code in one place like this, it's quite clear what's going on:

```
s = 0
for i = 1:10
    s += i
end
```

Obviously the intention is to modify the existing global variable `s`. What else could it mean? However, not all real world code is so short or so clear. We found that code like the following often occurs in the wild:

```

x = 123

# much later
# maybe in a different file

for i = 1:10
    x = "hello"
    println(x)
end

# much later
# maybe in yet another file
# or maybe back in the first one where `x = 123`

y = x + 234

```

It's far less clear what should happen here. Since `x + "hello"` is a method error, it seems probable that the intention is for `x` to be local to the `for` loop. But runtime values and what methods happen to exist cannot be used to determine the scopes of variables. With the Julia ≤ 0.6 behavior, it's especially concerning that someone might have written the `for` loop first, had it working just fine, but later when someone else adds a new global far away—possibly in a different file—the code suddenly changes meaning and either breaks noisily or, worse still, silently does the wrong thing. This kind of "spooky action at a distance" is something that good programming language designs should prevent.

So in Julia 1.0, we simplified the rules for scope: in any local scope, assignment to a name that wasn't already a local variable created a new local variable. This eliminated the notion of soft scope entirely as well as removing the potential for spooky action. We uncovered and fixed a significant number of bugs due to the removal of soft scope, vindicating the choice to get rid of it. And there was much rejoicing! Well, no, not really. Because some people were angry that they now had to write:

```

s = 0
for i = 1:10
    global s += i
end

```

Do you see that `global` annotation in there? Hideous. Obviously this situation could not be tolerated. But seriously, there are two main issues with requiring `global` for this kind of top-level code:

1. It's no longer convenient to copy and paste the code from inside a function body into the REPL to debug it—you have to add `global` annotations and then remove them again to go back;
2. Beginners will write this kind of code without the `global` and have no idea why their code doesn't work—the error that they get is that `s` is undefined, which does not seem to enlighten anyone who happens to make this mistake.

As of Julia 1.5, this code works without the `global` annotation in interactive contexts like the REPL or Jupyter notebooks (just like Julia 0.6) and in files and other non-interactive contexts, it prints this very direct warning:

Assignment to `s` in soft scope is ambiguous because a global variable by the same name exists: `s` will be treated as a new local. Disambiguate by using `local s` to suppress this warning or `global s` to assign to the existing global variable.

This addresses both issues while preserving the "programming at scale" benefits of the 1.0 behavior: global variables have no spooky effect on the meaning of code that may be far away; in the REPL copy-and-paste debugging works and beginners don't have any issues; any time someone either forgets a global annotation or accidentally shadows an existing global with a local in a soft scope, which would be confusing anyway, they get a nice clear warning.

An important property of this design is that any code that executes in a file without a warning will behave the same way in a fresh REPL. And on the flip side, if you take a REPL session and save it to file, if it behaves differently than it did in the REPL, then you will get a warning.

Let Blocks

`let` statements create a new hard scope block (see above) and introduce new variable bindings each time they run. The variable need not be immediately assigned:

```
julia> var1 = let x
           for i in 1:5
               (i == 4) && (x = i; break)
           end
           x
       end
4
```

Whereas assignments might reassign a new value to an existing value location, `let` always creates a new location. This difference is usually not important, and is only detectable in the case of variables that outlive their scope via closures. The `let` syntax accepts a comma-separated series of assignments and variable names:

```
julia> x, y, z = -1, -1, -1;

julia> let x = 1, z
           println("x: $x, y: $y") # x is local variable, y the global
           println("z: $z") # errors as z has not been assigned yet but is local
       end
x: 1, y: -1
ERROR: UndefVarError: `z` not defined
```

The assignments are evaluated in order, with each right-hand side evaluated in the scope before the new variable on the left-hand side has been introduced. Therefore it makes sense to write something like `let x = x` since the two `x` variables are distinct and have separate storage. Here is an example where the behavior of `let` is needed:

```
julia> Fs = Vector{Any}(undef, 2); i = 1;

julia> while i <= 2
```

```

        Fs[i] = ()->i
        global i += 1
    end

julia> Fs[1]()
3

julia> Fs[2]()
3

```

Here we create and store two closures that return variable `i`. However, it is always the same variable `i`, so the two closures behave identically. We can use `let` to create a new binding for `i`:

```

julia> Fs = Vector{Any}(undef, 2); i = 1;

julia> while i <= 2
        let i = i
            Fs[i] = ()->i
        end
        global i += 1
    end

julia> Fs[1]()
1

julia> Fs[2]()
2

```

Since the `begin` construct does not introduce a new scope, it can be useful to use a zero-argument `let` to just introduce a new scope block without creating any new bindings immediately:

```

julia> let
        local x = 1
        let
            local x = 2
        end
        x
    end
1

```

Since `let` introduces a new scope block, the inner local `x` is a different variable than the outer local `x`. This particular example is equivalent to:

```

julia> let x = 1
        let x = 2
        end
        x
    end
1

```

Loops and Comprehensions

In loops and [comprehensions](#), new variables introduced in their body scopes are freshly allocated for each loop iteration, as if the loop body were surrounded by a `let` block, as demonstrated by this example:

```
julia> Fs = Vector{Any}(undef, 2);

julia> for j = 1:2
           Fs[j] = ()->j
       end

julia> Fs[1]()
1

julia> Fs[2]()
2
```

A for loop or comprehension iteration variable is always a new variable:

```
julia> function f()
           i = 0
           for i = 1:3
               # empty
           end
           return i
       end;

julia> f()
0
```

However, it is occasionally useful to reuse an existing local variable as the iteration variable. This can be done conveniently by adding the keyword `outer`:

```
julia> function f()
           i = 0
           for outer i = 1:3
               # empty
           end
           return i
       end;

julia> f()
3
```

10.3 Constants

A common use of variables is giving names to specific, unchanging values. Such variables are only assigned once. This intent can be conveyed to the compiler using the `const` keyword:

```
julia> const e = 2.71828182845904523536;

julia> const pi = 3.14159265358979323846;
```

Multiple variables can be declared in a single `const` statement:

```
julia> const a, b = 1, 2
(1, 2)
```

The `const` declaration should only be used in global scope on globals. It is difficult for the compiler to optimize code involving global variables, since their values (or even their types) might change at almost any time. If a global variable will not change, adding a `const` declaration solves this performance problem.

Local constants are quite different. The compiler is able to determine automatically when a local variable is constant, so local constant declarations are not necessary, and in fact are currently not supported.

Special top-level assignments, such as those performed by the `function` and `struct` keywords, are constant by default.

Note that `const` only affects the variable binding; the variable may be bound to a mutable object (such as an array), and that object may still be modified. Additionally when one tries to assign a value to a variable that is declared constant the following scenarios are possible:

- if a new value has a different type than the type of the constant then an error is thrown:

```
julia> const x = 1.0
1.0

julia> x = 1
ERROR: invalid redefinition of constant x
```

- if a new value has the same type as the constant then a warning is printed:

```
julia> const y = 1.0
1.0

julia> y = 2.0
WARNING: redefinition of constant y. This may fail, cause incorrect answers, or produce other
↪ errors.
2.0
```

- if an assignment would not result in the change of variable value no message is given:

```
julia> const z = 100
100

julia> z = 100
100
```

The last rule applies to immutable objects even if the variable binding would change, e.g.:

```
julia> const s1 = "1"
"1"

julia> s2 = "1"
"1"

julia> pointer.([s1, s2], 1)
2-element Array{Ptr{UInt8},1}:
 Ptr{UInt8} @0x00000000132c9638
 Ptr{UInt8} @0x0000000013dd3d18

julia> s1 = s2
"1"

julia> pointer.([s1, s2], 1)
2-element Array{Ptr{UInt8},1}:
 Ptr{UInt8} @0x0000000013dd3d18
 Ptr{UInt8} @0x0000000013dd3d18
```

However, for mutable objects the warning is printed as expected:

```
julia> const a = [1]
1-element Vector{Int64}:
 1

julia> a = [1]
WARNING: redefinition of constant a. This may fail, cause incorrect answers, or produce other
↪ errors.
1-element Vector{Int64}:
 1
```

Note that although sometimes possible, changing the value of a `const` variable is strongly discouraged, and is intended only for convenience during interactive use. Changing constants can cause various problems or unexpected behaviors. For instance, if a method references a constant and is already compiled before the constant is changed, then it might keep using the old value:

```
julia> const x = 1
1

julia> f() = x
f (generic function with 1 method)

julia> f()
1

julia> x = 2
WARNING: redefinition of constant x. This may fail, cause incorrect answers, or produce other
↪ errors.
2

julia> f()
1
```

10.4 Typed Globals

Julia 1.8

Support for typed globals was added in Julia 1.8

Similar to being declared as constants, global bindings can also be declared to always be of a constant type. This can either be done without assigning an actual value using the syntax `global x::T` or upon assignment as `x::T = 123`.

```
julia> x::Float64 = 2.718
2.718

julia> f() = x
f (generic function with 1 method)

julia> Base.return_types(f)
1-element Vector{Any}:
 Float64
```

For any assignment to a global, Julia will first try to convert it to the appropriate type using `convert`:

```
julia> global y::Int

julia> y = 1.0
1.0

julia> y
1

julia> y = 3.14
ERROR: InexactError: Int64(3.14)
Stacktrace:
[...]
```

The type does not need to be concrete, but annotations with abstract types typically have little performance benefit.

Once a global has either been assigned to or its type has been set, the binding type is not allowed to change:

```
julia> x = 1
1

julia> global x::Int
ERROR: cannot set type for global x. It already has a value or is already set to a different
↪ type.
Stacktrace:
[...]
```

Chapter 11

Types

Type systems have traditionally fallen into two quite different camps: static type systems, where every program expression must have a type computable before the execution of the program, and dynamic type systems, where nothing is known about types until run time, when the actual values manipulated by the program are available. Object orientation allows some flexibility in statically typed languages by letting code be written without the precise types of values being known at compile time. The ability to write code that can operate on different types is called polymorphism. All code in classic dynamically typed languages is polymorphic: only by explicitly checking types, or when objects fail to support operations at run-time, are the types of any values ever restricted.

Julia's type system is dynamic, but gains some of the advantages of static type systems by making it possible to indicate that certain values are of specific types. This can be of great assistance in generating efficient code, but even more significantly, it allows method dispatch on the types of function arguments to be deeply integrated with the language. Method dispatch is explored in detail in [Methods](#), but is rooted in the type system presented here.

The default behavior in Julia when types are omitted is to allow values to be of any type. Thus, one can write many useful Julia functions without ever explicitly using types. When additional expressiveness is needed, however, it is easy to gradually introduce explicit type annotations into previously "untyped" code. Adding annotations serves three primary purposes: to take advantage of Julia's powerful multiple-dispatch mechanism, to improve human readability, and to catch programmer errors.

Describing Julia in the lingo of [type systems](#), it is: dynamic, nominative and parametric. Generic types can be parameterized, and the hierarchical relationships between types are [explicitly declared](#), rather than [implied by compatible structure](#). One particularly distinctive feature of Julia's type system is that concrete types may not subtype each other: all concrete types are final and may only have abstract types as their supertypes. While this might at first seem unduly restrictive, it has many beneficial consequences with surprisingly few drawbacks. It turns out that being able to inherit behavior is much more important than being able to inherit structure, and inheriting both causes significant difficulties in traditional object-oriented languages. Other high-level aspects of Julia's type system that should be mentioned up front are:

- There is no division between object and non-object values: all values in Julia are true objects having a type that belongs to a single, fully connected type graph, all nodes of which are equally first-class as types.

- There is no meaningful concept of a "compile-time type": the only type a value has is its actual type when the program is running. This is called a "run-time type" in object-oriented languages where the combination of static compilation with polymorphism makes this distinction significant.
- Only values, not variables, have types – variables are simply names bound to values, although for simplicity we may say "type of a variable" as shorthand for "type of the value to which a variable refers".
- Both abstract and concrete types can be parameterized by other types. They can also be parameterized by symbols, by values of any type for which `isbits` returns true (essentially, things like numbers and bools that are stored like C types or structs with no pointers to other objects), and also by tuples thereof. Type parameters may be omitted when they do not need to be referenced or restricted.

Julia's type system is designed to be powerful and expressive, yet clear, intuitive and unobtrusive. Many Julia programmers may never feel the need to write code that explicitly uses types. Some kinds of programming, however, become clearer, simpler, faster and more robust with declared types.

11.1 Type Declarations

The `::` operator can be used to attach type annotations to expressions and variables in programs. There are two primary reasons to do this:

1. As an assertion to help confirm that your program works the way you expect, and
2. To provide extra type information to the compiler, which can then improve performance in some cases.

When appended to an expression computing a value, the `::` operator is read as "is an instance of". It can be used anywhere to assert that the value of the expression on the left is an instance of the type on the right. When the type on the right is concrete, the value on the left must have that type as its implementation – recall that all concrete types are final, so no implementation is a subtype of any other. When the type is abstract, it suffices for the value to be implemented by a concrete type that is a subtype of the abstract type. If the type assertion is not true, an exception is thrown, otherwise, the left-hand value is returned:

```
julia> (1+2)::AbstractFloat
ERROR: TypeError: in typeassert, expected AbstractFloat, got a value of type Int64

julia> (1+2)::Int
3
```

This allows a type assertion to be attached to any expression in-place.

When appended to a variable on the left-hand side of an assignment, or as part of a local declaration, the `::` operator means something a bit different: it declares the variable to always have the specified type, like a type declaration in a statically-typed language such as C. Every value assigned to the variable will be converted to the declared type using `convert`:

```
julia> function foo()
    x::Int8 = 100
    x
end
foo (generic function with 1 method)

julia> x = foo()
100

julia> typeof(x)
Int8
```

This feature is useful for avoiding performance "gotchas" that could occur if one of the assignments to a variable changed its type unexpectedly.

This "declaration" behavior only occurs in specific contexts:

```
local x::Int8 # in a local declaration
x::Int8 = 10  # as the left-hand side of an assignment
```

and applies to the whole current scope, even before the declaration.

As of Julia 1.8, type declarations can now be used in global scope i.e. type annotations can be added to global variables to make accessing them type stable.

```
julia> x::Int = 10
10

julia> x = 3.5
ERROR: InexactError: Int64(3.5)

julia> function foo(y)
    global x = 15.8 # throws an error when foo is called
    return x + y
end
foo (generic function with 1 method)

julia> foo(10)
ERROR: InexactError: Int64(15.8)
```

Declarations can also be attached to function definitions:

```
function sinc(x)::Float64
    if x == 0
        return 1
    end
    return sin(pi*x)/(pi*x)
end
```

Returning from this function behaves just like an assignment to a variable with a declared type: the value is always converted to Float64.

11.2 Abstract Types

Abstract types cannot be instantiated, and serve only as nodes in the type graph, thereby describing sets of related concrete types: those concrete types which are their descendants. We begin with abstract types even though they have no instantiation because they are the backbone of the type system: they form the conceptual hierarchy which makes Julia's type system more than just a collection of object implementations.

Recall that in [Integers and Floating-Point Numbers](#), we introduced a variety of concrete types of numeric values: `Int8`, `UInt8`, `Int16`, `UInt16`, `Int32`, `UInt32`, `Int64`, `UInt64`, `Int128`, `UInt128`, `Float16`, `Float32`, and `Float64`. Although they have different representation sizes, `Int8`, `Int16`, `Int32`, `Int64` and `Int128` all have in common that they are signed integer types. Likewise `UInt8`, `UInt16`, `UInt32`, `UInt64` and `UInt128` are all unsigned integer types, while `Float16`, `Float32` and `Float64` are distinct in being floating-point types rather than integers. It is common for a piece of code to make sense, for example, only if its arguments are some kind of integer, but not really depend on what particular kind of integer. For example, the greatest common denominator algorithm works for all kinds of integers, but will not work for floating-point numbers. Abstract types allow the construction of a hierarchy of types, providing a context into which concrete types can fit. This allows you, for example, to easily program to any type that is an integer, without restricting an algorithm to a specific type of integer.

Abstract types are declared using the `abstract type` keyword. The general syntaxes for declaring an abstract type are:

```
abstract type «name» end
abstract type «name» <: «supertype» end
```

The `abstract type` keyword introduces a new abstract type, whose name is given by «name». This name can be optionally followed by `<:` and an already-existing type, indicating that the newly declared abstract type is a subtype of this "parent" type.

When no supertype is given, the default supertype is `Any` – a predefined abstract type that all objects are instances of and all types are subtypes of. In type theory, `Any` is commonly called "top" because it is at the apex of the type graph. Julia also has a predefined abstract "bottom" type, at the nadir of the type graph, which is written as `Union{}`. It is the exact opposite of `Any`: no object is an instance of `Union{}` and all types are supertypes of `Union{}`.

Let's consider some of the abstract types that make up Julia's numerical hierarchy:

```
abstract type Number end
abstract type Real      <: Number end
abstract type AbstractFloat <: Real end
abstract type Integer    <: Real end
abstract type Signed     <: Integer end
abstract type Unsigned   <: Integer end
```

The `Number` type is a direct child type of `Any`, and `Real` is its child. In turn, `Real` has two children (it has more, but only two are shown here; we'll get to the others later): `Integer` and `AbstractFloat`, separating the world into representations of integers and representations of real numbers. Representations of real numbers include floating-point types, but also include other types, such as rationals. `AbstractFloat` includes only floating-point representations of real numbers. Integers are further subdivided into `Signed` and `Unsigned` varieties.

The `<:` operator in general means "is a subtype of", and, used in declarations like those above, declares the right-hand type to be an immediate supertype of the newly declared type. It can also be used in expressions as a subtype operator which returns `true` when its left operand is a subtype of its right operand:

```
julia> Integer <: Number
true

julia> Integer <: AbstractFloat
false
```

An important use of abstract types is to provide default implementations for concrete types. To give a simple example, consider:

```
function myplus(x,y)
    x+y
end
```

The first thing to note is that the above argument declarations are equivalent to `x::Any` and `y::Any`. When this function is invoked, say as `myplus(2,5)`, the dispatcher chooses the most specific method named `myplus` that matches the given arguments. (See [Methods](#) for more information on multiple dispatch.)

Assuming no method more specific than the above is found, Julia next internally defines and compiles a method called `myplus` specifically for two `Int` arguments based on the generic function given above, i.e., it implicitly defines and compiles:

```
function myplus(x::Int,y::Int)
    x+y
end
```

and finally, it invokes this specific method.

Thus, abstract types allow programmers to write generic functions that can later be used as the default method by many combinations of concrete types. Thanks to multiple dispatch, the programmer has full control over whether the default or more specific method is used.

An important point to note is that there is no loss in performance if the programmer relies on a function whose arguments are abstract types, because it is recompiled for each tuple of concrete argument types with which it is invoked. (There may be a performance issue, however, in the case of function arguments that are containers of abstract types; see [Performance Tips](#).)

11.3 Primitive Types

Warning

It is almost always preferable to wrap an existing primitive type in a new composite type than to define your own primitive type.

This functionality exists to allow Julia to bootstrap the standard primitive types that LLVM supports. Once they are defined, there is very little reason to define more.

A primitive type is a concrete type whose data consists of plain old bits. Classic examples of primitive types are integers and floating-point values. Unlike most languages, Julia lets you declare your own primitive types, rather than providing only a fixed set of built-in ones. In fact, the standard primitive types are all defined in the language itself:

```

primitive type Float16 <: AbstractFloat 16 end
primitive type Float32 <: AbstractFloat 32 end
primitive type Float64 <: AbstractFloat 64 end

primitive type Bool <: Integer 8 end
primitive type Char <: AbstractChar 32 end

primitive type Int8 <: Signed 8 end
primitive type UInt8 <: Unsigned 8 end
primitive type Int16 <: Signed 16 end
primitive type UInt16 <: Unsigned 16 end
primitive type Int32 <: Signed 32 end
primitive type UInt32 <: Unsigned 32 end
primitive type Int64 <: Signed 64 end
primitive type UInt64 <: Unsigned 64 end
primitive type Int128 <: Signed 128 end
primitive type UInt128 <: Unsigned 128 end

```

The general syntaxes for declaring a primitive type are:

```

primitive type «name» «bits» end
primitive type «name» <: «supertype» «bits» end

```

The number of bits indicates how much storage the type requires and the name gives the new type a name. A primitive type can optionally be declared to be a subtype of some supertype. If a supertype is omitted, then the type defaults to having `Any` as its immediate supertype. The declaration of `Bool` above therefore means that a boolean value takes eight bits to store, and has `Integer` as its immediate supertype. Currently, only sizes that are multiples of 8 bits are supported and you are likely to experience LLVM bugs with sizes other than those used above. Therefore, boolean values, although they really need just a single bit, cannot be declared to be any smaller than eight bits.

The types `Bool`, `Int8` and `UInt8` all have identical representations: they are eight-bit chunks of memory. Since Julia's type system is nominative, however, they are not interchangeable despite having identical structure. A fundamental difference between them is that they have different supertypes: `Bool`'s direct supertype is `Integer`, `Int8`'s is `Signed`, and `UInt8`'s is `Unsigned`. All other differences between `Bool`, `Int8`, and `UInt8` are matters of behavior – the way functions are defined to act when given objects of these types as arguments. This is why a nominative type system is necessary: if structure determined type, which in turn dictates behavior, then it would be impossible to make `Bool` behave any differently than `Int8` or `UInt8`.

11.4 Composite Types

Composite types are called records, structs, or objects in various languages. A composite type is a collection of named fields, an instance of which can be treated as a single value. In many languages, composite types are the only kind of user-definable type, and they are by far the most commonly used user-defined type in Julia as well.

In mainstream object oriented languages, such as C++, Java, Python and Ruby, composite types also have named functions associated with them, and the combination is called an "object". In purer object-oriented languages, such as Ruby or Smalltalk, all values are objects whether they are composites or not. In less pure object oriented languages, including C++ and Java, some values, such as integers and floating-point values, are not objects, while instances of user-defined composite types are true objects with associated methods. In Julia, all values are objects, but functions are not bundled with the objects they operate on.

This is necessary since Julia chooses which method of a function to use by multiple dispatch, meaning that the types of all of a function's arguments are considered when selecting a method, rather than just the first one (see [Methods](#) for more information on methods and dispatch). Thus, it would be inappropriate for functions to "belong" to only their first argument. Organizing methods into function objects rather than having named bags of methods "inside" each object ends up being a highly beneficial aspect of the language design.

Composite types are introduced with the `struct` keyword followed by a block of field names, optionally annotated with types using the `::` operator:

```
julia> struct Foo
        bar
        baz::Int
        qux::Float64
    end
```

Fields with no type annotation default to `Any`, and can accordingly hold any type of value.

New objects of type `Foo` are created by applying the `Foo` type object like a function to values for its fields:

```
julia> foo = Foo("Hello, world.", 23, 1.5)
Foo("Hello, world.", 23, 1.5)

julia> typeof(foo)
Foo
```

When a type is applied like a function it is called a constructor. Two constructors are generated automatically (these are called default constructors). One accepts any arguments and calls `convert` to convert them to the types of the fields, and the other accepts arguments that match the field types exactly. The reason both of these are generated is that this makes it easier to add new definitions without inadvertently replacing a default constructor.

Since the `bar` field is unconstrained in type, any value will do. However, the value for `baz` must be convertible to `Int`:

```
julia> Foo(), 23.5, 1)
ERROR: InexactError: Int64(23.5)
Stacktrace:
[...]
```

You may find a list of field names using the `fieldnames` function.

```
julia> fieldnames(Foo)
(:bar, :baz, :qux)
```

You can access the field values of a composite object using the traditional `foo.bar` notation:

```
julia> foo.bar
"Hello, world."

julia> foo.baz
23

julia> foo.qux
1.5
```

Composite objects declared with `struct` are immutable; they cannot be modified after construction. This may seem odd at first, but it has several advantages:

- It can be more efficient. Some structs can be packed efficiently into arrays, and in some cases the compiler is able to avoid allocating immutable objects entirely.
- It is not possible to violate the invariants provided by the type's constructors.
- Code using immutable objects can be easier to reason about.

An immutable object might contain mutable objects, such as arrays, as fields. Those contained objects will remain mutable; only the fields of the immutable object itself cannot be changed to point to different objects.

Where required, mutable composite objects can be declared with the keyword `mutable struct`, to be discussed in the next section.

If all the fields of an immutable structure are indistinguishable (`===`) then two immutable values containing those fields are also indistinguishable:

```
julia> struct X
    a::Int
    b::Float64
end

julia> X(1, 2) === X(1, 2)
true
```

There is much more to say about how instances of composite types are created, but that discussion depends on both [Parametric Types](#) and on [Methods](#), and is sufficiently important to be addressed in its own section: [Constructors](#).

For many user-defined types `X`, you may want to define a method `Base.broadcastable(x::X) = Ref(x)` so that instances of that type act as 0-dimensional "scalars" for [broadcasting](#).

11.5 Mutable Composite Types

If a composite type is declared with `mutable struct` instead of `struct`, then instances of it can be modified:

```
julia> mutable struct Bar
    baz
    qux::Float64
```

```
        end

julia> bar = Bar("Hello", 1.5);

julia> bar.qux = 2.0
2.0

julia> bar.baz = 1//2
1//2
```

An extra interface between the fields and the user can be provided through [Instance Properties](#). This grants more control on what can be accessed and modified using the `bar.baz` notation.

In order to support mutation, such objects are generally allocated on the heap, and have stable memory addresses. A mutable object is like a little container that might hold different values over time, and so can only be reliably identified with its address. In contrast, an instance of an immutable type is associated with specific field values -- the field values alone tell you everything about the object. In deciding whether to make a type mutable, ask whether two instances with the same field values would be considered identical, or if they might need to change independently over time. If they would be considered identical, the type should probably be immutable.

To recap, two essential properties define immutability in Julia:

- It is not permitted to modify the value of an immutable type.
 - For bits types this means that the bit pattern of a value once set will never change and that value is the identity of a bits type.
 - For composite types, this means that the identity of the values of its fields will never change. When the fields are bits types, that means their bits will never change, for fields whose values are mutable types like arrays, that means the fields will always refer to the same mutable value even though that mutable value's content may itself be modified.
- An object with an immutable type may be copied freely by the compiler since its immutability makes it impossible to programmatically distinguish between the original object and a copy.
 - In particular, this means that small enough immutable values like integers and floats are typically passed to functions in registers (or stack allocated).
 - Mutable values, on the other hand are heap-allocated and passed to functions as pointers to heap-allocated values except in cases where the compiler is sure that there's no way to tell that this is not what is happening.

In cases where one or more fields of an otherwise mutable struct is known to be immutable, one can declare these fields as such using `const` as shown below. This enables some, but not all of the optimizations of immutable structs, and can be used to enforce invariants on the particular fields marked as `const`.

Julia 1.8

`const` annotating fields of mutable structs requires at least Julia 1.8.

```
julia> mutable struct Baz
    a::Int
    const b::Float64
end

julia> baz = Baz(1, 1.5);

julia> baz.a = 2
2

julia> baz.b = 2.0
ERROR: setfield!: const field .b of type Baz cannot be changed
[...]
```

11.6 Declared Types

The three kinds of types (abstract, primitive, composite) discussed in the previous sections are actually all closely related. They share the same key properties:

- They are explicitly declared.
- They have names.
- They have explicitly declared supertypes.
- They may have parameters.

Because of these shared properties, these types are internally represented as instances of the same concept, `DataType`, which is the type of any of these types:

```
julia> typeof(Real)
DataType

julia> typeof(Int)
DataType
```

A `DataType` may be abstract or concrete. If it is concrete, it has a specified size, storage layout, and (optionally) field names. Thus a primitive type is a `DataType` with nonzero size, but no field names. A composite type is a `DataType` that has field names or is empty (zero size).

Every concrete value in the system is an instance of some `DataType`.

11.7 Type Unions

A type union is a special abstract type which includes as objects all instances of any of its argument types, constructed using the special `Union` keyword:

```
julia> IntOrString = Union{Int, AbstractString}
Union{Int64, AbstractString}
```

```
julia> 1 :: IntOrString
1

julia> "Hello!" :: IntOrString
"Hello!"

julia> 1.0 :: IntOrString
ERROR: TypeError: in typeassert, expected Union{Int64, AbstractString}, got a value of type
↳ Float64
```

The compilers for many languages have an internal union construct for reasoning about types; Julia simply exposes it to the programmer. The Julia compiler is able to generate efficient code in the presence of Union types with a small number of types¹, by generating specialized code in separate branches for each possible type.

A particularly useful case of a Union type is `Union{T, Nothing}`, where `T` can be any type and `Nothing` is the singleton type whose only instance is the object `nothing`. This pattern is the Julia equivalent of `Nullable`, `Option` or `Maybe` types in other languages. Declaring a function argument or a field as `Union{T, Nothing}` allows setting it either to a value of type `T`, or to `nothing` to indicate that there is no value. See [this FAQ entry](#) for more information.

11.8 Parametric Types

An important and powerful feature of Julia's type system is that it is parametric: types can take parameters, so that type declarations actually introduce a whole family of new types – one for each possible combination of parameter values. There are many languages that support some version of [generic programming](#), wherein data structures and algorithms to manipulate them may be specified without specifying the exact types involved. For example, some form of generic programming exists in ML, Haskell, Ada, Eiffel, C++, Java, C#, F#, and Scala, just to name a few. Some of these languages support true parametric polymorphism (e.g. ML, Haskell, Scala), while others support ad-hoc, template-based styles of generic programming (e.g. C++, Java). With so many different varieties of generic programming and parametric types in various languages, we won't even attempt to compare Julia's parametric types to other languages, but will instead focus on explaining Julia's system in its own right. We will note, however, that because Julia is a dynamically typed language and doesn't need to make all type decisions at compile time, many traditional difficulties encountered in static parametric type systems can be relatively easily handled.

All declared types (the `Data` type variety) can be parameterized, with the same syntax in each case. We will discuss them in the following order: first, parametric composite types, then parametric abstract types, and finally parametric primitive types.

Parametric Composite Types

Type parameters are introduced immediately after the type name, surrounded by curly braces:

```
julia> struct Point{T}
    x::T
    y::T
end
```

This declaration defines a new parametric type, `Point{T}`, holding two "coordinates" of type `T`. What, one may ask, is `T`? Well, that's precisely the point of parametric types: it can be any type at all (or a value

of any bits type, actually, although here it's clearly used as a type). `Point{Float64}` is a concrete type equivalent to the type defined by replacing `T` in the definition of `Point` with `Float64`. Thus, this single declaration actually declares an unlimited number of types: `Point{Float64}`, `Point{AbstractString}`, `Point{Int64}`, etc. Each of these is now a usable concrete type:

```
julia> Point{Float64}
Point{Float64}

julia> Point{AbstractString}
Point{AbstractString}
```

The type `Point{Float64}` is a point whose coordinates are 64-bit floating-point values, while the type `Point{AbstractString}` is a "point" whose "coordinates" are string objects (see [Strings](#)).

`Point` itself is also a valid type object, containing all instances `Point{Float64}`, `Point{AbstractString}`, etc. as subtypes:

```
julia> Point{Float64} <: Point
true

julia> Point{AbstractString} <: Point
true
```

Other types, of course, are not subtypes of it:

```
julia> Float64 <: Point
false

julia> AbstractString <: Point
false
```

Concrete `Point` types with different values of `T` are never subtypes of each other:

```
julia> Point{Float64} <: Point{Int64}
false

julia> Point{Float64} <: Point{Real}
false
```

Warning

This last point is very important: even though `Float64 <: Real` we **DO NOT** have `Point{Float64} <: Point{Real}`.

In other words, in the parlance of type theory, Julia's type parameters are invariant, rather than being [covariant \(or even contravariant\)](#). This is for practical reasons: while any instance of `Point{Float64}` may conceptually be like an instance of `Point{Real}` as well, the two types have different representations in memory:

- An instance of `Point{Float64}` can be represented compactly and efficiently as an immediate pair of 64-bit values;
- An instance of `Point{Real}` must be able to hold any pair of instances of `Real`. Since objects that are instances of `Real` can be of arbitrary size and structure, in practice an instance of `Point{Real}` must be represented as a pair of pointers to individually allocated `Real` objects.

The efficiency gained by being able to store `Point{Float64}` objects with immediate values is magnified enormously in the case of arrays: an `Array{Float64}` can be stored as a contiguous memory block of 64-bit floating-point values, whereas an `Array{Real}` must be an array of pointers to individually allocated `Real` objects – which may well be `boxed` 64-bit floating-point values, but also might be arbitrarily large, complex objects, which are declared to be implementations of the `Real` abstract type.

Since `Point{Float64}` is not a subtype of `Point{Real}`, the following method can't be applied to arguments of type `Point{Float64}`:

```
function norm(p::Point{Real})
    sqrt(p.x^2 + p.y^2)
end
```

A correct way to define a method that accepts all arguments of type `Point{T}` where `T` is a subtype of `Real` is:

```
function norm(p::Point{<:Real})
    sqrt(p.x^2 + p.y^2)
end
```

(Equivalently, one could define `function norm(p::Point{T} where T<:Real)` or `function norm(p::Point{T}) where T<:Real`; see [UnionAll Types](#).)

More examples will be discussed later in [Methods](#).

How does one construct a `Point` object? It is possible to define custom constructors for composite types, which will be discussed in detail in [Constructors](#), but in the absence of any special constructor declarations, there are two default ways of creating new composite objects, one in which the type parameters are explicitly given and the other in which they are implied by the arguments to the object constructor.

Since the type `Point{Float64}` is a concrete type equivalent to `Point` declared with `Float64` in place of `T`, it can be applied as a constructor accordingly:

```
julia> p = Point{Float64}(1.0, 2.0)
Point{Float64}(1.0, 2.0)

julia> typeof(p)
Point{Float64}
```

For the default constructor, exactly one argument must be supplied for each field:

```
julia> Point{Float64}(1.0)
ERROR: MethodError: no method matching Point{Float64}(::Float64)
[...]

julia> Point{Float64}(1.0,2.0,3.0)
ERROR: MethodError: no method matching Point{Float64}(::Float64, ::Float64, ::Float64)
[...]
```

Only one default constructor is generated for parametric types, since overriding it is not possible. This constructor accepts any arguments and converts them to the field types.

In many cases, it is redundant to provide the type of `Point` object one wants to construct, since the types of arguments to the constructor call already implicitly provide type information. For that reason, you can also apply `Point` itself as a constructor, provided that the implied value of the parameter type `T` is unambiguous:

```
julia> p1 = Point(1.0,2.0)
Point{Float64}(1.0, 2.0)

julia> typeof(p1)
Point{Float64}

julia> p2 = Point(1,2)
Point{Int64}(1, 2)

julia> typeof(p2)
Point{Int64}
```

In the case of `Point`, the type of `T` is unambiguously implied if and only if the two arguments to `Point` have the same type. When this isn't the case, the constructor will fail with a `MethodError`:

```
julia> Point(1,2.5)
ERROR: MethodError: no method matching Point(::Int64, ::Float64)

Closest candidates are:
  Point{::T, !Matched::T} where T
    @ Main none:2

Stacktrace:
[...]
```

Constructor methods to appropriately handle such mixed cases can be defined, but that will not be discussed until later on in [Constructors](#).

Parametric Abstract Types

Parametric abstract type declarations declare a collection of abstract types, in much the same way:

```
julia> abstract type Pointy{T} end
```

With this declaration, `Pointy{T}` is a distinct abstract type for each type or integer value of `T`. As with parametric composite types, each such instance is a subtype of `Pointy`:

```
julia> Pointy{Int64} <: Pointy
true

julia> Pointy{1} <: Pointy
true
```

Parametric abstract types are invariant, much as parametric composite types are:

```
julia> Pointy{Float64} <: Pointy{Real}
false

julia> Pointy{Real} <: Pointy{Float64}
false
```

The notation `Pointy{<:Real}` can be used to express the Julia analogue of a covariant type, while `Pointy{>:Int}` the analogue of a contravariant type, but technically these represent sets of types (see [UnionAll Types](#)).

```
julia> Pointy{Float64} <: Pointy{<:Real}
true

julia> Pointy{Real} <: Pointy{>:Int}
true
```

Much as plain old abstract types serve to create a useful hierarchy of types over concrete types, parametric abstract types serve the same purpose with respect to parametric composite types. We could, for example, have declared `Point{T}` to be a subtype of `Pointy{T}` as follows:

```
julia> struct Point{T} <: Pointy{T}
    x::T
    y::T
end
```

Given such a declaration, for each choice of `T`, we have `Point{T}` as a subtype of `Pointy{T}`:

```
julia> Point{Float64} <: Pointy{Float64}
true

julia> Point{Real} <: Pointy{Real}
true

julia> Point{AbstractString} <: Pointy{AbstractString}
true
```

This relationship is also invariant:

```
julia> Point{Float64} <: Pointy{Real}
false

julia> Point{Float64} <: Pointy{<:Real}
true
```

What purpose do parametric abstract types like `Pointy` serve? Consider if we create a point-like implementation that only requires a single coordinate because the point is on the diagonal line $x = y$:

```
julia> struct DiagPoint{T} <: Pointy{T}
        x::T
    end
```

Now both `Point{Float64}` and `DiagPoint{Float64}` are implementations of the `Pointy{Float64}` abstraction, and similarly for every other possible choice of type `T`. This allows programming to a common interface shared by all `Pointy` objects, implemented for both `Point` and `DiagPoint`. This cannot be fully demonstrated, however, until we have introduced methods and dispatch in the next section, [Methods](#).

There are situations where it may not make sense for type parameters to range freely over all possible types. In such situations, one can constrain the range of `T` like so:

```
julia> abstract type Pointy{T<:Real} end
```

With such a declaration, it is acceptable to use any type that is a subtype of `Real` in place of `T`, but not types that are not subtypes of `Real`:

```
julia> Pointy{Float64}
Pointy{Float64}

julia> Pointy{Real}
Pointy{Real}

julia> Pointy{AbstractString}
ERROR: TypeError: in Pointy, in T, expected T<:Real, got Type{AbstractString}

julia> Pointy{1}
ERROR: TypeError: in Pointy, in T, expected T<:Real, got a value of type Int64
```

Type parameters for parametric composite types can be restricted in the same manner:

```
struct Point{T<:Real} <: Pointy{T}
    x::T
    y::T
end
```

To give a real-world example of how all this parametric type machinery can be useful, here is the actual definition of Julia's `Rational` immutable type (except that we omit the constructor here for simplicity), representing an exact ratio of integers:

```
struct Rational{T<:Integer} <: Real
    num::T
    den::T
end
```

It only makes sense to take ratios of integer values, so the parameter type `T` is restricted to being a subtype of `Integer`, and a ratio of integers represents a value on the real number line, so any `Rational` is an instance of the `Real` abstraction.

Tuple Types

Tuples are an abstraction of the arguments of a function – without the function itself. The salient aspects of a function's arguments are their order and their types. Therefore a tuple type is similar to a parameterized immutable type where each parameter is the type of one field. For example, a 2-element tuple type resembles the following immutable type:

```
struct Tuple2{A,B}
    a::A
    b::B
end
```

However, there are three key differences:

- Tuple types may have any number of parameters.
- Tuple types are covariant in their parameters: `Tuple{Int}` is a subtype of `Tuple{Any}`. Therefore `Tuple{Any}` is considered an abstract type, and tuple types are only concrete if their parameters are.
- Tuples do not have field names; fields are only accessed by index.

Tuple values are written with parentheses and commas. When a tuple is constructed, an appropriate tuple type is generated on demand:

```
julia> typeof((1,"foo",2.5))
Tuple{Int64, String, Float64}
```

Note the implications of covariance:

```
julia> Tuple{Int,AbstractString} <: Tuple{Real,Any}
true

julia> Tuple{Int,AbstractString} <: Tuple{Real,Real}
false

julia> Tuple{Int,AbstractString} <: Tuple{Real,}
false
```

Intuitively, this corresponds to the type of a function's arguments being a subtype of the function's signature (when the signature matches).

Vararg Tuple Types

The last parameter of a tuple type can be the special value `Vararg`, which denotes any number of trailing elements:

```
julia> mytupletype = Tuple{AbstractString,Vararg{Int}}
Tuple{AbstractString, Vararg{Int64}}

julia> isa(("1",), mytupletype)
true

julia> isa(("1",1), mytupletype)
true

julia> isa(("1",1,2), mytupletype)
true

julia> isa(("1",1,2,3.0), mytupletype)
false
```

Moreover `Vararg{T}` corresponds to zero or more elements of type `T`. `Vararg` tuple types are used to represent the arguments accepted by `varargs` methods (see [Varargs Functions](#)).

The special value `Vararg{T,N}` (when used as the last parameter of a tuple type) corresponds to exactly `N` elements of type `T`. `NTuple{N,T}` is a convenient alias for `Tuple{Vararg{T,N}}`, i.e. a tuple type containing exactly `N` elements of type `T`.

Named Tuple Types

Named tuples are instances of the `NamedTuple` type, which has two parameters: a tuple of symbols giving the field names, and a tuple type giving the field types. For convenience, `NamedTuple` types are printed using the `@NamedTuple` macro which provides a convenient struct-like syntax for declaring these types via `key::Type` declarations, where an omitted `::Type` corresponds to `::Any`.

```
julia> typeof((a=1,b="hello")) # prints in macro form
@NamedTuple{a::Int64, b::String}

julia> NamedTuple{(:a, :b), Tuple{Int64, String}} # long form of the type
@NamedTuple{a::Int64, b::String}
```

The `begin ... end` form of the `@NamedTuple` macro allows the declarations to be split across multiple lines (similar to a struct declaration), but is otherwise equivalent:

```
julia> @NamedTuple begin
    a::Int
    b::String
end
@NamedTuple{a::Int64, b::String}
```

A `NamedTuple` type can be used as a constructor, accepting a single tuple argument. The constructed `NamedTuple` type can be either a concrete type, with both parameters specified, or a type that specifies only field names:

```
julia> @NamedTuple{a::Float32,b::String}((1, ""))
(a = 1.0f0, b = "")
```

```
julia> NamedTuple{(:a, :b)}((1, ""))
(a = 1, b = "")
```

If field types are specified, the arguments are converted. Otherwise the types of the arguments are used directly.

Parametric Primitive Types

Primitive types can also be declared parametrically. For example, pointers are represented as primitive types which would be declared in Julia like this:

```
# 32-bit system:
primitive type Ptr{T} 32 end

# 64-bit system:
primitive type Ptr{T} 64 end
```

The slightly odd feature of these declarations as compared to typical parametric composite types, is that the type parameter `T` is not used in the definition of the type itself – it is just an abstract tag, essentially defining an entire family of types with identical structure, differentiated only by their type parameter. Thus, `Ptr{Float64}` and `Ptr{Int64}` are distinct types, even though they have identical representations. And of course, all specific pointer types are subtypes of the umbrella `Ptr` type:

```
julia> Ptr{Float64} <: Ptr
true

julia> Ptr{Int64} <: Ptr
true
```

11.9 UnionAll Types

We have said that a parametric type like `Ptr` acts as a supertype of all its instances (`Ptr{Int64}` etc.). How does this work? `Ptr` itself cannot be a normal data type, since without knowing the type of the referenced data the type clearly cannot be used for memory operations. The answer is that `Ptr` (or other parametric types like `Array`) is a different kind of type called a `UnionAll` type. Such a type expresses the iterated union of types for all values of some parameter.

`UnionAll` types are usually written using the keyword `where`. For example `Ptr` could be more accurately written as `Ptr{T}` where `T`, meaning all values whose type is `Ptr{T}` for some value of `T`. In this context, the parameter `T` is also often called a "type variable" since it is like a variable that ranges over types. Each `where` introduces a single type variable, so these expressions are nested for types with multiple parameters, for example `Array{T,N}` where `N` where `T`.

The type application syntax `A{B,C}` requires `A` to be a `UnionAll` type, and first substitutes `B` for the outermost type variable in `A`. The result is expected to be another `UnionAll` type, into which `C` is then substituted. So `A{B,C}` is equivalent to `A{B}{C}`. This explains why it is possible to partially instantiate a type, as in `Array{Float64}`: the first parameter value has been fixed, but the second still ranges over all possible values. Using explicit `where` syntax, any subset of parameters can be fixed. For example, the type of all 1-dimensional arrays can be written as `Array{T,1}` where `T`.

Type variables can be restricted with subtype relations. `Array{T}` where `T<:Integer` refers to all arrays whose element type is some kind of [Integer](#). The syntax `Array{<:Integer}` is a convenient shorthand for `Array{T}` where `T<:Integer`. Type variables can have both lower and upper bounds. `Array{T}` where `Int<:T<:Number` refers to all arrays of [Numbers](#) that are able to contain `Int`s (since `T` must be at least as big as `Int`). The syntax where `T>:Int` also works to specify only the lower bound of a type variable, and `Array{>:Int}` is equivalent to `Array{T}` where `T>:Int`.

Since where expressions nest, type variable bounds can refer to outer type variables. For example `Tuple{T,Array{S}}` where `S<:AbstractArray{T}` where `T<:Real` refers to 2-tuples whose first element is some [Real](#), and whose second element is an `Array` of any kind of array whose element type contains the type of the first tuple element.

The `where` keyword itself can be nested inside a more complex declaration. For example, consider the two types created by the following declarations:

```
julia> const T1 = Array{Array{T, 1} where T, 1}
Vector{Vector{<:Integer}} (alias for Array{Array{T, 1} where T, 1})

julia> const T2 = Array{Array{T, 1}, 1} where T
Array{Vector{<:Integer}, 1} where T
```

Type `T1` defines a 1-dimensional array of 1-dimensional arrays; each of the inner arrays consists of objects of the same type, but this type may vary from one inner array to the next. On the other hand, type `T2` defines a 1-dimensional array of 1-dimensional arrays all of whose inner arrays must have the same type. Note that `T2` is an abstract type, e.g., `Array{Array{Int, 1}, 1} <: T2`, whereas `T1` is a concrete type. As a consequence, `T1` can be constructed with a zero-argument constructor `a=T1()` but `T2` cannot.

There is a convenient syntax for naming such types, similar to the short form of function definition syntax:

```
Vector{T} = Array{T, 1}
```

This is equivalent to `const Vector = Array{T, 1} where T`. Writing `Vector{Float64}` is equivalent to writing `Array{Float64, 1}`, and the umbrella type `Vector` has as instances all `Array` objects where the second parameter – the number of array dimensions – is 1, regardless of what the element type is. In languages where parametric types must always be specified in full, this is not especially helpful, but in Julia, this allows one to write just `Vector` for the abstract type including all one-dimensional dense arrays of any element type.

11.10 Singleton types

Immutable composite types with no fields are called singletons. Formally, if

1. `T` is an immutable composite type (i.e. defined with `struct`),
2. `a isa T && b isa T` implies `a === b`,

then `T` is a singleton type.² [Base.issingletontype](#) can be used to check if a type is a singleton type. [Abstract types](#) cannot be singleton types by construction.

From the definition, it follows that there can be only one instance of such types:

```
julia> struct NoFields
        end

julia> NoFields() == NoFields()
true

julia> Base.issingletontype(NoFields)
true
```

The `==` function confirms that the constructed instances of `NoFields` are actually one and the same.

Parametric types can be singleton types when the above condition holds. For example,

```
julia> struct NoFieldsParam{T}
        end

julia> Base.issingletontype(NoFieldsParam) # Can't be a singleton type ...
false

julia> NoFieldsParam{Int}() isa NoFieldsParam # ... because it has ...
true

julia> NoFieldsParam{Bool}() isa NoFieldsParam # ... multiple instances.
true

julia> Base.issingletontype(NoFieldsParam{Int}) # Parametrized, it is a singleton.
true

julia> NoFieldsParam{Int}() == NoFieldsParam{Int}()
true
```

11.11 Types of functions

Each function has its own type, which is a subtype of `Function`.

```
julia> foo41(x) = x + 1
foo41 (generic function with 1 method)

julia> typeof(foo41)
typeof(foo41) (singleton type of function foo41, subtype of Function)
```

Note how `typeof(foo41)` prints as itself. This is merely a convention for printing, as it is a first-class object that can be used like any other value:

```
julia> T = typeof(foo41)
typeof(foo41) (singleton type of function foo41, subtype of Function)

julia> T <: Function
true
```

Types of functions defined at top-level are singletons. When necessary, you can compare them with `===`.

[Closures](#) also have their own type, which is usually printed with names that end in `#<number>`. Names and types for functions defined at different locations are distinct, but not guaranteed to be printed the same way across sessions.

```
julia> typeof(x -> x + 1)
var"#9#10"
```

Types of closures are not necessarily singletons.

```
julia> addy(y) = x -> x + y
addy (generic function with 1 method)

julia> typeof(addy(1)) === typeof(addy(2))
true

julia> addy(1) === addy(2)
false

julia> Base.issingletontype(typeof(addy(1)))
false
```

11.12 Type{T} type selectors

For each type `T`, `Type{T}` is an abstract parametric type whose only instance is the object `T`. Until we discuss [Parametric Methods](#) and [conversions](#), it is difficult to explain the utility of this construct, but in short, it allows one to specialize function behavior on specific types as values. This is useful for writing methods (especially parametric ones) whose behavior depends on a type that is given as an explicit argument rather than implied by the type of one of its arguments.

Since the definition is a little difficult to parse, let's look at some examples:

```
julia> isa(Float64, Type{Float64})
true

julia> isa(Real, Type{Float64})
false

julia> isa(Real, Type{Real})
true

julia> isa(Float64, Type{Real})
false
```

In other words, `isa(A, Type{B})` is true if and only if `A` and `B` are the same object and that object is a type.

In particular, since parametric types are [invariant](#), we have

```
julia> struct TypeParamExample{T}
    x::T
end
```

```

        end

julia> TypeParamExample isa Type{TypeParamExample}
true

julia> TypeParamExample{Int} isa Type{TypeParamExample}
false

julia> TypeParamExample{Int} isa Type{TypeParamExample{Int}}
true

```

Without the parameter, `Type` is simply an abstract type which has all type objects as its instances:

```

julia> isa(Type{Float64}, Type)
true

julia> isa(Float64, Type)
true

julia> isa(Real, Type)
true

```

Any object that is not a type is not an instance of `Type`:

```

julia> isa(1, Type)
false

julia> isa("foo", Type)
false

```

While `Type` is part of Julia's type hierarchy like any other abstract parametric type, it is not commonly used outside method signatures except in some special cases. Another important use case for `Type` is sharpening field types which would otherwise be captured less precisely, e.g. as `DataType` in the example below where the default constructor could lead to performance problems in code relying on the precise wrapped type (similarly to [abstract type parameters](#)).

```

julia> struct WrapType{T}
    value::T
end

julia> WrapType{Float64} # default constructor, note DataType
WrapType{DataType}(Float64)

julia> WrapType{::Type{T}} where T = WrapType{Type{T}}(T)
WrapType

julia> WrapType{Float64} # sharpened constructor, note more precise Type{Float64}
WrapType{Type{Float64}}(Float64)

```

11.13 Type Aliases

Sometimes it is convenient to introduce a new name for an already expressible type. This can be done with a simple assignment statement. For example, `UInt` is aliased to either `UInt32` or `UInt64` as is appropriate for the size of pointers on the system:

```
# 32-bit system:
julia> UInt
UInt32

# 64-bit system:
julia> UInt
UInt64
```

This is accomplished via the following code in `base/boot.jl`:

```
if Int == Int64
    const UInt = UInt64
else
    const UInt = UInt32
end
```

Of course, this depends on what `Int` is aliased to – but that is predefined to be the correct type – either `Int32` or `Int64`.

(Note that unlike `Int`, `Float` does not exist as a type alias for a specific sized `AbstractFloat`. Unlike with integer registers, where the size of `Int` reflects the size of a native pointer on that machine, the floating point register sizes are specified by the IEEE-754 standard.)

11.14 Operations on Types

Since types in Julia are themselves objects, ordinary functions can operate on them. Some functions that are particularly useful for working with or exploring types have already been introduced, such as the `<` operator, which indicates whether its left hand operand is a subtype of its right hand operand.

The `isa` function tests if an object is of a given type and returns true or false:

```
julia> isa(1, Int)
true

julia> isa(1, AbstractFloat)
false
```

The `typeof` function, already used throughout the manual in examples, returns the type of its argument. Since, as noted above, types are objects, they also have types, and we can ask what their types are:

```
julia> typeof(Rational{Int})
DataType

julia> typeof(Union{Real,String})
Union
```

What if we repeat the process? What is the type of a type of a type? As it happens, types are all composite values and thus all have a type of `DataType`:

```
julia> typeof(DataType)
DataType

julia> typeof(Union)
DataType
```

`DataType` is its own type.

Another operation that applies to some types is `supertype`, which reveals a type's supertype. Only declared types (`DataType`) have unambiguous supertypes:

```
julia> supertype(Float64)
AbstractFloat

julia> supertype(Number)
Any

julia> supertype(AbstractString)
Any

julia> supertype(Any)
Any
```

If you apply `supertype` to other type objects (or non-type objects), a `MethodError` is raised:

```
julia> supertype(Union{Float64,Int64})
ERROR: MethodError: no method matching supertype(::Type{Union{Float64, Int64}})
Closest candidates are:
[...]
```

11.15 Custom pretty-printing

Often, one wants to customize how instances of a type are displayed. This is accomplished by overloading the `show` function. For example, suppose we define a type to represent complex numbers in polar form:

```
julia> struct Polar{T<:Real} <: Number
    r::T
    θ::T
end

julia> Polar(r::Real,θ::Real) = Polar(promote(r,θ)...)
Polar
```

Here, we've added a custom constructor function so that it can take arguments of different `Real` types and promote them to a common type (see [Constructors](#) and [Conversion and Promotion](#)). (Of course, we would have to define lots of other methods, too, to make it act like a `Number`, e.g. `+`, `*`, `one`, `zero`, promotion rules

and so on.) By default, instances of this type display rather simply, with information about the type name and the field values, as e.g. `Polar{Float64}(3.0,4.0)`.

If we want it to display instead as `3.0 * exp(4.0im)`, we would define the following method to print the object to a given output object `io` (representing a file, terminal, buffer, etcetera; see [Networking and Streams](#)):

```
julia> Base.show(io::IO, z::Polar) = print(io, z.r, " * exp(", z.θ, "im")
```

More fine-grained control over display of `Polar` objects is possible. In particular, sometimes one wants both a verbose multi-line printing format, used for displaying a single object in the REPL and other interactive environments, and also a more compact single-line format used for `print` or for displaying the object as part of another object (e.g. in an array). Although by default the `show(io, z)` function is called in both cases, you can define a different multi-line format for displaying an object by overloading a three-argument form of `show` that takes the text/plain MIME type as its second argument (see [Multimedia I/O](#)), for example:

```
julia> Base.show(io::IO, ::MIME"text/plain", z::Polar{T}) where{T} =
    print(io, "Polar{${T}} complex number:\n", z)
```

(Note that `print(..., z)` here will call the 2-argument `show(io, z)` method.) This results in:

```
julia> Polar(3, 4.0)
Polar{Float64} complex number:
 3.0 * exp(4.0im)

julia> [Polar(3, 4.0), Polar(4.0,5.3)]
2-element Vector{Polar{Float64}}:
 3.0 * exp(4.0im)
 4.0 * exp(5.3im)
```

where the single-line `show(io, z)` form is still used for an array of `Polar` values. Technically, the REPL calls `display(z)` to display the result of executing a line, which defaults to `show(stdout, MIME("text/plain"), z)`, which in turn defaults to `show(stdout, z)`, but you should not define new `display` methods unless you are defining a new multimedia display handler (see [Multimedia I/O](#)).

Moreover, you can also define `show` methods for other MIME types in order to enable richer display (HTML, images, etcetera) of objects in environments that support this (e.g. `IJulia`). For example, we can define formatted HTML display of `Polar` objects, with superscripts and italics, via:

```
julia> Base.show(io::IO, ::MIME"text/html", z::Polar{T}) where{T} =
    println(io, "<code>Polar{${T}}</code> complex number: ",
            z.r, " <i>e</i><sup>", z.θ, " <i>i</i></sup>")
```

A `Polar` object will then display automatically using HTML in an environment that supports HTML display, but you can call `show` manually to get HTML output if you want:

```
julia> show(stdout, "text/html", Polar(3.0,4.0))
<code>Polar{Float64}</code> complex number: 3.0 <i>e</i><sup>4.0 <i>i</i></sup>
```

As a rule of thumb, the single-line show method should print a valid Julia expression for creating the shown object. When this show method contains infix operators, such as the multiplication operator (`*`) in our single-line show method for `Polar` above, it may not parse correctly when printed as part of another object. To see this, consider the expression object (see [Program representation](#)) which takes the square of a specific instance of our `Polar` type:

```
julia> a = Polar(3, 4.0)
Polar{Float64} complex number:
 3.0 * exp(4.0im)

julia> print(:($a^2))
3.0 * exp(4.0im) ^ 2
```

Because the operator `^` has higher precedence than `*` (see [Operator Precedence and Associativity](#)), this output does not faithfully represent the expression `a ^ 2` which should be equal to `(3.0 * exp(4.0im)) ^ 2`. To solve this issue, we must make a custom method for `Base.show_unquoted(io::IO, z::Polar, indent::Int, precedence::Int)`, which is called internally by the expression object when printing:

```
julia> function Base.show_unquoted(io::IO, z::Polar, ::Int, precedence::Int)
    if Base.operator_precedence(:*) <= precedence
        print(io, "(")
        show(io, z)
        print(io, ")")
    else
        show(io, z)
    end
end

julia> :($a^2)
:((3.0 * exp(4.0im)) ^ 2)
```

The method defined above adds parentheses around the call to `show` when the precedence of the calling operator is higher than or equal to the precedence of multiplication. This check allows expressions which parse correctly without the parentheses (such as `:(a + 2)` and `:(a == 2)`) to omit them when printing:

```
julia> :($a + 2)
:(3.0 * exp(4.0im) + 2)

julia> :($a == 2)
:(3.0 * exp(4.0im) == 2)
```

In some cases, it is useful to adjust the behavior of show methods depending on the context. This can be achieved via the `IOContext` type, which allows passing contextual properties together with a wrapped IO stream. For example, we can build a shorter representation in our show method when the `:compact` property is set to `true`, falling back to the long representation if the property is `false` or absent:

```
julia> function Base.show(io::IO, z::Polar)
    if get(io, :compact, false)::Bool
        print(io, z.r, " ", z.θ, "im")
    end
end
```

```

        else
            print(io, z.r, " * exp(", z.θ, "im)")
        end
    end
end

```

This new compact representation will be used when the passed IO stream is an `IOContext` object with the `:compact` property set. In particular, this is the case when printing arrays with multiple columns (where horizontal space is limited):

```

julia> show(IOContext(stdout, :compact=>true), Polar(3, 4.0))
3.04.0im

julia> [Polar(3, 4.0) Polar(4.0,5.3)]
1×2 Matrix{Polar{Float64}}:
 3.04.0im  4.05.3im

```

See the [IOContext](#) documentation for a list of common properties which can be used to adjust printing.

11.16 "Value types"

In Julia, you can't dispatch on a value such as `true` or `false`. However, you can dispatch on parametric types, and Julia allows you to include "plain bits" values (Types, Symbols, Integers, floating-point numbers, tuples, etc.) as type parameters. A common example is the dimensionality parameter in `Array{T,N}`, where `T` is a type (e.g., `Float64`) but `N` is just an `Int`.

You can create your own custom types that take values as parameters, and use them to control dispatch of custom types. By way of illustration of this idea, let's introduce the parametric type `Val{x}`, and its constructor `Val(x) = Val{x}()`, which serves as a customary way to exploit this technique for cases where you don't need a more elaborate hierarchy.

`Val` is defined as:

```

julia> struct Val{x}
    end

julia> Val(x) = Val{x}()
Val

```

There is no more to the implementation of `Val` than this. Some functions in Julia's standard library accept `Val` instances as arguments, and you can also use it to write your own functions. For example:

```

julia> firstlast(::Val{true}) = "First"
firstlast (generic function with 1 method)

julia> firstlast(::Val{false}) = "Last"
firstlast (generic function with 2 methods)

julia> firstlast(Val{true})
"First"

julia> firstlast(Val{false})
"Last"

```

For consistency across Julia, the call site should always pass a `Val` instance rather than using a type, i.e., use `foo(Val{ :bar })` rather than `foo(Val{ :bar })`.

It's worth noting that it's extremely easy to mis-use parametric "value" types, including `Val`; in unfavorable cases, you can easily end up making the performance of your code much worse. In particular, you would never want to write actual code as illustrated above. For more information about the proper (and improper) uses of `Val`, please read [the more extensive discussion in the performance tips](#).

¹"Small" is defined by the `max_union_splitting` configuration, which currently defaults to 4.

²A few popular languages have singleton types, including Haskell, Scala and Ruby.

Chapter 12

Methods

Recall from [Functions](#) that a function is an object that maps a tuple of arguments to a return value, or throws an exception if no appropriate value can be returned. It is common for the same conceptual function or operation to be implemented quite differently for different types of arguments: adding two integers is very different from adding two floating-point numbers, both of which are distinct from adding an integer to a floating-point number. Despite their implementation differences, these operations all fall under the general concept of "addition". Accordingly, in Julia, these behaviors all belong to a single object: the `+` function.

To facilitate using many different implementations of the same concept smoothly, functions need not be defined all at once, but can rather be defined piecewise by providing specific behaviors for certain combinations of argument types and counts. A definition of one possible behavior for a function is called a method. Thus far, we have presented only examples of functions defined with a single method, applicable to all types of arguments. However, the signatures of method definitions can be annotated to indicate the types of arguments in addition to their number, and more than a single method definition may be provided. When a function is applied to a particular tuple of arguments, the most specific method applicable to those arguments is applied. Thus, the overall behavior of a function is a patchwork of the behaviors of its various method definitions. If the patchwork is well designed, even though the implementations of the methods may be quite different, the outward behavior of the function will appear seamless and consistent.

The choice of which method to execute when a function is applied is called dispatch. Julia allows the dispatch process to choose which of a function's methods to call based on the number of arguments given, and on the types of all of the function's arguments. This is different than traditional object-oriented languages, where dispatch occurs based only on the first argument, which often has a special argument syntax, and is sometimes implied rather than explicitly written as an argument. ¹ Using all of a function's arguments to choose which method should be invoked, rather than just the first, is known as [multiple dispatch](#). Multiple dispatch is particularly useful for mathematical code, where it makes little sense to artificially deem the operations to "belong" to one argument more than any of the others: does the addition operation in `x + y` belong to `x` any more than it does to `y`? The implementation of a mathematical operator generally depends on the types of all of its arguments. Even beyond mathematical operations, however, multiple dispatch ends up being a powerful and convenient paradigm for structuring and organizing programs.

Note

¹In C++ or Java, for example, in a method call like `obj.meth(arg1,arg2)`, the object `obj` "receives" the method call and is implicitly passed to the method via the `this` keyword, rather than as an explicit method argument. When the current `this` object is the receiver of a method call, it can be omitted altogether, writing just `meth(arg1,arg2)`, with `this` implied as the receiving object.

All the examples in this chapter assume that you are defining methods for a function in the same module. If you want to add methods to a function in another module, you have to `import` it or use the name qualified with module names. See the section on [namespace management](#).

12.1 Defining Methods

Until now, we have, in our examples, defined only functions with a single method having unconstrained argument types. Such functions behave just like they would in traditional dynamically typed languages. Nevertheless, we have used multiple dispatch and methods almost continually without being aware of it: all of Julia's standard functions and operators, like the aforementioned `+` function, have many methods defining their behavior over various possible combinations of argument type and count.

When defining a function, one can optionally constrain the types of parameters it is applicable to, using the `::` type-assertion operator, introduced in the section on [Composite Types](#):

```
julia> f(x::Float64, y::Float64) = 2x + y
f (generic function with 1 method)
```

This function definition applies only to calls where `x` and `y` are both values of type `Float64`:

```
julia> f(2.0, 3.0)
7.0
```

Applying it to any other types of arguments will result in a `MethodError`:

```
julia> f(2.0, 3)
ERROR: MethodError: no method matching f(::Float64, ::Int64)

Closest candidates are:
  f(::Float64, !Matched::Float64)
    @ Main none:1

Stacktrace:
[...]

julia> f(Float32(2.0), 3.0)
ERROR: MethodError: no method matching f(::Float32, ::Float64)

Closest candidates are:
  f(!Matched::Float64, ::Float64)
    @ Main none:1

Stacktrace:
[...]

julia> f(2.0, "3.0")
ERROR: MethodError: no method matching f(::Float64, ::String)

Closest candidates are:
  f(::Float64, !Matched::Float64)
```

```

@ Main none:1

Stacktrace:
[...]

julia> f("2.0", "3.0")
ERROR: MethodError: no method matching f(::String, ::String)

```

As you can see, the arguments must be precisely of type `Float64`. Other numeric types, such as integers or 32-bit floating-point values, are not automatically converted to 64-bit floating-point, nor are strings parsed as numbers. Because `Float64` is a concrete type and concrete types cannot be subclassed in Julia, such a definition can only be applied to arguments that are exactly of type `Float64`. It may often be useful, however, to write more general methods where the declared parameter types are abstract:

```

julia> f(x::Number, y::Number) = 2x - y
f (generic function with 2 methods)

julia> f(2.0, 3)
1.0

```

This method definition applies to any pair of arguments that are instances of `Number`. They need not be of the same type, so long as they are each numeric values. The problem of handling disparate numeric types is delegated to the arithmetic operations in the expression $2x - y$.

To define a function with multiple methods, one simply defines the function multiple times, with different numbers and types of arguments. The first method definition for a function creates the function object, and subsequent method definitions add new methods to the existing function object. The most specific method definition matching the number and types of the arguments will be executed when the function is applied. Thus, the two method definitions above, taken together, define the behavior for `f` over all pairs of instances of the abstract type `Number` – but with a different behavior specific to pairs of `Float64` values. If one of the arguments is a 64-bit float but the other one is not, then the `f(Float64, Float64)` method cannot be called and the more general `f(Number, Number)` method must be used:

```

julia> f(2.0, 3.0)
7.0

julia> f(2, 3.0)
1.0

julia> f(2.0, 3)
1.0

julia> f(2, 3)
1

```

The $2x + y$ definition is only used in the first case, while the $2x - y$ definition is used in the others. No automatic casting or conversion of function arguments is ever performed: all conversion in Julia is non-magical and completely explicit. [Conversion and Promotion](#), however, shows how clever application of sufficiently advanced technology can be indistinguishable from magic. ²

For non-numeric values, and for fewer or more than two arguments, the function `f` remains undefined, and applying it will still result in a `MethodError`:

```
julia> f("foo", 3)
ERROR: MethodError: no method matching f(::String, ::Int64)

Closest candidates are:
  f(!Matched::Number, ::Number)
    @ Main none:1

Stacktrace:
[...]

julia> f()
ERROR: MethodError: no method matching f()

Closest candidates are:
  f(!Matched::Float64, !Matched::Float64)
    @ Main none:1
  f(!Matched::Number, !Matched::Number)
    @ Main none:1

Stacktrace:
[...]
```

You can easily see which methods exist for a function by entering the function object itself in an interactive session:

```
julia> f
f (generic function with 2 methods)
```

This output tells us that `f` is a function object with two methods. To find out what the signatures of those methods are, use the `methods` function:

```
julia> methods(f)
# 2 methods for generic function "f" from Main:
 [1] f(x::Float64, y::Float64)
      @ none:1
 [2] f(x::Number, y::Number)
      @ none:1
```

which shows that `f` has two methods, one taking two `Float64` arguments and one taking arguments of type `Number`. It also indicates the file and line number where the methods were defined: because these methods were defined at the REPL, we get the apparent line number `none:1`.

In the absence of a type declaration with `::`, the type of a method parameter is `Any` by default, meaning that it is unconstrained since all values in Julia are instances of the abstract type `Any`. Thus, we can define a catch-all method for `f` like so:

```
julia> f(x,y) = println("Whoa there, Nelly.")
f (generic function with 3 methods)

julia> methods(f)
```

```
# 3 methods for generic function "f" from Main:
[1] f(x::Float64, y::Float64)
    @ none:1
[2] f(x::Number, y::Number)
    @ none:1
[3] f(x, y)
    @ none:1

julia> f("foo", 1)
Whoa there, Nelly.
```

This catch-all is less specific than any other possible method definition for a pair of parameter values, so it will only be called on pairs of arguments to which no other method definition applies.

Note that in the signature of the third method, there is no type specified for the arguments `x` and `y`. This is a shortened way of expressing `f(x::Any, y::Any)`.

Although it seems a simple concept, multiple dispatch on the types of values is perhaps the single most powerful and central feature of the Julia language. Core operations typically have dozens of methods:

```
julia> methods(+)
# 180 methods for generic function "+":
[1] +(x::Bool, z::Complex{Bool}) in Base at complex.jl:227
[2] +(x::Bool, y::Bool) in Base at bool.jl:89
[3] +(x::Bool) in Base at bool.jl:86
[4] +(x::Bool, y::T) where T<:AbstractFloat in Base at bool.jl:96

Multiple dispatch together with the flexible parametric type system give Julia its ability to abstractly express high-level algorithms decoupled from implementation details.

12.2 Method specializations

When you create multiple methods of the same function, this is sometimes called "specialization." In this case, you're specializing the function by adding additional methods to it: each new method is a new specialization of the function. As shown above, these specializations are returned by `methods`.

There's another kind of specialization that occurs without programmer intervention: Julia's compiler can automatically specialize the method for the specific argument types used. Such specializations are not

listed by methods, as this doesn't create new Methods, but tools like `@code_typed` allow you to inspect such specializations.

For example, if you create a method

```
mysum(x::Real, y::Real) = x + y
```

you've given the function `mysum` one new method (possibly its only method), and that method takes any pair of `Real` number inputs. But if you then execute

```
julia> mysum(1, 2)
3
julia> mysum(1.0, 2.0)
3.0
```

Julia will compile `mysum` twice, once for `x::Int, y::Int` and again for `x::Float64, y::Float64`. The point of compiling twice is performance: the methods that get called for `+` (which `mysum` uses) vary depending on the specific types of `x` and `y`, and by compiling different specializations Julia can do all the method lookup ahead of time. This allows the program to run much more quickly, since it does not have to bother with method lookup while it is running. Julia's automatic specialization allows you to write generic algorithms and expect that the compiler will generate efficient, specialized code to handle each case you need.

In cases where the number of potential specializations might be effectively unlimited, Julia may avoid this default specialization. See [Be aware of when Julia avoids specializing](#) for more information.

12.3 Method Ambiguities

It is possible to define a set of function methods such that there is no unique most specific method applicable to some combinations of arguments:

```
julia> g(x::Float64, y) = 2x + y
g (generic function with 1 method)

julia> g(x, y::Float64) = x + 2y
g (generic function with 2 methods)

julia> g(2.0, 3)
7.0

julia> g(2, 3.0)
8.0

julia> g(2.0, 3.0)
ERROR: MethodError: g(::Float64, ::Float64) is ambiguous.

Candidates:
  g(x, y::Float64)
    @ Main none:1
  g(x::Float64, y)
    @ Main none:1
```

```
Possible fix, define
    g(::Float64, ::Float64)

Stacktrace:
[...]

```

Here the call `g(2.0, 3.0)` could be handled by either the `g(Float64, Any)` or the `g(Any, Float64)` method, and neither is more specific than the other. In such cases, Julia raises a `MethodError` rather than arbitrarily picking a method. You can avoid method ambiguities by specifying an appropriate method for the intersection case:

```
julia> g(x::Float64, y::Float64) = 2x + 2y
g (generic function with 3 methods)

julia> g(2.0, 3)
7.0

julia> g(2, 3.0)
8.0

julia> g(2.0, 3.0)
10.0

```

It is recommended that the disambiguating method be defined first, since otherwise the ambiguity exists, if transiently, until the more specific method is defined.

In more complex cases, resolving method ambiguities involves a certain element of design; this topic is explored further [below](#).

12.4 Parametric Methods

Method definitions can optionally have type parameters qualifying the signature:

```
julia> same_type(x::T, y::T) where {T} = true
same_type (generic function with 1 method)

julia> same_type(x,y) = false
same_type (generic function with 2 methods)

```

The first method applies whenever both arguments are of the same concrete type, regardless of what type that is, while the second method acts as a catch-all, covering all other cases. Thus, overall, this defines a boolean function that checks whether its two arguments are of the same type:

```
julia> same_type(1, 2)
true

julia> same_type(1, 2.0)
false

julia> same_type(1.0, 2.0)

```

```

true

julia> same_type("foo", 2.0)
false

julia> same_type("foo", "bar")
true

julia> same_type{Int32}(1), Int64(2))
false

```

Such definitions correspond to methods whose type signatures are `UnionAll` types (see [UnionAll Types](#)).

This kind of definition of function behavior by dispatch is quite common – idiomatic, even – in Julia. Method type parameters are not restricted to being used as the types of arguments: they can be used anywhere a value would be in the signature of the function or body of the function. Here's an example where the method type parameter `T` is used as the type parameter to the parametric type `Vector{T}` in the method signature:

```

julia> myappend(v::Vector{T}, x::T) where {T} = [v..., x]
myappend (generic function with 1 method)

julia> myappend([1,2,3],4)
4-element Vector{Int64}:
 1
 2
 3
 4

julia> myappend([1,2,3],2.5)
ERROR: MethodError: no method matching myappend(::Vector{Int64}, ::Float64)

Closest candidates are:
  myappend(::Vector{T}, !Matched::T) where T
    @ Main none:1

Stacktrace:
[...]

julia> myappend([1.0,2.0,3.0],4.0)
4-element Vector{Float64}:
 1.0
 2.0
 3.0
 4.0

julia> myappend([1.0,2.0,3.0],4)
ERROR: MethodError: no method matching myappend(::Vector{Float64}, ::Int64)

Closest candidates are:
  myappend(::Vector{T}, !Matched::T) where T
    @ Main none:1

```

```
Stacktrace:
[...]
```

As you can see, the type of the appended element must match the element type of the vector it is appended to, or else a `MethodError` is raised. In the following example, the method type parameter `T` is used as the return value:

```
julia> mytypeof(x::T) where {T} = T
mytypeof (generic function with 1 method)

julia> mytypeof(1)
Int64

julia> mytypeof(1.0)
Float64
```

Just as you can put subtype constraints on type parameters in type declarations (see [Parametric Types](#)), you can also constrain type parameters of methods:

```
julia> same_type_numeric(x::T, y::T) where {T<:Number} = true
same_type_numeric (generic function with 1 method)

julia> same_type_numeric(x::Number, y::Number) = false
same_type_numeric (generic function with 2 methods)

julia> same_type_numeric(1, 2)
true

julia> same_type_numeric(1, 2.0)
false

julia> same_type_numeric(1.0, 2.0)
true

julia> same_type_numeric("foo", 2.0)
ERROR: MethodError: no method matching same_type_numeric(::String, ::Float64)

Closest candidates are:
  same_type_numeric(!Matched::T, ::T) where T<:Number
    @ Main none:1
  same_type_numeric(!Matched::Number, ::Number)
    @ Main none:1

Stacktrace:
[...]
```

```
julia> same_type_numeric("foo", "bar")
ERROR: MethodError: no method matching same_type_numeric(::String, ::String)

julia> same_type_numeric(Int32(1), Int64(2))
false
```

The `same_type_numeric` function behaves much like the `same_type` function defined above, but is only defined for pairs of numbers.

Parametric methods allow the same syntax as where expressions used to write types (see [UnionAll Types](#)). If there is only a single parameter, the enclosing curly braces (in where `{T}`) can be omitted, but are often preferred for clarity. Multiple parameters can be separated with commas, e.g. where `{T, S<:Real}`, or written using nested where, e.g. where `S<:Real` where `T`.

12.5 Redefining Methods

When redefining a method or adding new methods, it is important to realize that these changes don't take effect immediately. This is key to Julia's ability to statically infer and compile code to run fast, without the usual JIT tricks and overhead. Indeed, any new method definition won't be visible to the current runtime environment, including Tasks and Threads (and any previously defined `@generated` functions). Let's start with an example to see what this means:

```
julia> function tryeval()
    @eval newfun() = 1
    newfun()
end
tryeval (generic function with 1 method)

julia> tryeval()
ERROR: MethodError: no method matching newfun()
The applicable method may be too new: running in world age xxxx1, while current world is xxxx2.
Closest candidates are:
  newfun() at none:1 (method too new to be called from this world context.)
  in tryeval() at none:1
...

julia> newfun()
1
```

In this example, observe that the new definition for `newfun` has been created, but can't be immediately called. The new global is immediately visible to the `tryeval` function, so you could write `return newfun` (without parentheses). But neither you, nor any of your callers, nor the functions they call, or etc. can call this new method definition!

But there's an exception: future calls to `newfun` from the REPL work as expected, being able to both see and call the new definition of `newfun`.

However, future calls to `tryeval` will continue to see the definition of `newfun` as it was at the previous statement at the REPL, and thus before that call to `tryeval`.

You may want to try this for yourself to see how it works.

The implementation of this behavior is a "world age counter". This monotonically increasing value tracks each method definition operation. This allows describing "the set of method definitions visible to a given runtime environment" as a single number, or "world age". It also allows comparing the methods available in two worlds just by comparing their ordinal value. In the example above, we see that the "current world" (in which the method `newfun` exists), is one greater than the task-local "runtime world" that was fixed when the execution of `tryeval` started.

Sometimes it is necessary to get around this (for example, if you are implementing the above REPL). Fortunately, there is an easy solution: call the function using `Base.invokelatest`:

```
julia> function tryeval2()
    @eval newfun2() = 2
    Base.invokelatest(newfun2)
end
tryeval2 (generic function with 1 method)

julia> tryeval2()
2
```

Finally, let's take a look at some more complex examples where this rule comes into play. Define a function `f(x)`, which initially has one method:

```
julia> f(x) = "original definition"
f (generic function with 1 method)
```

Start some other operations that use `f(x)`:

```
julia> g(x) = f(x)
g (generic function with 1 method)

julia> t = @async f(wait()); yield();
```

Now we add some new methods to `f(x)`:

```
julia> f(x::Int) = "definition for Int"
f (generic function with 2 methods)

julia> f(x::Type{Int}) = "definition for Type{Int}"
f (generic function with 3 methods)
```

Compare how these results differ:

```
julia> f(1)
"definition for Int"

julia> g(1)
"definition for Int"

julia> fetch(schedule(t, 1))
"original definition"

julia> t = @async f(wait()); yield();

julia> fetch(schedule(t, 1))
"definition for Int"
```

12.6 Design Patterns with Parametric Methods

While complex dispatch logic is not required for performance or usability, sometimes it can be the best way to express some algorithm. Here are a few common design patterns that come up sometimes when using dispatch in this way.

Extracting the type parameter from a super-type

Here is a correct code template for returning the element-type T of any arbitrary subtype of `AbstractArray` that has well-defined element type:

```
abstract type AbstractArray{T, N} end
eltype(::Type{<:AbstractArray{T}}) where {T} = T
```

using so-called triangular dispatch. Note that `UnionAll` types, for example `eltype(AbstractArray{T} where T <: Integer)`, do not match the above method. The implementation of `eltype` in `Base` adds a fallback method to `Any` for such cases.

One common mistake is to try and get the element-type by using introspection:

```
eltype_wrong(::Type{A}) where {A<:AbstractArray} = A.parameters[1]
```

However, it is not hard to construct cases where this will fail:

```
struct BitVector <: AbstractArray{Bool, 1}; end
```

Here we have created a type `BitVector` which has no parameters, but where the element-type is still fully specified, with T equal to `Bool`!

Another mistake is to try to walk up the type hierarchy using `supertype`:

```
eltype_wrong(::Type{AbstractArray{T}}) where {T} = T
eltype_wrong(::Type{AbstractArray{T, N}}) where {T, N} = T
eltype_wrong(::Type{A}) where {A<:AbstractArray} = eltype_wrong(supertype(A))
```

While this works for declared types, it fails for types without supertypes:

```
julia> eltype_wrong(Union{AbstractArray{Int}, AbstractArray{Float64}})
ERROR: MethodError: no method matching supertype(::Type{Union{AbstractArray{Float64,N} where N,
↳ AbstractArray{Int64,N} where N}})
Closest candidates are:
  supertype(::DataType) at operators.jl:43
  supertype(::UnionAll) at operators.jl:48
```

Building a similar type with a different type parameter

When building generic code, there is often a need for constructing a similar object with some change made to the layout of the type, also necessitating a change of the type parameters. For instance, you might have some sort of abstract array with an arbitrary element type and want to write your computation on it with a specific element type. We must implement a method for each `AbstractArray{T}` subtype that describes how to compute this type transform. There is no general transform of one subtype into another subtype with a different parameter.

The subtypes of `AbstractArray` typically implement two methods to achieve this: A method to convert the input array to a subtype of a specific `AbstractArray{T, N}` abstract type; and a method to make a new uninitialized array with a specific element type. Sample implementations of these can be found in Julia Base. Here is a basic example usage of them, guaranteeing that input and output are of the same type:

```
input = convert(AbstractArray{Etype}, input)
output = similar(input, Etype)
```

As an extension of this, in cases where the algorithm needs a copy of the input array, `convert` is insufficient as the return value may alias the original input. Combining `similar` (to make the output array) and `copyto!` (to fill it with the input data) is a generic way to express the requirement for a mutable copy of the input argument:

```
copy_with_etype(input, Etype) = copyto!(similar(input, Etype), input)
```

Iterated dispatch

In order to dispatch a multi-level parametric argument list, often it is best to separate each level of dispatch into distinct functions. This may sound similar in approach to single-dispatch, but as we shall see below, it is still more flexible.

For example, trying to dispatch on the element-type of an array will often run into ambiguous situations. Instead, commonly code will dispatch first on the container type, then recurse down to a more specific method based on `etype`. In most cases, the algorithms lend themselves conveniently to this hierarchical approach, while in other cases, this rigor must be resolved manually. This dispatching branching can be observed, for example, in the logic to sum two matrices:

```
# First dispatch selects the map algorithm for element-wise summation.
+(a::Matrix, b::Matrix) = map(+, a, b)
# Then dispatch handles each element and selects the appropriate
# common element type for the computation.
+(a, b) = +(promote(a, b)...)
# Once the elements have the same type, they can be added.
# For example, via primitive operations exposed by the processor.
+(a::Float64, b::Float64) = Core.add(a, b)
```

Trait-based dispatch

A natural extension to the iterated dispatch above is to add a layer to method selection that allows to dispatch on sets of types which are independent from the sets defined by the type hierarchy. We could construct such a set by writing out a Union of the types in question, but then this set would not be extensible

as Union-types cannot be altered after creation. However, such an extensible set can be programmed with a design pattern often referred to as a "Holy-trait".

This pattern is implemented by defining a generic function which computes a different singleton value (or type) for each trait-set to which the function arguments may belong to. If this function is pure there is no impact on performance compared to normal dispatch.

The example in the previous section glossed over the implementation details of `map` and `promote`, which both operate in terms of these traits. When iterating over a matrix, such as in the implementation of `map`, one important question is what order to use to traverse the data. When `AbstractArray` subtypes implement the `Base.IndexStyle` trait, other functions such as `map` can dispatch on this information to pick the best algorithm (see [Abstract Array Interface](#)). This means that each subtype does not need to implement a custom version of `map`, since the generic definitions + trait classes will enable the system to select the fastest version. Here is a toy implementation of `map` illustrating the trait-based dispatch:

```
map(f, a::AbstractArray, b::AbstractArray) = map(Base.IndexStyle(a, b), f, a, b)
# generic implementation:
map(::Base.IndexCartesian, f, a::AbstractArray, b::AbstractArray) = ...
# linear-indexing implementation (faster)
map(::Base.IndexLinear, f, a::AbstractArray, b::AbstractArray) = ...
```

This trait-based approach is also present in the `promote` mechanism employed by the scalar `+`. It uses `promote_type`, which returns the optimal common type to compute the operation given the two types of the operands. This makes it possible to reduce the problem of implementing every function for every pair of possible type arguments, to the much smaller problem of implementing a conversion operation from each type to a common type, plus a table of preferred pair-wise promotion rules.

Output-type computation

The discussion of trait-based promotion provides a transition into our next design pattern: computing the output element type for a matrix operation.

For implementing primitive operations, such as addition, we use the `promote_type` function to compute the desired output type. (As before, we saw this at work in the `promote` call in the call to `+`).

For more complex functions on matrices, it may be necessary to compute the expected return type for a more complex sequence of operations. This is often performed by the following steps:

1. Write a small function `op` that expresses the set of operations performed by the kernel of the algorithm.
2. Compute the element type `R` of the result matrix as `promote_op(op, argument_types...)`, where `argument_types` is computed from `eltype` applied to each input array.
3. Build the output matrix as `similar(R, dims)`, where `dims` are the desired dimensions of the output array.

For a more specific example, a generic square-matrix multiply pseudo-code might look like:

```
function matmul(a::AbstractMatrix, b::AbstractMatrix)
    op = (ai, bi) -> ai * bi + ai * bi
```

```

## this is insufficient because it assumes `one(eltype(a))` is constructable:
# R = typeof(op(one(eltype(a)), one(eltype(b))))

## this fails because it assumes `a[1]` exists and is representative of all elements of the
↪ array
# R = typeof(op(a[1], b[1]))

## this is incorrect because it assumes that `+` calls `promote_type`
## but this is not true for some types, such as Bool:
# R = promote_type(ai, bi)

# this is wrong, since depending on the return value
# of type-inference is very brittle (as well as not being optimizable):
# R = Base.return_types(op, (eltype(a), eltype(b)))

## but, finally, this works:
R = promote_op(op, eltype(a), eltype(b))
## although sometimes it may give a larger type than desired
## it will always give a correct type

output = similar(b, R, (size(a, 1), size(b, 2)))
if size(a, 2) > 0
    for j in 1:size(b, 2)
        for i in 1:size(a, 1)
            ## here we don't use `ab = zero(R)`,
            ## since `R` might be `Any` and `zero(Any)` is not defined
            ## we also must declare `ab::R` to make the type of `ab` constant in the loop,
            ## since it is possible that `typeof(a * b) != typeof(a * b + a * b) == R`
            ab::R = a[i, 1] * b[1, j]
            for k in 2:size(a, 2)
                ab += a[i, k] * b[k, j]
            end
            output[i, j] = ab
        end
    end
end
return output
end

```

Separate convert and kernel logic

One way to significantly cut down on compile-times and testing complexity is to isolate the logic for converting to the desired type and the computation. This lets the compiler specialize and inline the conversion logic independent from the rest of the body of the larger kernel.

This is a common pattern seen when converting from a larger class of types to the one specific argument type that is actually supported by the algorithm:

```

complexfunction(arg::Int) = ...
complexfunction(arg::Any) = complexfunction(convert(Int, arg))

```

```
| matmul(a::T, b::T) = ...
| matmul(a, b) = matmul(promote(a, b)...)
|
```

12.7 Parametrically-constrained Varargs methods

Function parameters can also be used to constrain the number of arguments that may be supplied to a "varargs" function ([Varargs Functions](#)). The notation `Vararg{T,N}` is used to indicate such a constraint. For example:

```
| julia> bar(a,b,x::Vararg{Any,2}) = (a,b,x)
| bar (generic function with 1 method)
|
| julia> bar(1,2,3)
| ERROR: MethodError: no method matching bar(::Int64, ::Int64, ::Int64)
|
| Closest candidates are:
|   bar(::Any, ::Any, ::Any, !Matched::Any)
|     @ Main none:1
|
| Stacktrace:
| [...]
|
| julia> bar(1,2,3,4)
| (1, 2, (3, 4))
|
| julia> bar(1,2,3,4,5)
| ERROR: MethodError: no method matching bar(::Int64, ::Int64, ::Int64, ::Int64, ::Int64)
|
| Closest candidates are:
|   bar(::Any, ::Any, ::Any, ::Any)
|     @ Main none:1
|
| Stacktrace:
| [...]
```

More usefully, it is possible to constrain varargs methods by a parameter. For example:

```
| function getindex(A::AbstractArray{T,N}, indices::Vararg{Number,N}) where {T,N}
```

would be called only when the number of indices matches the dimensionality of the array.

When only the type of supplied arguments needs to be constrained `Vararg{T}` can be equivalently written as `T...`. For instance `f(x::Int...) = x` is a shorthand for `f(x::Vararg{Int}) = x`.

12.8 Note on Optional and keyword Arguments

As mentioned briefly in [Functions](#), optional arguments are implemented as syntax for multiple method definitions. For example, this definition:

```
| f(a=1,b=2) = a+2b
```

translates to the following three methods:

```
f(a,b) = a+2b
f(a) = f(a,2)
f() = f(1,2)
```

This means that calling `f()` is equivalent to calling `f(1,2)`. In this case the result is 5, because `f(1,2)` invokes the first method of `f` above. However, this need not always be the case. If you define a fourth method that is more specialized for integers:

```
f(a::Int,b::Int) = a-2b
```

then the result of both `f()` and `f(1,2)` is -3. In other words, optional arguments are tied to a function, not to any specific method of that function. It depends on the types of the optional arguments which method is invoked. When optional arguments are defined in terms of a global variable, the type of the optional argument may even change at run-time.

Keyword arguments behave quite differently from ordinary positional arguments. In particular, they do not participate in method dispatch. Methods are dispatched based only on positional arguments, with keyword arguments processed after the matching method is identified.

12.9 Function-like objects

Methods are associated with types, so it is possible to make any arbitrary Julia object "callable" by adding methods to its type. (Such "callable" objects are sometimes called "functors.")

For example, you can define a type that stores the coefficients of a polynomial, but behaves like a function evaluating the polynomial:

```
julia> struct Polynomial{R}
        coeffs::Vector{R}
    end

julia> function (p::Polynomial)(x)
    v = p.coeffs[end]
    for i = (length(p.coeffs)-1):-1:1
        v = v*x + p.coeffs[i]
    end
    return v
end

julia> (p::Polynomial)() = p(5)
```

Notice that the function is specified by type instead of by name. As with normal functions there is a terse syntax form. In the function body, `p` will refer to the object that was called. A `Polynomial` can be used as follows:

```
julia> p = Polynomial([1,10,100])
Polynomial{Int64}([1, 10, 100])
```

```
julia> p(3)
931

julia> p()
2551
```

This mechanism is also the key to how type constructors and closures (inner functions that refer to their surrounding environment) work in Julia.

12.10 Empty generic functions

Occasionally it is useful to introduce a generic function without yet adding methods. This can be used to separate interface definitions from implementations. It might also be done for the purpose of documentation or code readability. The syntax for this is an empty function block without a tuple of arguments:

```
function emptyfunc end
```

12.11 Method design and the avoidance of ambiguities

Julia's method polymorphism is one of its most powerful features, yet exploiting this power can pose design challenges. In particular, in more complex method hierarchies it is not uncommon for [ambiguities](#) to arise.

Above, it was pointed out that one can resolve ambiguities like

```
f(x, y::Int) = 1
f(x::Int, y) = 2
```

by defining a method

```
f(x::Int, y::Int) = 3
```

This is often the right strategy; however, there are circumstances where following this advice mindlessly can be counterproductive. In particular, the more methods a generic function has, the more possibilities there are for ambiguities. When your method hierarchies get more complicated than this simple example, it can be worth your while to think carefully about alternative strategies.

Below we discuss particular challenges and some alternative ways to resolve such issues.

Tuple and NTuple arguments

Tuple (and NTuple) arguments present special challenges. For example,

```
f(x::NTuple{N,Int}) where {N} = 1
f(x::NTuple{N,Float64}) where {N} = 2
```

are ambiguous because of the possibility that $N == 0$: there are no elements to determine whether the Int or Float64 variant should be called. To resolve the ambiguity, one approach is define a method for the empty tuple:

```
| f(x::Tuple{}) = 3
```

Alternatively, for all methods but one you can insist that there is at least one element in the tuple:

```
| f(x::NTuple{N,Int}) where {N} = 1      # this is the fallback
| f(x::Tuple{Float64, Vararg{Float64}}) = 2 # this requires at least one Float64
```

Orthogonalize your design

When you might be tempted to dispatch on two or more arguments, consider whether a "wrapper" function might make for a simpler design. For example, instead of writing multiple variants:

```
| f(x::A, y::A) = ...
| f(x::A, y::B) = ...
| f(x::B, y::A) = ...
| f(x::B, y::B) = ...
```

you might consider defining

```
| f(x::A, y::A) = ...
| f(x, y) = f(g(x), g(y))
```

where `g` converts the argument to type `A`. This is a very specific example of the more general principle of [orthogonal design](#), in which separate concepts are assigned to separate methods. Here, `g` will most likely need a fallback definition

```
| g(x::A) = x
```

A related strategy exploits `promote` to bring `x` and `y` to a common type:

```
| f(x::T, y::T) where {T} = ...
| f(x, y) = f(promote(x, y)...)

```

One risk with this design is the possibility that if there is no suitable promotion method converting `x` and `y` to the same type, the second method will recurse on itself infinitely and trigger a stack overflow.

Dispatch on one argument at a time

If you need to dispatch on multiple arguments, and there are many fallbacks with too many combinations to make it practical to define all possible variants, then consider introducing a "name cascade" where (for example) you dispatch on the first argument and then call an internal method:

```
| f(x::A, y) = _fA(x, y)
| f(x::B, y) = _fB(x, y)
```

Then the internal methods `_fA` and `_fB` can dispatch on `y` without concern about ambiguities with each other with respect to `x`.

Be aware that this strategy has at least one major disadvantage: in many cases, it is not possible for users to further customize the behavior of `f` by defining further specializations of your exported function `f`. Instead, they have to define specializations for your internal methods `_fA` and `_fB`, and this blurs the lines between exported and internal methods.

Abstract containers and element types

Where possible, try to avoid defining methods that dispatch on specific element types of abstract containers. For example,

```
| - (A::AbstractArray{T}, b::Date) where {T<:Date}
```

generates ambiguities for anyone who defines a method

```
| - (A::MyArrayType{T}, b::T) where {T}
```

The best approach is to avoid defining either of these methods: instead, rely on a generic method `-(A::AbstractArray, b)` and make sure this method is implemented with generic calls (like `similar` and `-`) that do the right thing for each container type and element type separately. This is just a more complex variant of the advice to [orthogonalize](#) your methods.

When this approach is not possible, it may be worth starting a discussion with other developers about resolving the ambiguity; just because one method was defined first does not necessarily mean that it can't be modified or eliminated. As a last resort, one developer can define the "band-aid" method

```
| - (A::MyArrayType{T}, b::Date) where {T<:Date} = ...
```

that resolves the ambiguity by brute force.

Complex method "cascades" with default arguments

If you are defining a method "cascade" that supplies defaults, be careful about dropping any arguments that correspond to potential defaults. For example, suppose you're writing a digital filtering algorithm and you have a method that handles the edges of the signal by applying padding:

```
function myfilter(A, kernel, ::Replicate)
    Apadded = replicate_edges(A, size(kernel))
    myfilter(Apadded, kernel) # now perform the "real" computation
end
```

This will run afoul of a method that supplies default padding:

```
| myfilter(A, kernel) = myfilter(A, kernel, Replicate()) # replicate the edge by default
```

Together, these two methods generate an infinite recursion with `A` constantly growing bigger.

The better design would be to define your call hierarchy like this:

```
struct NoPad end # indicate that no padding is desired, or that it's already applied

myfilter(A, kernel) = myfilter(A, kernel, Replicate()) # default boundary conditions

function myfilter(A, kernel, ::Replicate)
    Apadded = replicate_edges(A, size(kernel))
```

```

    myfilter(Apadded, kernel, NoPad()) # indicate the new boundary conditions
end

# other padding methods go here

function myfilter(A, kernel, ::NoPad)
    # Here's the "real" implementation of the core computation
end

```

NoPad is supplied in the same argument position as any other kind of padding, so it keeps the dispatch hierarchy well organized and with reduced likelihood of ambiguities. Moreover, it extends the "public" myfilter interface: a user who wants to control the padding explicitly can call the NoPad variant directly.

12.12 Defining methods in local scope

You can define methods within a [local scope](#), for example

```

julia> function f(x)
           g(y::Int) = y + x
           g(y) = y - x
           g
       end
f (generic function with 1 method)

julia> h = f(3);

julia> h(4)
7

julia> h(4.0)
1.0

```

However, you should not define local methods conditionally or subject to control flow, as in

```

function f2(inc)
    if inc
        g(x) = x + 1
    else
        g(x) = x - 1
    end
end

function f3()
    function g end
    return g
    g() = 0
end

```

as it is not clear what function will end up getting defined. In the future, it might be an error to define local methods in this manner.

For cases like this use anonymous functions instead:

```
function f2(inc)
  g = if inc
    x -> x + 1
  else
    x -> x - 1
  end
end
```

Chapter 13

Constructors

Constructors ¹ are functions that create new objects – specifically, instances of [Composite Types](#). In Julia, type objects also serve as constructor functions: they create new instances of themselves when applied to an argument tuple as a function. This much was already mentioned briefly when composite types were introduced. For example:

```
julia> struct Foo
           bar
           baz
       end

julia> foo = Foo(1, 2)
Foo{1, 2}

julia> foo.bar
1

julia> foo.baz
2
```

For many types, forming new objects by binding their field values together is all that is ever needed to create instances. However, in some cases more functionality is required when creating composite objects. Sometimes invariants must be enforced, either by checking arguments or by transforming them. [Recursive data structures](#), especially those that may be self-referential, often cannot be constructed cleanly without first being created in an incomplete state and then altered programmatically to be made whole, as a separate step from object creation. Sometimes, it's just convenient to be able to construct objects with fewer or different types of parameters than they have fields. Julia's system for object construction addresses all of these cases and more.

¹Nomenclature: while the term "constructor" generally refers to the entire function which constructs objects of a type, it is common to abuse terminology slightly and refer to specific constructor methods as "constructors". In such situations, it is generally clear from the context that the term is used to mean "constructor method" rather than "constructor function", especially as it is often used in the sense of singling out a particular method of the constructor from all of the others.

13.1 Outer Constructor Methods

A constructor is just like any other function in Julia in that its overall behavior is defined by the combined behavior of its methods. Accordingly, you can add functionality to a constructor by simply defining new methods. For example, let's say you want to add a constructor method for `Foo` objects that takes only one argument and uses the given value for both the `bar` and `baz` fields. This is simple:

```
julia> Foo(x) = Foo(x,x)
Foo

julia> Foo(1)
Foo(1, 1)
```

You could also add a zero-argument `Foo` constructor method that supplies default values for both of the `bar` and `baz` fields:

```
julia> Foo() = Foo(0)
Foo

julia> Foo()
Foo(0, 0)
```

Here the zero-argument constructor method calls the single-argument constructor method, which in turn calls the automatically provided two-argument constructor method. For reasons that will become clear very shortly, additional constructor methods declared as normal methods like this are called outer constructor methods. Outer constructor methods can only ever create a new instance by calling another constructor method, such as the automatically provided default ones.

13.2 Inner Constructor Methods

While outer constructor methods succeed in addressing the problem of providing additional convenience methods for constructing objects, they fail to address the other two use cases mentioned in the introduction of this chapter: enforcing invariants, and allowing construction of self-referential objects. For these problems, one needs inner constructor methods. An inner constructor method is like an outer constructor method, except for two differences:

1. It is declared inside the block of a type declaration, rather than outside of it like normal methods.
2. It has access to a special locally existent function called `new` that creates objects of the block's type.

For example, suppose one wants to declare a type that holds a pair of real numbers, subject to the constraint that the first number is not greater than the second one. One could declare it like this:

```
julia> struct OrderedPair
    x::Real
    y::Real
    OrderedPair(x,y) = x > y ? error("out of order") : new(x,y)
end
```

Now `OrderedPair` objects can only be constructed such that $x \leq y$:

```
julia> OrderedPair(1, 2)
OrderedPair{Int64}(1, 2)

julia> OrderedPair(2,1)
ERROR: out of order
Stacktrace:
 [1] error at ./error.jl:33 [inlined]
 [2] OrderedPair{::Int64, ::Int64} at ./none:4
 [3] top-level scope
```

If the type were declared mutable, you could reach in and directly change the field values to violate this invariant. Of course, messing around with an object's internals uninvited is bad practice. You (or someone else) can also provide additional outer constructor methods at any later point, but once a type is declared, there is no way to add more inner constructor methods. Since outer constructor methods can only create objects by calling other constructor methods, ultimately, some inner constructor must be called to create an object. This guarantees that all objects of the declared type must come into existence by a call to one of the inner constructor methods provided with the type, thereby giving some degree of enforcement of a type's invariants.

If any inner constructor method is defined, no default constructor method is provided: it is presumed that you have supplied yourself with all the inner constructors you need. The default constructor is equivalent to writing your own inner constructor method that takes all of the object's fields as parameters (constrained to be of the correct type, if the corresponding field has a type), and passes them to `new`, returning the resulting object:

```
julia> struct Foo
    bar
    baz
    Foo(bar,baz) = new(bar,baz)
end
```

This declaration has the same effect as the earlier definition of the `Foo` type without an explicit inner constructor method. The following two types are equivalent – one with a default constructor, the other with an explicit constructor:

```
julia> struct T1
    x::Int64
end

julia> struct T2
    x::Int64
    T2(x) = new(x)
end

julia> T1(1)
T1{Int64}(1)

julia> T2(1)
T2{Int64}(1)
```

```

T2(1)

julia> T1(1.0)
T1(1)

julia> T2(1.0)
T2(1)

```

It is good practice to provide as few inner constructor methods as possible: only those taking all arguments explicitly and enforcing essential error checking and transformation. Additional convenience constructor methods, supplying default values or auxiliary transformations, should be provided as outer constructors that call the inner constructors to do the heavy lifting. This separation is typically quite natural.

13.3 Incomplete Initialization

The final problem which has still not been addressed is construction of self-referential objects, or more generally, recursive data structures. Since the fundamental difficulty may not be immediately obvious, let us briefly explain it. Consider the following recursive type declaration:

```

julia> mutable struct SelfReferential
    obj::SelfReferential
end

```

This type may appear innocuous enough, until one considers how to construct an instance of it. If `a` is an instance of `SelfReferential`, then a second instance can be created by the call:

```

julia> b = SelfReferential(a)

```

But how does one construct the first instance when no instance exists to provide as a valid value for its `obj` field? The only solution is to allow creating an incompletely initialized instance of `SelfReferential` with an unassigned `obj` field, and using that incomplete instance as a valid value for the `obj` field of another instance, such as, for example, itself.

To allow for the creation of incompletely initialized objects, Julia allows the `new` function to be called with fewer than the number of fields that the type has, returning an object with the unspecified fields uninitialized. The inner constructor method can then use the incomplete object, finishing its initialization before returning it. Here, for example, is another attempt at defining the `SelfReferential` type, this time using a zero-argument inner constructor returning instances having `obj` fields pointing to themselves:

```

julia> mutable struct SelfReferential
    obj::SelfReferential
    SelfReferential() = (x = new(); x.obj = x)
end

```

We can verify that this constructor works and constructs objects that are, in fact, self-referential:

```
julia> x = SelfReferential();

julia> x === x
true

julia> x === x.obj
true

julia> x === x.obj.obj
true
```

Although it is generally a good idea to return a fully initialized object from an inner constructor, it is possible to return incompletely initialized objects:

```
julia> mutable struct Incomplete
    data
    Incomplete() = new()
end

julia> z = Incomplete();
```

While you are allowed to create objects with uninitialized fields, any access to an uninitialized reference is an immediate error:

```
julia> z.data
ERROR: UndefRefError: access to undefined reference
```

This avoids the need to continually check for null values. However, not all object fields are references. Julia considers some types to be "plain data", meaning all of their data is self-contained and does not reference other objects. The plain data types consist of primitive types (e.g. `Int`) and immutable structs of other plain data types (see also: `isbits`, `isbitstype`). The initial contents of a plain data type is undefined:

```
julia> struct HasPlain
    n::Int
    HasPlain() = new()
end

julia> HasPlain()
HasPlain(438103441441)
```

Arrays of plain data types exhibit the same behavior.

You can pass incomplete objects to other functions from inner constructors to delegate their completion:

```
julia> mutable struct Lazy
    data
    Lazy(v) = complete_me(new(), v)
end
```

As with incomplete objects returned from constructors, if `complete_me` or any of its callees try to access the `data` field of the `Lazy` object before it has been initialized, an error will be thrown immediately.

13.4 Parametric Constructors

Parametric types add a few wrinkles to the constructor story. Recall from [Parametric Types](#) that, by default, instances of parametric composite types can be constructed either with explicitly given type parameters or with type parameters implied by the types of the arguments given to the constructor. Here are some examples:

```
julia> struct Point{T<:Real}
           x::T
           y::T
       end

julia> Point(1,2) ## implicit T ##
Point{Int64}(1, 2)

julia> Point(1.0,2.5) ## implicit T ##
Point{Float64}(1.0, 2.5)

julia> Point(1,2.5) ## implicit T ##
ERROR: MethodError: no method matching Point{::Int64, ::Float64}
Closest candidates are:
  Point{::T, ::T} where T<:Real at none:2

julia> Point{Int64}(1, 2) ## explicit T ##
Point{Int64}(1, 2)

julia> Point{Int64}(1.0,2.5) ## explicit T ##
ERROR: InexactError: Int64(2.5)
Stacktrace:
[...]

julia> Point{Float64}(1.0, 2.5) ## explicit T ##
Point{Float64}(1.0, 2.5)

julia> Point{Float64}(1,2) ## explicit T ##
Point{Float64}(1.0, 2.0)
```

As you can see, for constructor calls with explicit type parameters, the arguments are converted to the implied field types: `Point{Int64}(1,2)` works, but `Point{Int64}(1.0,2.5)` raises an [InexactError](#) when converting 2.5 to `Int64`. When the type is implied by the arguments to the constructor call, as in `Point(1,2)`, then the types of the arguments must agree – otherwise the `T` cannot be determined – but any pair of real arguments with matching type may be given to the generic `Point` constructor.

What's really going on here is that `Point`, `Point{Float64}` and `Point{Int64}` are all different constructor functions. In fact, `Point{T}` is a distinct constructor function for each type `T`. Without any explicitly provided inner constructors, the declaration of the composite type `Point{T<:Real}` automatically provides an inner constructor, `Point{T}`, for each possible type `T<:Real`, that behaves just like non-parametric default inner constructors do. It also provides a single general outer `Point` constructor that takes pairs of real arguments, which must be of the same type. This automatic provision of constructors is equivalent to the following explicit declaration:

```
julia> struct Point{T<:Real}
    x::T
    y::T
    Point{T}(x,y) where {T<:Real} = new(x,y)
end

julia> Point(x::T, y::T) where {T<:Real} = Point{T}(x,y);
```

Notice that each definition looks like the form of constructor call that it handles. The call `Point{Int64}(1,2)` will invoke the definition `Point{T}(x,y)` inside the `struct` block. The outer constructor declaration, on the other hand, defines a method for the general `Point` constructor which only applies to pairs of values of the same real type. This declaration makes constructor calls without explicit type parameters, like `Point(1,2)` and `Point(1.0,2.5)`, work. Since the method declaration restricts the arguments to being of the same type, calls like `Point(1,2.5)`, with arguments of different types, result in "no method" errors.

Suppose we wanted to make the constructor call `Point(1,2.5)` work by "promoting" the integer value 1 to the floating-point value 1.0. The simplest way to achieve this is to define the following additional outer constructor method:

```
julia> Point(x::Int64, y::Float64) = Point(convert(Float64,x),y);
```

This method uses the `convert` function to explicitly convert `x` to `Float64` and then delegates construction to the general constructor for the case where both arguments are `Float64`. With this method definition what was previously a `MethodError` now successfully creates a point of type `Point{Float64}`:

```
julia> p = Point(1,2.5)
Point{Float64}(1.0, 2.5)

julia> typeof(p)
Point{Float64}
```

However, other similar calls still don't work:

```
julia> Point(1.5,2)
ERROR: MethodError: no method matching Point(::Float64, ::Int64)

Closest candidates are:
  Point(::T, !Matched::T) where T<:Real
    @ Main none:1

Stacktrace:
[...]
```

For a more general way to make all such calls work sensibly, see [Conversion and Promotion](#). At the risk of spoiling the suspense, we can reveal here that all it takes is the following outer method definition to make all calls to the general `Point` constructor work as one would expect:

```
julia> Point(x::Real, y::Real) = Point(promote(x,y)...);
```

The `promote` function converts all its arguments to a common type – in this case `Float64`. With this method definition, the `Point` constructor promotes its arguments the same way that numeric operators like `+` do, and works for all kinds of real numbers:

```
julia> Point(1.5,2)
Point{Float64}(1.5, 2.0)

julia> Point(1,1//2)
Point{Rational{Int64}}(1//1, 1//2)

julia> Point(1.0,1//2)
Point{Float64}(1.0, 0.5)
```

Thus, while the implicit type parameter constructors provided by default in Julia are fairly strict, it is possible to make them behave in a more relaxed but sensible manner quite easily. Moreover, since constructors can leverage all of the power of the type system, methods, and multiple dispatch, defining sophisticated behavior is typically quite simple.

13.5 Case Study: Rational

Perhaps the best way to tie all these pieces together is to present a real world example of a parametric composite type and its constructor methods. To that end, we implement our own rational number type `OurRational`, similar to Julia's built-in `Rational` type, defined in `rational.jl`:

```
julia> struct OurRational{T<:Integer} <: Real
    num::T
    den::T
    function OurRational{T}(num::T, den::T) where T<:Integer
        if num == 0 && den == 0
            error("invalid rational: 0//0")
        end
        num = flpsign(num, den)
        den = flpsign(den, den)
        g = gcd(num, den)
        num = div(num, g)
        den = div(den, g)
        new(num, den)
    end
end

julia> OurRational{n::T, d::T} where {T<:Integer} = OurRational{T}(n,d)
OurRational

julia> OurRational{n::Integer, d::Integer} = OurRational(promote(n,d)...)
OurRational

julia> OurRational{n::Integer} = OurRational(n,one(n))
OurRational

julia> ⅉ(n::Integer, d::Integer) = OurRational(n,d)
ⅉ (generic function with 1 method)
```

```

julia> ⚪(x::OurRational, y::Integer) = x.num ⚪ (x.den*y)
⚪ (generic function with 2 methods)

julia> ⚪(x::Integer, y::OurRational) = (x*y.den) ⚪ y.num
⚪ (generic function with 3 methods)

julia> ⚪(x::Complex, y::Real) = complex(real(x) ⚪ y, imag(x) ⚪ y)
⚪ (generic function with 4 methods)

julia> ⚪(x::Real, y::Complex) = (x*y') ⚪ real(y*y')
⚪ (generic function with 5 methods)

julia> function ⚪(x::Complex, y::Complex)
    xy = x*y'
    yy = real(y*y')
    complex(real(xy) ⚪ yy, imag(xy) ⚪ yy)
end
⚪ (generic function with 6 methods)

```

The first line – `struct OurRational{T<:Integer} <: Real` – declares that `OurRational` takes one type parameter of an integer type, and is itself a real type. The field declarations `num::T` and `den::T` indicate that the data held in a `OurRational{T}` object are a pair of integers of type `T`, one representing the rational value's numerator and the other representing its denominator.

Now things get interesting. `OurRational` has a single inner constructor method which checks that `num` and `den` aren't both zero and ensures that every rational is constructed in "lowest terms" with a non-negative denominator. This is accomplished by first flipping the signs of numerator and denominator if the denominator is negative. Then, both are divided by their greatest common divisor (`gcd` always returns a non-negative number, regardless of the sign of its arguments). Because this is the only inner constructor for `OurRational`, we can be certain that `OurRational` objects are always constructed in this normalized form.

`OurRational` also provides several outer constructor methods for convenience. The first is the "standard" general constructor that infers the type parameter `T` from the type of the numerator and denominator when they have the same type. The second applies when the given numerator and denominator values have different types: it promotes them to a common type and then delegates construction to the outer constructor for arguments of matching type. The third outer constructor turns integer values into rationals by supplying a value of 1 as the denominator.

Following the outer constructor definitions, we defined a number of methods for the `⚪` operator, which provides a syntax for writing rationals (e.g. `1 ⚪ 2`). Julia's `Rational` type uses the `//` operator for this purpose. Before these definitions, `⚪` is a completely undefined operator with only syntax and no meaning. Afterwards, it behaves just as described in [Rational Numbers](#) – its entire behavior is defined in these few lines. The first and most basic definition just makes a `⚪ b` construct a `OurRational` by applying the `OurRational` constructor to `a` and `b` when they are integers. When one of the operands of `⚪` is already a rational number, we construct a new rational for the resulting ratio slightly differently; this behavior is actually identical to division of a rational with an integer. Finally, applying `⚪` to complex integral values creates an instance of `Complex{<:OurRational}` – a complex number whose real and imaginary parts are rationals:

```

julia> z = (1 + 2im) ⚪ (1 - 2im);

```

```
julia> typeof(z)
Complex{OurRational{Int64}}

julia> typeof(z) <: Complex{<:OurRational}
true
```

Thus, although the `∘` operator usually returns an instance of `OurRational`, if either of its arguments are complex integers, it will return an instance of `Complex{<:OurRational}` instead. The interested reader should consider perusing the rest of `rational.jl`: it is short, self-contained, and implements an entire basic Julia type.

13.6 Outer-only constructors

As we have seen, a typical parametric type has inner constructors that are called when type parameters are known; e.g. they apply to `Point{Int}` but not to `Point`. Optionally, outer constructors that determine type parameters automatically can be added, for example constructing a `Point{Int}` from the call `Point(1,2)`. Outer constructors call inner constructors to actually make instances. However, in some cases one would rather not provide inner constructors, so that specific type parameters cannot be requested manually.

For example, say we define a type that stores a vector along with an accurate representation of its sum:

```
julia> struct SummedArray{T<:Number,S<:Number}
    data::Vector{T}
    sum::S
end

julia> SummedArray{Int32[1; 2; 3], Int32(6)}
SummedArray{Int32, Int32}{Int32[1, 2, 3], 6}
```

The problem is that we want `S` to be a larger type than `T`, so that we can sum many elements with less information loss. For example, when `T` is `Int32`, we would like `S` to be `Int64`. Therefore we want to avoid an interface that allows the user to construct instances of the type `SummedArray{Int32,Int32}`. One way to do this is to provide a constructor only for `SummedArray`, but inside the `struct` definition block to suppress generation of default constructors:

```
julia> struct SummedArray{T<:Number,S<:Number}
    data::Vector{T}
    sum::S
    function SummedArray(a::Vector{T}) where T
        S = widen(T)
        new{T,S}(a, sum(S, a))
    end
end

julia> SummedArray{Int32[1; 2; 3], Int32(6)}
ERROR: MethodError: no method matching SummedArray(::Vector{Int32}, ::Int32)

Closest candidates are:
  SummedArray(::Vector{T}) where T
```

```
@ Main none:4  
Stacktrace:  
[...]
```

This constructor will be invoked by the syntax `SummedArray(a)`. The syntax `new{T,S}` allows specifying parameters for the type to be constructed, i.e. this call will return a `SummedArray{T,S}`. `new{T,S}` can be used in any constructor definition, but for convenience the parameters to `new{}` are automatically derived from the type being constructed when possible.

Chapter 14

Conversion and Promotion

Julia has a system for promoting arguments of mathematical operators to a common type, which has been mentioned in various other sections, including [Integers and Floating-Point Numbers](#), [Mathematical Operations and Elementary Functions](#), [Types](#), and [Methods](#). In this section, we explain how this promotion system works, as well as how to extend it to new types and apply it to functions besides built-in mathematical operators. Traditionally, programming languages fall into two camps with respect to promotion of arithmetic arguments:

- **Automatic promotion for built-in arithmetic types and operators.** In most languages, built-in numeric types, when used as operands to arithmetic operators with infix syntax, such as `+`, `-`, `*`, and `/`, are automatically promoted to a common type to produce the expected results. C, Java, Perl, and Python, to name a few, all correctly compute the sum `1 + 1.5` as the floating-point value `2.5`, even though one of the operands to `+` is an integer. These systems are convenient and designed carefully enough that they are generally all-but-invisible to the programmer: hardly anyone consciously thinks of this promotion taking place when writing such an expression, but compilers and interpreters must perform conversion before addition since integers and floating-point values cannot be added as-is. Complex rules for such automatic conversions are thus inevitably part of specifications and implementations for such languages.
- **No automatic promotion.** This camp includes Ada and ML – very “strict” statically typed languages. In these languages, every conversion must be explicitly specified by the programmer. Thus, the example expression `1 + 1.5` would be a compilation error in both Ada and ML. Instead one must write `real(1) + 1.5`, explicitly converting the integer `1` to a floating-point value before performing addition. Explicit conversion everywhere is so inconvenient, however, that even Ada has some degree of automatic conversion: integer literals are promoted to the expected integer type automatically, and floating-point literals are similarly promoted to appropriate floating-point types.

In a sense, Julia falls into the “no automatic promotion” category: mathematical operators are just functions with special syntax, and the arguments of functions are never automatically converted. However, one may observe that applying mathematical operations to a wide variety of mixed argument types is just an extreme case of polymorphic multiple dispatch – something which Julia’s dispatch and type systems are particularly well-suited to handle. “Automatic” promotion of mathematical operands simply emerges as a special application: Julia comes with pre-defined catch-all dispatch rules for mathematical operators, invoked when no specific implementation exists for some combination of operand types. These catch-all rules first promote all operands to a common type using user-definable promotion rules, and then invoke

a specialized implementation of the operator in question for the resulting values, now of the same type. User-defined types can easily participate in this promotion system by defining methods for conversion to and from other types, and providing a handful of promotion rules defining what types they should promote to when mixed with other types.

14.1 Conversion

The standard way to obtain a value of a certain type T is to call the type's constructor, $T(x)$. However, there are cases where it's convenient to convert a value from one type to another without the programmer asking for it explicitly. One example is assigning a value into an array: if A is a `Vector{Float64}`, the expression `A[1] = 2` should work by automatically converting the 2 from `Int` to `Float64`, and storing the result in the array. This is done via the `convert` function.

The `convert` function generally takes two arguments: the first is a type object and the second is a value to convert to that type. The returned value is the value converted to an instance of given type. The simplest way to understand this function is to see it in action:

```
julia> x = 12
12

julia> typeof(x)
Int64

julia> xu = convert{UInt8, x}
0x0c

julia> typeof(xu)
UInt8

julia> xf = convert{AbstractFloat, x}
12.0

julia> typeof(xf)
Float64

julia> a = Any[1 2 3; 4 5 6]
2×3 Matrix{Any}:
 1  2  3
 4  5  6

julia> convert{Array{Float64}, a}
2×3 Matrix{Float64}:
 1.0  2.0  3.0
 4.0  5.0  6.0
```

Conversion isn't always possible, in which case a `MethodError` is thrown indicating that `convert` doesn't know how to perform the requested conversion:

```
julia> convert{AbstractFloat, "foo"}
ERROR: MethodError: Cannot `convert` an object of type String to an object of type AbstractFloat
[...]
```

Some languages consider parsing strings as numbers or formatting numbers as strings to be conversions (many dynamic languages will even perform conversion for you automatically). This is not the case in Julia. Even though some strings can be parsed as numbers, most strings are not valid representations of numbers, and only a very limited subset of them are. Therefore in Julia the dedicated `parse` function must be used to perform this operation, making it more explicit.

When is `convert` called?

The following language constructs call `convert`:

- Assigning to an array converts to the array's element type.
- Assigning to a field of an object converts to the declared type of the field.
- Constructing an object with `new` converts to the object's declared field types.
- Assigning to a variable with a declared type (e.g. `local x::T`) converts to that type.
- A function with a declared return type converts its return value to that type.
- Passing a value to `ccall` converts it to the corresponding argument type.

Conversion vs. Construction

Note that the behavior of `convert(T, x)` appears to be nearly identical to `T(x)`. Indeed, it usually is. However, there is a key semantic difference: since `convert` can be called implicitly, its methods are restricted to cases that are considered "safe" or "unsurprising". `convert` will only convert between types that represent the same basic kind of thing (e.g. different representations of numbers, or different string encodings). It is also usually lossless; converting a value to a different type and back again should result in the exact same value.

There are four general kinds of cases where constructors differ from `convert`:

Constructors for types unrelated to their arguments

Some constructors don't implement the concept of "conversion". For example, `Timer(2)` creates a 2-second timer, which is not really a "conversion" from an integer to a timer.

Mutable collections

`convert(T, x)` is expected to return the original `x` if `x` is already of type `T`. In contrast, if `T` is a mutable collection type then `T(x)` should always make a new collection (copying elements from `x`).

Wrapper types

For some types which "wrap" other values, the constructor may wrap its argument inside a new object even if it is already of the requested type. For example `Some(x)` wraps `x` to indicate that a value is present (in a context where the result might be a `Some` or nothing). However, `x` itself might be the object `Some(y)`, in which case the result is `Some(Some(y))`, with two levels of wrapping. `convert(Some, x)`, on the other hand, would just return `x` since it is already a `Some`.

Constructors that don't return instances of their own type

In very rare cases it might make sense for the constructor `T(x)` to return an object not of type `T`. This could happen if a wrapper type is its own inverse (e.g. `Flip(Flip(x)) == x`), or to support an old calling syntax for backwards compatibility when a library is restructured. But `convert(T, x)` should always return a value of type `T`.

Defining New Conversions

When defining a new type, initially all ways of creating it should be defined as constructors. If it becomes clear that implicit conversion would be useful, and that some constructors meet the above "safety" criteria, then `convert` methods can be added. These methods are typically quite simple, as they only need to call the appropriate constructor. Such a definition might look like this:

```
| convert(::Type{MyType}, x) = MyType(x)
```

The type of the first argument of this method is `Type{MyType}`, the only instance of which is `MyType`. Thus, this method is only invoked when the first argument is the type value `MyType`. Notice the syntax used for the first argument: the argument name is omitted prior to the `::` symbol, and only the type is given. This is the syntax in Julia for a function argument whose type is specified but whose value does not need to be referenced by name.

All instances of some abstract types are by default considered "sufficiently similar" that a universal `convert` definition is provided in Julia Base. For example, this definition states that it's valid to convert any `Number` type to any other by calling a 1-argument constructor:

```
| convert(::Type{T}, x::Number) where {T<:Number} = T(x)::T
```

This means that new `Number` types only need to define constructors, since this definition will handle `convert` for them. An identity conversion is also provided to handle the case where the argument is already of the requested type:

```
| convert(::Type{T}, x::T) where {T<:Number} = x
```

Similar definitions exist for `AbstractString`, `AbstractArray`, and `AbstractDict`.

14.2 Promotion

Promotion refers to converting values of mixed types to a single common type. Although it is not strictly necessary, it is generally implied that the common type to which the values are converted can faithfully represent all of the original values. In this sense, the term "promotion" is appropriate since the values are converted to a "greater" type – i.e. one which can represent all of the input values in a single common type. It is important, however, not to confuse this with object-oriented (structural) super-typing, or Julia's notion of abstract super-types: promotion has nothing to do with the type hierarchy, and everything to do with converting between alternate representations. For instance, although every `Int32` value can also be represented as a `Float64` value, `Int32` is not a subtype of `Float64`.

Promotion to a common "greater" type is performed in Julia by the `promote` function, which takes any number of arguments, and returns a tuple of the same number of values, converted to a common type, or throws an exception if promotion is not possible. The most common use case for promotion is to convert numeric arguments to a common type:

```

julia> promote(1, 2.5)
(1.0, 2.5)

julia> promote(1, 2.5, 3)
(1.0, 2.5, 3.0)

julia> promote(2, 3//4)
(2//1, 3//4)

julia> promote(1, 2.5, 3, 3//4)
(1.0, 2.5, 3.0, 0.75)

julia> promote(1.5, im)
(1.5 + 0.0im, 0.0 + 1.0im)

julia> promote(1 + 2im, 3//4)
(1//1 + 2//1*im, 3//4 + 0//1*im)

```

Floating-point values are promoted to the largest of the floating-point argument types. Integer values are promoted to the largest of the integer argument types. If the types are the same size but differ in signedness, the unsigned type is chosen. Mixtures of integers and floating-point values are promoted to a floating-point type big enough to hold all the values. Integers mixed with rationals are promoted to rationals. Rationals mixed with floats are promoted to floats. Complex values mixed with real values are promoted to the appropriate kind of complex value.

That is really all there is to using promotions. The rest is just a matter of clever application, the most typical "clever" application being the definition of catch-all methods for numeric operations like the arithmetic operators `+`, `-`, `*` and `/`. Here are some of the catch-all method definitions given in `promotion.jl`:

```

+(x::Number, y::Number) = +(promote(x,y)...)
-(x::Number, y::Number) = -(promote(x,y)...)
*(x::Number, y::Number) = *(promote(x,y)...)
/(x::Number, y::Number) = /(promote(x,y)...)

```

These method definitions say that in the absence of more specific rules for adding, subtracting, multiplying and dividing pairs of numeric values, promote the values to a common type and then try again. That's all there is to it: nowhere else does one ever need to worry about promotion to a common numeric type for arithmetic operations – it just happens automatically. There are definitions of catch-all promotion methods for a number of other arithmetic and mathematical functions in `promotion.jl`, but beyond that, there are hardly any calls to `promote` required in Julia Base. The most common usages of `promote` occur in outer constructors methods, provided for convenience, to allow constructor calls with mixed types to delegate to an inner type with fields promoted to an appropriate common type. For example, recall that `rational.jl` provides the following outer constructor method:

```

Rational(n::Integer, d::Integer) = Rational(promote(n,d)...)

```

This allows calls like the following to work:

```

julia> x = Rational{Int8,Int32}(15,-5)
-3//1

```

```
julia> typeof(x)
Rational{Int32}
```

For most user-defined types, it is better practice to require programmers to supply the expected types to constructor functions explicitly, but sometimes, especially for numeric problems, it can be convenient to do promotion automatically.

Defining Promotion Rules

Although one could, in principle, define methods for the `promote` function directly, this would require many redundant definitions for all possible permutations of argument types. Instead, the behavior of `promote` is defined in terms of an auxiliary function called `promote_rule`, which one can provide methods for. The `promote_rule` function takes a pair of type objects and returns another type object, such that instances of the argument types will be promoted to the returned type. Thus, by defining the rule:

```
promote_rule(::Type{Float64}, ::Type{Float32}) = Float64
```

one declares that when 64-bit and 32-bit floating-point values are promoted together, they should be promoted to 64-bit floating-point. The promotion type does not need to be one of the argument types. For example, the following promotion rules both occur in Julia Base:

```
promote_rule(::Type{BigInt}, ::Type{Float64}) = BigFloat
promote_rule(::Type{BigInt}, ::Type{Int8}) = BigInt
```

In the latter case, the result type is `BigInt` since `BigInt` is the only type large enough to hold integers for arbitrary-precision integer arithmetic. Also note that one does not need to define both `promote_rule(::Type{A}, ::Type{B})` and `promote_rule(::Type{B}, ::Type{A})` – the symmetry is implied by the way `promote_rule` is used in the promotion process.

The `promote_rule` function is used as a building block to define a second function called `promote_type`, which, given any number of type objects, returns the common type to which those values, as arguments to `promote` should be promoted. Thus, if one wants to know, in absence of actual values, what type a collection of values of certain types would promote to, one can use `promote_type`:

```
julia> promote_type{Int8, Int64}
Int64
```

Note that we do **not** overload `promote_type` directly: we overload `promote_rule` instead. `promote_type` uses `promote_rule`, and adds the symmetry. Overloading it directly can cause ambiguity errors. We overload `promote_rule` to define how things should be promoted, and we use `promote_type` to query that.

Internally, `promote_type` is used inside of `promote` to determine what type argument values should be converted to for promotion. The curious reader can read the code in `promotion.jl`, which defines the complete promotion mechanism in about 35 lines.

Case Study: Rational Promotions

Finally, we finish off our ongoing case study of Julia's rational number type, which makes relatively sophisticated use of the promotion mechanism with the following promotion rules:

```
promote_rule(::Type{Rational{T}}, ::Type{S}) where {T<:Integer,S<:Integer} =
↳ Rational{promote_type(T,S)}
promote_rule(::Type{Rational{T}}, ::Type{Rational{S}}) where {T<:Integer,S<:Integer} =
↳ Rational{promote_type(T,S)}
promote_rule(::Type{Rational{T}}, ::Type{S}) where {T<:Integer,S<:AbstractFloat} =
↳ promote_type(T,S)
```

The first rule says that promoting a rational number with any other integer type promotes to a rational type whose numerator/denominator type is the result of promotion of its numerator/denominator type with the other integer type. The second rule applies the same logic to two different types of rational numbers, resulting in a rational of the promotion of their respective numerator/denominator types. The third and final rule dictates that promoting a rational with a float results in the same type as promoting the numerator/denominator type with the float.

This small handful of promotion rules, together with the type's constructors and the default convert method for numbers, are sufficient to make rational numbers interoperate completely naturally with all of Julia's other numeric types – integers, floating-point numbers, and complex numbers. By providing appropriate conversion methods and promotion rules in the same manner, any user-defined numeric type can interoperate just as naturally with Julia's predefined numerics.

Chapter 15

Interfaces

A lot of the power and extensibility in Julia comes from a collection of informal interfaces. By extending a few specific methods to work for a custom type, objects of that type not only receive those functionalities, but they are also able to be used in other methods that are written to generically build upon those behaviors.

15.1 Iteration

Required methods		Brief description
<code>iterate(iter)</code>		Returns either a tuple of the first item and initial state or <code>nothing</code> if empty
<code>iterate(iter, state)</code>		Returns either a tuple of the next item and next state or nothing if no items remain
Important optional methods	Default definition	Brief description
<code>Base.IteratorSize{IterType}(iter)</code>	<code>Base.IteratorSize{IterType}()</code>	One of <code>Base.HasLength()</code> , <code>Base.HasShape{N}()</code> , <code>Base.IsInfinite()</code> , or <code>Base.SizeUnknown()</code> as appropriate
<code>Base.IteratorEltype{IterType}(iter)</code>	<code>Base.IteratorEltype{IterType}()</code>	One of <code>Base.EltypeUnknown()</code> or <code>Base.HasEltype()</code> as appropriate
<code>length(iter)</code>	(undefined)	The type of the first entry of the tuple returned by <code>iterate()</code>
<code>size(iter, [dim])</code>	(undefined)	The number of items, if known
<code>Base.isdone(iter, [missing state])</code>	(undefined)	The number of items in each dimension, if known
		Fast-path hint for iterator completion. Should be defined for stateful iterators, or else <code>isempty(iter)</code> may call <code>iterate(iter[, state])</code> and mutate the iterator.

Value returned by <code>IteratorSize{IterType}</code>	Required Methods
<code>Base.HasLength()</code>	<code>length(iter)</code>
<code>Base.HasShape{N}()</code>	<code>length(iter)</code> and <code>size(iter, [dim])</code>
<code>Base.IsInfinite()</code>	(none)
<code>Base.SizeUnknown()</code>	(none)

Value returned by <code>IteratorEltypes{IterType}</code>	Required Methods
<code>Base.HasEltypes{}</code>	<code>eltypes{IterType}</code>
<code>Base.EltypesUnknown{}</code>	<code>(none)</code>

Sequential iteration is implemented by the `iterate` function. Instead of mutating objects as they are iterated over, Julia iterators may keep track of the iteration state externally from the object. The return value from `iterate` is always either a tuple of a value and a state, or `nothing` if no elements remain. The state object will be passed back to the `iterate` function on the next iteration and is generally considered an implementation detail private to the iterable object.

Any object that defines this function is iterable and can be used in the [many functions that rely upon iteration](#). It can also be used directly in a `for` loop since the syntax:

```
for item in iter # or "for item = iter"
    # body
end
```

is translated into:

```
next = iterate(iter)
while next != nothing
    (item, state) = next
    # body
    next = iterate(iter, state)
end
```

A simple example is an iterable sequence of square numbers with a defined length:

```
julia> struct Squares
        count::Int
    end

julia> Base.iterate(S::Squares, state=1) = state > S.count ? nothing : (state*state, state+1)
```

With only `iterate` definition, the `Squares` type is already pretty powerful. We can iterate over all the elements:

```
julia> for item in Squares(7)
        println(item)
    end

1
4
9
16
25
36
49
```

We can use many of the builtin methods that work with iterables, like `in` or `sum`:

```
julia> 25 in Squares(10)
true

julia> sum(Squares(100))
338350
```

There are a few more methods we can extend to give Julia more information about this iterable collection. We know that the elements in a `Squares` sequence will always be `Int`. By extending the `eltype` method, we can give that information to Julia and help it make more specialized code in the more complicated methods. We also know the number of elements in our sequence, so we can extend `length`, too:

```
julia> Base.eltype{::Type{Squares}} = Int # Note that this is defined for the type

julia> Base.length(S::Squares) = S.count
```

Now, when we ask Julia to `collect` all the elements into an array it can preallocate a `Vector{Int}` of the right size instead of naively `push!`ing each element into a `Vector{Any}`:

```
julia> collect(Squares(4))
4-element Vector{Int64}:
 1
 4
 9
16
```

While we can rely upon generic implementations, we can also extend specific methods where we know there is a simpler algorithm. For example, there's a formula to compute the sum of squares, so we can override the generic iterative version with a more performant solution:

```
julia> Base.sum(S::Squares) = (n = S.count; return n*(n+1)*(2n+1)÷6)

julia> sum(Squares(1803))
1955361914
```

This is a very common pattern throughout Julia Base: a small set of required methods define an informal interface that enable many fancier behaviors. In some cases, types will want to additionally specialize those extra behaviors when they know a more efficient algorithm can be used in their specific case.

It is also often useful to allow iteration over a collection in reverse order by iterating over `Iterators.reverse(iterator)`. To actually support reverse-order iteration, however, an iterator type `T` needs to implement `iterate` for `Iterators.Reverse{T}`. (Given `r::Iterators.Reverse{T}`, the underlying iterator of type `T` is `r.itr`.) In our `Squares` example, we would implement `Iterators.Reverse{Squares}` methods:

```
julia> Base.iterate(rS::Iterators.Reverse{Squares}, state=rS.itr.count) = state < 1 ? nothing :
↳ (state*state, state-1)

julia> collect(Iterators.reverse(Squares(4)))
4-element Vector{Int64}:
16
 9
 4
 1
```

15.2 Indexing

Methods to implement	Brief description
<code>getindex(X, i)</code>	<code>X[i]</code> , indexed element access
<code>setindex!(X, v, i)</code>	<code>X[i] = v</code> , indexed assignment
<code>firstindex(X)</code>	The first index, used in <code>X[begin]</code>
<code>lastindex(X)</code>	The last index, used in <code>X[end]</code>

For the Squares iterable above, we can easily compute the *i*th element of the sequence by squaring it. We can expose this as an indexing expression `S[i]`. To opt into this behavior, Squares simply needs to define `getindex`:

```
julia> function Base.getindex(S::Squares, i::Int)
    1 <= i <= S.count || throw(BoundsError(S, i))
    return i*i
end

julia> Squares(100)[23]
529
```

Additionally, to support the syntax `S[begin]` and `S[end]`, we must define `firstindex` and `lastindex` to specify the first and last valid indices, respectively:

```
julia> Base.firstindex(S::Squares) = 1

julia> Base.lastindex(S::Squares) = length(S)

julia> Squares(23)[end]
529
```

For multi-dimensional begin/end indexing as in `a[3, begin, 7]`, for example, you should define `firstindex(a, dim)` and `lastindex(a, dim)` (which default to calling `first` and `last` on `axes(a, dim)`, respectively).

Note, though, that the above only defines `getindex` with one integer index. Indexing with anything other than an `Int` will throw a `MethodError` saying that there was no matching method. In order to support indexing with ranges or vectors of `Ints`, separate methods must be written:

```
julia> Base.getindex(S::Squares, i::Number) = S[convert{Int}(i)]

julia> Base.getindex(S::Squares, I) = [S[i] for i in I]

julia> Squares(10)[[3,4,5]]
3-element Vector{Int64}:
 9
16
25
```

While this is starting to support more of the [indexing operations supported by some of the builtin types](#), there's still quite a number of behaviors missing. This Squares sequence is starting to look more and more like a vector as we've added behaviors to it. Instead of defining all these behaviors ourselves, we can officially define it as a subtype of an [AbstractArray](#).

15.3 Abstract Arrays

If a type is defined as a subtype of `AbstractArray`, it inherits a very large set of rich behaviors including iteration and multidimensional indexing built on top of single-element access. See the [arrays manual page](#) and the [Julia Base section](#) for more supported methods.

A key part in defining an `AbstractArray` subtype is `IndexStyle`. Since indexing is such an important part of an array and often occurs in hot loops, it's important to make both indexing and indexed assignment as efficient as possible. Array data structures are typically defined in one of two ways: either it most efficiently accesses its elements using just one index (linear indexing) or it intrinsically accesses the elements with indices specified for every dimension. These two modalities are identified by Julia as `IndexLinear()` and `IndexCartesian()`. Converting a linear index to multiple indexing subscripts is typically very expensive, so this provides a traits-based mechanism to enable efficient generic code for all array types.

This distinction determines which scalar indexing methods the type must define. `IndexLinear()` arrays are simple: just define `getindex(A::ArrayType, i::Int)`. When the array is subsequently indexed with a multidimensional set of indices, the fallback `getindex(A::AbstractArray, I...)` efficiently converts the indices into one linear index and then calls the above method. `IndexCartesian()` arrays, on the other hand, require methods to be defined for each supported dimensionality with `ndims(A)` `Int` indices. For example, `SparseMatrixCSC` from the `SparseArrays` standard library module, only supports two dimensions, so it just defines `getindex(A::SparseMatrixCSC, i::Int, j::Int)`. The same holds for `setindex!`.

Returning to the sequence of squares from above, we could instead define it as a subtype of an `AbstractArray{Int, 1}`:

```
julia> struct SquaresVector <: AbstractArray{Int, 1}
        count::Int
    end

julia> Base.size(S::SquaresVector) = (S.count,)

julia> Base.IndexStyle{<:Type{<:SquaresVector}} = IndexLinear()

julia> Base.getindex(S::SquaresVector, i::Int) = i*i
```

Note that it's very important to specify the two parameters of the `AbstractArray`; the first defines the `eltype`, and the second defines the `ndims`. That supertype and those three methods are all it takes for `SquaresVector` to be an iterable, indexable, and completely functional array:

```
julia> s = SquaresVector(4)
4-element SquaresVector:
 1
 4
 9
16

julia> s[s .> 8]
2-element Vector{Int64}:
 9
16

julia> s + s
```

```
4-element Vector{Int64}:
 2
 8
18
32

julia> sin.(s)
4-element Vector{Float64}:
 0.8414709848078965
-0.7568024953079282
 0.4121184852417566
-0.2879033166650653
```

As a more complicated example, let's define our own toy N-dimensional sparse-like array type built on top of `Dict`:

```
julia> struct SparseArray{T,N} <: AbstractArray{T,N}
    data::Dict{NTuple{N,Int}, T}
    dims::NTuple{N,Int}
end

julia> SparseArray{::Type{T}, dims::Int...} where {T} = SparseArray{T, dims};

julia> SparseArray{::Type{T}, dims::NTuple{N,Int}} where {T,N} =
↳ SparseArray{T,N}(Dict{NTuple{N,Int}, T}(), dims);

julia> Base.size(A::SparseArray) = A.dims

julia> Base.similar(A::SparseArray, ::Type{T}, dims::Dims) where {T} = SparseArray{T, dims}

julia> Base.getindex(A::SparseArray{T,N}, I::Vararg{Int,N}) where {T,N} = get(A.data, I, zero(T))

julia> Base.setindex!(A::SparseArray{T,N}, v, I::Vararg{Int,N}) where {T,N} = (A.data[I] = v)
```

Notice that this is an `IndexCartesian` array, so we must manually define `getindex` and `setindex!` at the dimensionality of the array. Unlike the `SquaresVector`, we are able to define `setindex!`, and so we can mutate the array:

```
julia> A = SparseArray{Float64, 3, 3}
3×3 SparseArray{Float64, 2}:
 0.0  0.0  0.0
 0.0  0.0  0.0
 0.0  0.0  0.0

julia> fill!(A, 2)
3×3 SparseArray{Float64, 2}:
 2.0  2.0  2.0
 2.0  2.0  2.0
 2.0  2.0  2.0

julia> A[:] = 1:length(A); A
```

```
3×3 SparseArray{Float64, 2}:
 1.0  4.0  7.0
 2.0  5.0  8.0
 3.0  6.0  9.0
```

The result of indexing an `AbstractArray` can itself be an array (for instance when indexing by an `AbstractRange`). The `AbstractArray` fallback methods use `similar` to allocate an `Array` of the appropriate size and element type, which is filled in using the basic indexing method described above. However, when implementing an array wrapper you often want the result to be wrapped as well:

```
julia> A[1:2,:]
2×3 SparseArray{Float64, 2}:
 1.0  4.0  7.0
 2.0  5.0  8.0
```

In this example it is accomplished by defining `Base.similar(A::SparseArray, ::Type{T}, dims::Dims)` where `T` to create the appropriate wrapped array. (Note that while `similar` supports 1- and 2-argument forms, in most case you only need to specialize the 3-argument form.) For this to work it's important that `SparseArray` is mutable (supports `setindex!`). Defining `similar`, `getindex` and `setindex!` for `SparseArray` also makes it possible to `copy` the array:

```
julia> copy(A)
3×3 SparseArray{Float64, 2}:
 1.0  4.0  7.0
 2.0  5.0  8.0
 3.0  6.0  9.0
```

In addition to all the iterable and indexable methods from above, these types can also interact with each other and use most of the methods defined in Julia Base for `AbstractArrays`:

```
julia> A[SquaresVector(3)]
3-element SparseArray{Float64, 1}:
 1.0
 4.0
 9.0

julia> sum(A)
45.0
```

If you are defining an array type that allows non-traditional indexing (indices that start at something other than 1), you should specialize `axes`. You should also specialize `similar` so that the `dims` argument (ordinarily a `Dims` size-tuple) can accept `AbstractUnitRange` objects, perhaps range-types of your own design. For more information, see [Arrays with custom indices](#).

15.4 Strided Arrays

A strided array is a subtype of `AbstractArray` whose entries are stored in memory with fixed strides. Provided the element type of the array is compatible with BLAS, a strided array can utilize BLAS and LAPACK

routines for more efficient linear algebra routines. A typical example of a user-defined strided array is one that wraps a standard Array with additional structure.

Warning: do not implement these methods if the underlying storage is not actually strided, as it may lead to incorrect results or segmentation faults.

Here are some examples to demonstrate which type of arrays are strided and which are not:

```
1:5 # not strided (there is no storage associated with this array.)
Vector(1:5) # is strided with strides (1,)
A = [1 5; 2 6; 3 7; 4 8] # is strided with strides (1,4)
V = view(A, 1:2, :) # is strided with strides (1,4)
V = view(A, 1:2:3, 1:2) # is strided with strides (2,4)
V = view(A, [1,2,4], :) # is not strided, as the spacing between rows is not fixed.
```

15.5 Customizing broadcasting

[Broadcasting](#) is triggered by an explicit call to `broadcast` or `broadcast!`, or implicitly by "dot" operations like `A .+ b` or `f.(x, y)`. Any object that has [axes](#) and supports indexing can participate as an argument in broadcasting, and by default the result is stored in an Array. This basic framework is extensible in three major ways:

- Ensuring that all arguments support broadcast
- Selecting an appropriate output array for the given set of arguments
- Selecting an efficient implementation for the given set of arguments

Not all types support axes and indexing, but many are convenient to allow in broadcast. The [Base.broadcastable](#) function is called on each argument to broadcast, allowing it to return something different that supports axes and indexing. By default, this is the identity function for all AbstractArrays and Numbers — they already support axes and indexing.

If a type is intended to act like a "0-dimensional scalar" (a single object) rather than as a container for broadcasting, then the following method should be defined:

```
Base.broadcastable(o::MyType) = Ref(o)
```

that returns the argument wrapped in a 0-dimensional [Ref](#) container. For example, such a wrapper method is defined for types themselves, functions, special singletons like [missing](#) and [nothing](#), and dates.

Custom array-like types can specialize `Base.broadcastable` to define their shape, but they should follow the convention that `collect(Base.broadcastable(x)) == collect(x)`. A notable exception is `AbstractString`; strings are special-cased to behave as scalars for the purposes of broadcast even though they are iterable collections of their characters (see [Strings](#) for more).

The next two steps (selecting the output array and implementation) are dependent upon determining a single answer for a given set of arguments. Broadcast must take all the varied types of its arguments and collapse them down to just one output array and one implementation. Broadcast calls this single answer a "style". Every broadcastable object each has its own preferred style, and a promotion-like system is used to combine these styles into a single answer — the "destination style".

Broadcast Styles

`Base.BroadcastStyle` is the abstract type from which all broadcast styles are derived. When used as a function it has two possible forms, unary (single-argument) and binary. The unary variant states that you intend to implement specific broadcasting behavior and/or output type, and do not wish to rely on the default fallback `Broadcast.DefaultArrayStyle`.

To override these defaults, you can define a custom `BroadcastStyle` for your object:

```
struct MyStyle <: Broadcast.BroadcastStyle end
Base.BroadcastStyle{::Type{<:MyType}} = MyStyle()
```

In some cases it might be convenient not to have to define `MyStyle`, in which case you can leverage one of the general broadcast wrappers:

- `Base.BroadcastStyle{::Type{<:MyType}} = Broadcast.Style{MyType}()` can be used for arbitrary types.
- `Base.BroadcastStyle{::Type{<:MyType}} = Broadcast.ArrayStyle{MyType}()` is preferred if `MyType` is an `AbstractArray`.
- For `AbstractArrays` that only support a certain dimensionality, create a subtype of `Broadcast.AbstractArrayStyle{N}` (see below).

When your broadcast operation involves several arguments, individual argument styles get combined to determine a single `DestStyle` that controls the type of the output container. For more details, see [below](#).

Selecting an appropriate output array

The broadcast style is computed for every broadcasting operation to allow for dispatch and specialization. The actual allocation of the result array is handled by `similar`, using the `Broadcasted` object as its first argument.

```
Base.similar(bc::Broadcasted{DestStyle}, ::Type{ElType})
```

The fallback definition is

```
similar(bc::Broadcasted{DefaultArrayStyle{N}}, ::Type{ElType}) where {N,ElType} =
    similar(Array{ElType}, axes(bc))
```

However, if needed you can specialize on any or all of these arguments. The final argument `bc` is a lazy representation of a (potentially fused) broadcast operation, a `Broadcasted` object. For these purposes, the most important fields of the wrapper are `f` and `args`, describing the function and argument list, respectively. Note that the argument list can — and often does — include other nested `Broadcasted` wrappers.

For a complete example, let's say you have created a type, `ArrayAndChar`, that stores an array and a single character:

```

struct ArrayAndChar{T,N} <: AbstractArray{T,N}
    data::Array{T,N}
    char::Char
end
Base.size(A::ArrayAndChar) = size(A.data)
Base.getindex(A::ArrayAndChar{T,N}, inds::Vararg{Int,N}) where {T,N} = A.data[inds...]
Base.setindex!(A::ArrayAndChar{T,N}, val, inds::Vararg{Int,N}) where {T,N} = A.data[inds...] =
↳ val
Base.showarg(io::IO, A::ArrayAndChar, toplevel) = print(io, typeof(A), " with char '", A.char,
↳ "'")

```

You might want broadcasting to preserve the char "metadata". First we define

```
Base.BroadcastStyle(::Type{<:ArrayAndChar}) = Broadcast.ArrayStyle{ArrayAndChar}()
```

This means we must also define a corresponding similar method:

```

function Base.similar(bc::Broadcast.Broadcasted{Broadcast.ArrayStyle{ArrayAndChar}},
↳ ::Type{ElType}) where ElType
    # Scan the inputs for the ArrayAndChar:
    A = find_aac(bc)
    # Use the char field of A to create the output
    ArrayAndChar(similar(Array{ElType}, axes(bc)), A.char)
end

"A = find_aac(As)` returns the first ArrayAndChar among the arguments."
find_aac(bc::Base.Broadcast.Broadcasted) = find_aac(bc.args)
find_aac(args::Tuple) = find_aac(find_aac(args[1]), Base.tail(args))
find_aac(x) = x
find_aac(::Tuple{}) = nothing
find_aac(a::ArrayAndChar, rest) = a
find_aac(::Any, rest) = find_aac(rest)

```

From these definitions, one obtains the following behavior:

```

julia> a = ArrayAndChar([1 2; 3 4], 'x')
2×2 ArrayAndChar{Int64, 2} with char 'x':
 1  2
 3  4

julia> a .+ 1
2×2 ArrayAndChar{Int64, 2} with char 'x':
 2  3
 4  5

julia> a .+ [5,10]
2×2 ArrayAndChar{Int64, 2} with char 'x':
 6  7
13 14

```

Extending broadcast with custom implementations

In general, a broadcast operation is represented by a lazy `Broadcasted` container that holds onto the function to be applied alongside its arguments. Those arguments may themselves be more nested `Broadcasted` containers, forming a large expression tree to be evaluated. A nested tree of `Broadcasted` containers is directly constructed by the implicit dot syntax; `5 .+ 2.*x` is transiently represented by `Broadcasted(+, 5, Broadcasted(*, 2, x))`, for example. This is invisible to users as it is immediately realized through a call to `copyto!` (`::AbstractArray`, `::Broadcasted`) method. The built-in fallback `broadcast` and `broadcast!` methods similarly construct a transient `Broadcasted` representation of the operation so they can follow the same codepath. This allows custom array implementations to provide their own `copyto!` specialization to customize and optimize broadcasting. This is again determined by the computed broadcast style. This is such an important part of the operation that it is stored as the first type parameter of the `Broadcasted` type, allowing for dispatch and specialization.

For some types, the machinery to "fuse" operations across nested levels of broadcasting is not available or could be done more efficiently incrementally. In such cases, you may need or want to evaluate `x .*(x .+ 1)` as if it had been written `broadcast(*, x, broadcast(+, x, 1))`, where the inner operation is evaluated before tackling the outer operation. This sort of eager operation is directly supported by a bit of indirection; instead of directly constructing `Broadcasted` objects, Julia lowers the fused expression `x .*(x .+ 1)` to `Broadcast.broadcasted(*, x, Broadcast.broadcasted(+, x, 1))`. Now, by default, `broadcasted` just calls the `Broadcasted` constructor to create the lazy representation of the fused expression tree, but you can choose to override it for a particular combination of function and arguments.

As an example, the builtin `AbstractRange` objects use this machinery to optimize pieces of broadcasted expressions that can be eagerly evaluated purely in terms of the start, step, and length (or stop) instead of computing every single element. Just like all the other machinery, `broadcasted` also computes and exposes the combined broadcast style of its arguments, so instead of specializing on `broadcasted(f, args...)`, you can specialize on `broadcasted(::DestStyle, f, args...)` for any combination of style, function, and arguments.

For example, the following definition supports the negation of ranges:

```
| broadcasted(::DefaultArrayStyle{1}, ::typeof(-), r::OrdinalRange) = range(-first(r),  
| ↪ step=-step(r), length=length(r))
```

Extending in-place broadcasting

In-place broadcasting can be supported by defining the appropriate `copyto!(dest, bc::Broadcasted)` method. Because you might want to specialize either on `dest` or the specific subtype of `bc`, to avoid ambiguities between packages we recommend the following convention.

If you wish to specialize on a particular style `DestStyle`, define a method for

```
| copyto!(dest, bc::Broadcasted{DestStyle})
```

Optionally, with this form you can also specialize on the type of `dest`.

If instead you want to specialize on the destination type `DestType` without specializing on `DestStyle`, then you should define a method with the following signature:

```
| copyto!(dest::DestType, bc::Broadcasted{Nothing})
```

This leverages a fallback implementation of `copyto!` that converts the wrapper into a `Broadcasted{Nothing}`. Consequently, specializing on `DestType` has lower precedence than methods that specialize on `DestStyle`.

Similarly, you can completely override out-of-place broadcasting with a `copy(::Broadcasted)` method.

Working with Broadcasted objects

In order to implement such a `copy` or `copyto!`, method, of course, you must work with the `Broadcasted` wrapper to compute each element. There are two main ways of doing so:

- `Broadcast.flatten` recomputes the potentially nested operation into a single function and flat list of arguments. You are responsible for implementing the broadcasting shape rules yourself, but this may be helpful in limited situations.
- Iterating over the `CartesianIndices` of the `axes(::Broadcasted)` and using indexing with the resulting `CartesianIndex` object to compute the result.

Writing binary broadcasting rules

The precedence rules are defined by binary `BroadcastStyle` calls:

```
| Base.BroadcastStyle(::Style1, ::Style2) = Style12()
```

where `Style12` is the `BroadcastStyle` you want to choose for outputs involving arguments of `Style1` and `Style2`. For example,

```
| Base.BroadcastStyle(::Broadcast.Style{Tuple}, ::Broadcast.AbstractArrayStyle{0}) =  
| ↪ Broadcast.Style{Tuple}()
```

indicates that `Tuple` "wins" over zero-dimensional arrays (the output container will be a tuple). It is worth noting that you do not need to (and should not) define both argument orders of this call; defining one is sufficient no matter what order the user supplies the arguments in.

For `AbstractArray` types, defining a `BroadcastStyle` supersedes the fallback choice, `Broadcast.DefaultArrayStyle`. `DefaultArrayStyle` and the abstract supertype, `AbstractArrayStyle`, store the dimensionality as a type parameter to support specialized array types that have fixed dimensionality requirements.

`DefaultArrayStyle` "loses" to any other `AbstractArrayStyle` that has been defined because of the following methods:

```
| BroadcastStyle(a::AbstractArrayStyle{Any}, ::DefaultArrayStyle) = a  
| BroadcastStyle(a::AbstractArrayStyle{N}, ::DefaultArrayStyle{N}) where N = a  
| BroadcastStyle(a::AbstractArrayStyle{M}, ::DefaultArrayStyle{N}) where {M,N} =  
|     typeof(a)(Val(max(M, N)))
```

You do not need to write binary `BroadcastStyle` rules unless you want to establish precedence for two or more non-`DefaultArrayStyle` types.

If your array type does have fixed dimensionality requirements, then you should subtype `AbstractArrayStyle`. For example, the sparse array code has the following definitions:

```

struct SparseVecStyle <: Broadcast.AbstractArrayStyle{1} end
struct SparseMatStyle <: Broadcast.AbstractArrayStyle{2} end
Base.BroadcastStyle{::Type{<:SparseVector}} = SparseVecStyle()
Base.BroadcastStyle{::Type{<:SparseMatrixCSC}} = SparseMatStyle()

```

Whenever you subtype `AbstractArrayStyle`, you also need to define rules for combining dimensionalities, by creating a constructor for your style that takes a `Val(N)` argument. For example:

```

SparseVecStyle{::Val{0}} = SparseVecStyle()
SparseVecStyle{::Val{1}} = SparseVecStyle()
SparseVecStyle{::Val{2}} = SparseMatStyle()
SparseVecStyle{::Val{N}} where N = Broadcast.DefaultArrayStyle{N}()

```

These rules indicate that the combination of a `SparseVecStyle` with 0- or 1-dimensional arrays yields another `SparseVecStyle`, that its combination with a 2-dimensional array yields a `SparseMatStyle`, and anything of higher dimensionality falls back to the dense arbitrary-dimensional framework. These rules allow broadcasting to keep the sparse representation for operations that result in one or two dimensional outputs, but produce an `Array` for any other dimensionality.

15.6 Instance Properties

Sometimes, it is desirable to change how the end-user interacts with the fields of an object. Instead of granting direct access to type fields, an extra layer of abstraction between the user and the code can be provided by overloading `object.field`. Properties are what the user sees of the object, fields what the object actually is.

By default, properties and fields are the same. However, this behavior can be changed. For example, take this representation of a point in a plane in [polar coordinates](#):

```

julia> mutable struct Point
    r::Float64
    φ::Float64
end

julia> p = Point(7.0, pi/4)
Point{Float64}(7.0, 0.7853981633974483)

```

As described in the table above dot access `p.r` is the same as `getproperty(p, :r)` which is by default the same as `getfield(p, :r)`:

```

julia> propertynames(p)
(:r, :φ)

julia> getproperty(p, :r), getproperty(p, :φ)
(7.0, 0.7853981633974483)

julia> p.r, p.φ
(7.0, 0.7853981633974483)

julia> getfield(p, :r), getproperty(p, :φ)
(7.0, 0.7853981633974483)

```

However, we may want users to be unaware that `Point` stores the coordinates as `r` and `φ` (fields), and instead interact with `x` and `y` (properties). The methods in the first column can be defined to add new functionality:

```
julia> Base.propertynames(::Point, private::Bool=false) = private ? (:x, :y, :r, :φ) : (:x, :y)

julia> function Base.getproperty(p::Point, s::Symbol)
    if s === :x
        return getfield(p, :r) * cos(getfield(p, :φ))
    elseif s === :y
        return getfield(p, :r) * sin(getfield(p, :φ))
    else
        # This allows accessing fields with p.r and p.φ
        return getfield(p, s)
    end
end

julia> function Base.setproperty!(p::Point, s::Symbol, f)
    if s === :x
        y = p.y
        setfield!(p, :r, sqrt(f^2 + y^2))
        setfield!(p, :φ, atan(y, f))
        return f
    elseif s === :y
        x = p.x
        setfield!(p, :r, sqrt(x^2 + f^2))
        setfield!(p, :φ, atan(f, x))
        return f
    else
        # This allow modifying fields with p.r and p.φ
        return setfield!(p, s, f)
    end
end
```

It is important that `getfield` and `setfield` are used inside `getproperty` and `setproperty!` instead of the dot syntax, since the dot syntax would make the functions recursive which can lead to type inference issues. We can now try out the new functionality:

```
julia> propertynames(p)
(:x, :y)

julia> p.x
4.949747468305833

julia> p.y = 4.0
4.0

julia> p.r
6.363961030678928
```

Finally, it is worth noting that adding instance properties like this is quite rarely done in Julia and should in general only be done if there is a good reason for doing so.

Methods to implement		Brief description
<code>size(A)</code>		Returns a tuple containing the dimensions of A
<code>getindex(A, i::Int)</code>		(if <code>IndexLinear</code>) Linear scalar indexing
<code>getindex(A, I::Vararg{Int, N})</code>		(if <code>IndexCartesian</code> , where $N = \text{ndims}(A)$) N-dimensional scalar indexing
Optional methods	Default definition	Brief description
<code>IndexStyle{::Type{A}}</code>	<code>IndexCartesian{}</code>	Returns either <code>IndexLinear{}</code> or <code>IndexCartesian{}</code> . See the description below.
<code>setindex!(A, v, i::Int)</code>		(if <code>IndexLinear</code>) Scalar indexed assignment
<code>setindex!(A, v, I::Vararg{Int, N})</code>		(if <code>IndexCartesian</code> , where $N = \text{ndims}(A)$) N-dimensional scalar indexed assignment
<code>getindex(A, I...)</code>	defined in terms of scalar <code>getindex</code>	Multidimensional and nonscalar indexing
<code>setindex!(A, X, I...)</code>	defined in terms of scalar <code>setindex!</code>	Multidimensional and nonscalar indexed assignment
<code>iterate</code>	defined in terms of scalar <code>getindex</code>	Iteration
<code>length(A)</code>	<code>prod(size(A))</code>	Number of elements
<code>similar(A)</code>	<code>similar(A, eltype(A), size(A))</code>	Return a mutable array with the same shape and element type
<code>similar(A, ::Type{S})</code>	<code>similar(A, S, size(A))</code>	Return a mutable array with the same shape and the specified element type
<code>similar(A, dims::Dims)</code>	<code>similar(A, eltype(A), dims)</code>	Return a mutable array with the same element type and size dims
<code>similar(A, ::Type{S}, dims::Dims)</code>	<code>Array{S}(undef, dims)</code>	Return a mutable array with the specified element type and size
Non-traditional indices	Default definition	Brief description
<code>axes(A)</code>	<code>map(OneTo, size(A))</code>	Return a tuple of <code>AbstractUnitRange{<:Integer}</code> of valid indices. The axes should be their own axes, that is <code>axes.(axes(A), 1) == axes(A)</code> should be satisfied.
<code>similar(A, ::Type{S}, inds)</code>	<code>similar(A, S, Base.to_shape(inds))</code>	Return a mutable array with the specified indices <code>inds</code> (see below)
<code>similar(T::Union{Type{S}, Tuple{S, ...}}, inds)</code>	<code>similar(T, S, Base.to_shape(inds))</code>	Return an array similar to T with the specified indices <code>inds</code> (see below)

Methods to implement		Brief description
<code>strides(A)</code>		Return the distance in memory (in number of elements) between adjacent elements in each dimension as a tuple. If A is an <code>AbstractArray{T,0}</code> , this should return an empty tuple.
<code>Base.unsafe_convert{::Type{Ptr{T}}}(A)</code>		Return the native address of an array.
<code>Base.elsize{::Type{<:A}}(A)</code>		Return the stride between consecutive elements in the array.
Optional methods	Default definition	Brief description
<code>stride(A, i::Int)</code>	<code>strides(A)[i]</code>	Return the distance in memory (in number of elements) between adjacent elements in dimension k.

Methods to implement	Brief description
<code>Base.BroadcastStyle{::Type{SrcType}} = SrcStyle()</code>	Broadcasting behavior of SrcType
<code>Base.similar(bc::Broadcasted{DestStyle}, ::Type{ElType})</code>	Allocation of output container
Optional methods	
<code>Base.BroadcastStyle{::Style1, ::Style2} = Style12()</code>	Precedence rules for mixing styles
<code>Base.axes(x)</code>	Declaration of the indices of x, as per <code>axes(x)</code> .
<code>Base.broadcastable(x)</code>	Convert x to an object that has axes and supports indexing
Bypassing default machinery	
<code>Base.copy(bc::Broadcasted{DestStyle})</code>	Custom implementation of broadcast
<code>Base.copyto!(dest, bc::Broadcasted{DestStyle})</code>	Custom implementation of broadcast!, specializing on DestStyle
<code>Base.copyto!(dest::DestType, bc::Broadcasted{Nothing})</code>	Custom implementation of broadcast!, specializing on DestType
<code>Base.Broadcast.broadcasted(f, args...)</code>	Override the default lazy behavior within a fused expression
<code>Base.Broadcast.instantiate(bc::Broadcasted{DestStyle})</code>	Override the computation of the lazy broadcast's axes

Methods to implement	Default definition	Brief description
<code>propertynames(x::ObjType, private::Bool=false)</code>	<code>fieldnames(typeof(x))</code>	Return a tuple of the properties (x.property) of an object x. If private=true, also return property names intended to be kept as private
<code>getproperty(x::ObjType, s::Symbol)</code>	<code>getfield(x, s)</code>	Return property s of x. x.s calls <code>getproperty(x, :s)</code> .
<code>setproperty!(x::ObjType, s::Symbol, v)</code>	<code>setfield!(x, s, v)</code>	Set property s of x to v. x.s = v calls <code>setproperty!(x, :s, v)</code> . Should return v.

Chapter 16

Modules

Modules in Julia help organize code into coherent units. They are delimited syntactically inside `module` `ModuleName` `... end`, and have the following features:

1. Modules are separate namespaces, each introducing a new global scope. This is useful, because it allows the same name to be used for different functions or global variables without conflict, as long as they are in separate modules.
2. Modules have facilities for detailed namespace management: each defines a set of names it exports, and can import names from other modules with `using` and `import` (we explain these below).
3. Modules can be precompiled for faster loading, and may contain code for runtime initialization.

Typically, in larger Julia packages you will see module code organized into files, eg

```
module SomeModule

# export, using, import statements are usually here; we discuss these below

include("file1.jl")
include("file2.jl")

end
```

Files and file names are mostly unrelated to modules; modules are associated only with module expressions. One can have multiple files per module, and multiple modules per file. `include` behaves as if the contents of the source file were evaluated in the global scope of the including module. In this chapter, we use short and simplified examples, so we won't use `include`.

The recommended style is not to indent the body of the module, since that would typically lead to whole files being indented. Also, it is common to use `UpperCamelCase` for module names (just like types), and use the plural form if applicable, especially if the module contains a similarly named identifier, to avoid name clashes. For example,

```
module FastThings
```

```

struct FastThing
    ...
end
end

```

16.1 Namespace management

Namespace management refers to the facilities the language offers for making names in a module available in other modules. We discuss the related concepts and functionality below in detail.

Qualified names

Names for functions, variables and types in the global scope like `sin`, `ARGS`, and `UnitRange` always belong to a module, called the parent module, which can be found interactively with `parentmodule`, for example

```

julia> parentmodule(UnitRange)
Base

```

One can also refer to these names outside their parent module by prefixing them with their module, eg `Base.UnitRange`. This is called a qualified name. The parent module may be accessible using a chain of submodules like `Base.Math.sin`, where `Base.Math` is called the module path. Due to syntactic ambiguities, qualifying a name that contains only symbols, such as an operator, requires inserting a colon, e.g. `Base.:+`. A small number of operators additionally require parentheses, e.g. `Base.:(==)`.

If a name is qualified, then it is always accessible, and in case of a function, it can also have methods added to it by using the qualified name as the function name.

Within a module, a variable name can be “reserved” without assigning to it by declaring it as `global x`. This prevents name conflicts for globals initialized after load time. The syntax `M.x = y` does not work to assign a global in another module; global assignment is always module-local.

Export lists

Names (referring to functions, types, global variables, and constants) can be added to the export list of a module with `export`: these are the symbols that are imported when using the module. Typically, they are at or near the top of the module definition so that readers of the source code can find them easily, as in

```

julia> module NiceStuff
    export nice, DOG
    struct Dog end          # singleton type, not exported
    const DOG = Dog()       # named instance, exported
    nice(x) = "nice $x"     # function, exported
end;

```

but this is just a style suggestion — a module can have multiple export statements in arbitrary locations.

It is common to export names which form part of the API (application programming interface). In the above code, the export list suggests that users should use `nice` and `DOG`. However, since qualified names always make identifiers accessible, this is just an option for organizing APIs: unlike other languages, Julia has no facilities for truly hiding module internals.

Also, some modules don't export names at all. This is usually done if they use common words, such as `derivative`, in their API, which could easily clash with the export lists of other modules. We will see how to manage name clashes below.

Standalone using and import

Possibly the most common way of loading a module is using `ModuleName`. This [loads](#) the code associated with `ModuleName`, and brings

1. the module name
2. and the elements of the export list into the surrounding global namespace.

Technically, the statement `using ModuleName` means that a module called `ModuleName` will be available for resolving names as needed. When a global variable is encountered that has no definition in the current module, the system will search for it among variables exported by `ModuleName` and use it if it is found there. This means that all uses of that global within the current module will resolve to the definition of that variable in `ModuleName`.

To load a module from a package, the statement `using ModuleName` can be used. To load a module from a locally defined module, a dot needs to be added before the module name like `using .ModuleName`.

To continue with our example,

```
| julia> using .NiceStuff
```

would load the above code, making `NiceStuff` (the module name), `D0G` and `nice` available. `Dog` is not on the export list, but it can be accessed if the name is qualified with the module path (which here is just the module name) as `NiceStuff.Dog`.

Importantly, **using `ModuleName` is the only form for which export lists matter at all.**

In contrast,

```
| julia> import .NiceStuff
```

brings only the module name into scope. Users would need to use `NiceStuff.D0G`, `NiceStuff.Dog`, and `NiceStuff.nice` to access its contents. Usually, `import ModuleName` is used in contexts when the user wants to keep the namespace clean. As we will see in the next section `import .NiceStuff` is equivalent to `using .NiceStuff: NiceStuff`.

You can combine multiple `using` and `import` statements of the same kind in a comma-separated expression, e.g.

```
| julia> using LinearAlgebra, Statistics
```

using and import with specific identifiers, and adding methods

When using `ModuleName:` or `import ModuleName:` is followed by a comma-separated list of names, the module is loaded, but only those specific names are brought into the namespace by the statement. For example,

```
julia> using .NiceStuff: nice, DOG
```

will import the names `nice` and `DOG`.

Importantly, the module name `NiceStuff` will not be in the namespace. If you want to make it accessible, you have to list it explicitly, as

```
julia> using .NiceStuff: nice, DOG, NiceStuff
```

Julia has two forms for seemingly the same thing because only `import ModuleName: f` allows adding methods to `f` without a module path. That is to say, the following example will give an error:

```
julia> using .NiceStuff: nice

julia> struct Cat end

julia> nice(::Cat) = "nice "
ERROR: invalid method definition in Main: function NiceStuff.nice must be explicitly imported to
↳ be extended
Stacktrace:
 [1] top-level scope
      @ none:0
 [2] top-level scope
      @ none:1
```

This error prevents accidentally adding methods to functions in other modules that you only intended to use.

There are two ways to deal with this. You can always qualify function names with a module path:

```
julia> using .NiceStuff

julia> struct Cat end

julia> NiceStuff.nice(::Cat) = "nice "
```

Alternatively, you can import the specific function name:

```
julia> import .NiceStuff: nice

julia> struct Cat end

julia> nice(::Cat) = "nice "
nice (generic function with 2 methods)
```

Which one you choose is a matter of style. The first form makes it clear that you are adding a method to a function in another module (remember, that the imports and the method definition may be in separate files), while the second one is shorter, which is especially convenient if you are defining multiple methods.

Once a variable is made visible via `using` or `import`, a module may not create its own variable with the same name. Imported variables are read-only; assigning to a global variable always affects a variable owned by the current module, or else raises an error.

Renaming with `as`

An identifier brought into scope by `import` or `using` can be renamed with the keyword `as`. This is useful for working around name conflicts as well as for shortening names. For example, `Base` exports the function name `read`, but the `CSV.jl` package also provides `CSV.read`. If we are going to invoke CSV reading many times, it would be convenient to drop the `CSV.` qualifier. But then it is ambiguous whether we are referring to `Base.read` or `CSV.read`:

```
julia> read;

julia> import CSV: read
WARNING: ignoring conflicting import of CSV.read into Main
```

Renaming provides a solution:

```
julia> import CSV: read as rd
```

Imported packages themselves can also be renamed:

```
import BenchmarkTools as BT
```

`as` works with `using` only when a single identifier is brought into scope. For example `using CSV: read as rd` works, but `using CSV as C` does not, since it operates on all of the exported names in `CSV`.

Mixing multiple `using` and `import` statements

When multiple `using` or `import` statements of any of the forms above are used, their effect is combined in the order they appear. For example,

```
julia> using .NiceStuff           # exported names and the module name
julia> import .NiceStuff: nice   # allows adding methods to unqualified functions
```

would bring all the exported names of `NiceStuff` and the module name itself into scope, and also allow adding methods to `nice` without prefixing it with a module name.

Handling name conflicts

Consider the situation where two (or more) packages export the same name, as in

```
julia> module A
    export f
    f() = 1
end
A
julia> module B
    export f
    f() = 2
end
B
```

The statement using `.A`, `.B` works, but when you try to call `f`, you get a warning

```
julia> using .A, .B

julia> f
WARNING: both B and A export "f"; uses of it in module Main must be qualified
ERROR: UndefVarError: `f` not defined
```

Here, Julia cannot decide which `f` you are referring to, so you have to make a choice. The following solutions are commonly used:

1. Simply proceed with qualified names like `A.f` and `B.f`. This makes the context clear to the reader of your code, especially if `f` just happens to coincide but has different meaning in various packages. For example, `degree` has various uses in mathematics, the natural sciences, and in everyday life, and these meanings should be kept separate.
2. Use the `as` keyword above to rename one or both identifiers, eg

```
julia> using .A: f as f
julia> using .B: f as g
```

would make `B.f` available as `g`. Here, we are assuming that you did not use `using A` before, which would have brought `f` into the namespace.

3. When the names in question do share a meaning, it is common for one module to import it from another, or have a lightweight “base” package with the sole function of defining an interface like this, which can be used by other packages. It is conventional to have such package names end in `...Base` (which has nothing to do with Julia’s `Base` module).

Default top-level definitions and bare modules

Modules automatically contain `using Core`, `using Base`, and definitions of the `eval` and `include` functions, which evaluate expressions/files within the global scope of that module.

If these default definitions are not wanted, modules can be defined using the keyword `baremodule` instead (note: `Core` is still imported). In terms of `baremodule`, a standard module looks like this:

```

baremodule Mod

using Base

eval(x) = Core.eval(Mod, x)
include(p) = Base.include(Mod, p)

...

end

```

If even `Core` is not wanted, a module that imports nothing and defines no names at all can be defined with `Module(:YourNameHere, false, false)` and code can be evaluated into it with `@eval` or `Core.eval`:

```

julia> arithmetic = Module(:arithmetic, false, false)
Main.arithmetic

julia> @eval arithmetic add(x, y) = $(+)(x, y)
add (generic function with 1 method)

julia> arithmetic.add(12, 13)
25

```

Standard modules

There are three important standard modules:

- `Core` contains all functionality "built into" the language.
- `Base` contains basic functionality that is useful in almost all cases.
- `Main` is the top-level module and the current module, when Julia is started.

Standard library modules

By default Julia ships with some standard library modules. These behave like regular Julia packages except that you don't need to install them explicitly. For example, if you wanted to perform some unit testing, you could load the Test standard library as follows:

```

using Test

```

16.2 Submodules and relative paths

Modules can contain submodules, nesting the same syntax `module ... end`. They can be used to introduce separate namespaces, which can be helpful for organizing complex codebases. Note that each module introduces its own `scope`, so submodules do not automatically "inherit" names from their parent.

It is recommended that submodules refer to other modules within the enclosing parent module (including the latter) using relative module qualifiers in `using` and `import` statements. A relative module qualifier starts with a period (`.`), which corresponds to the current module, and each successive `.` leads to the parent of the current module. This should be followed by modules if necessary, and eventually the actual name to access, all separated by `.s`.

Consider the following example, where the submodule SubA defines a function, which is then extended in its “sibling” module:

```
julia> module ParentModule
    module SubA
        export add_D # exported interface
        const D = 3
        add_D(x) = x + D
    end
    using .SubA # brings `add_D` into the namespace
    export add_D # export it from ParentModule too
    module SubB
        import ..SubA: add_D # relative path for a “sibling” module
        struct Infinity end
        add_D(x::Infinity) = x
    end
end;
```

You may see code in packages, which, in a similar situation, uses

```
julia> import .ParentModule.SubA: add_D
```

However, this operates through [code loading](#), and thus only works if ParentModule is in a package. It is better to use relative paths.

Note that the order of definitions also matters if you are evaluating values. Consider

```
module TestPackage
    export x, y

    x = 0

    module Sub
        using ..TestPackage
        z = y # ERROR: UndefVarError: `y` not defined
    end

    y = 1
end
```

where Sub is trying to use TestPackage.y before it was defined, so it does not have a value.

For similar reasons, you cannot use a cyclic ordering:

```
module A
    module B
        using ..C # ERROR: UndefVarError: `C` not defined
    end
```

```
module C
using ..B
end

end
```

16.3 Module initialization and precompilation

Large modules can take several seconds to load because executing all of the statements in a module often involves compiling a large amount of code. Julia creates precompiled caches of the module to reduce this time.

Precompiled module files (sometimes called "cache files") are created and used automatically when `import` or `using` loads a module. If the cache file(s) do not yet exist, the module will be compiled and saved for future reuse. You can also manually call `Base.compilecache(Base.identify_package("modulename"))` to create these files without loading the module. The resulting cache files will be stored in the compiled subfolder of `DEPOT_PATH[1]`. If nothing about your system changes, such cache files will be used when you load the module with `import` or `using`.

Precompilation cache files store definitions of modules, types, methods, and constants. They may also store method specializations and the code generated for them, but this typically requires that the developer add explicit `precompile` directives or execute workloads that force compilation during the package build.

However, if you update the module's dependencies or change its source code, the module is automatically recompiled upon using or `import`. Dependencies are modules it imports, the Julia build, files it includes, or explicit dependencies declared by `include_dependency(path)` in the module file(s).

For file dependencies, a change is determined by examining whether the modification time (`mtime`) of each file loaded by `include` or added explicitly by `include_dependency` is unchanged, or equal to the modification time truncated to the nearest second (to accommodate systems that can't copy `mtime` with sub-second accuracy). It also takes into account whether the path to the file chosen by the search logic in `require` matches the path that had created the precompile file. It also takes into account the set of dependencies already loaded into the current process and won't recompile those modules, even if their files change or disappear, in order to avoid creating incompatibilities between the running system and the precompile cache. Finally, it takes account of changes in any [compile-time preferences](#).

If you know that a module is not safe to precompile (for example, for one of the reasons described below), you should put `__precompile__(false)` in the module file (typically placed at the top). This will cause `Base.compilecache` to throw an error, and will cause `using` / `import` to load it directly into the current process and skip the precompile and caching. This also thereby prevents the module from being imported by any other precompiled module.

You may need to be aware of certain behaviors inherent in the creation of incremental shared libraries which may require care when writing your module. For example, external state is not preserved. To accommodate this, explicitly separate any initialization steps that must occur at runtime from steps that can occur at compile time. For this purpose, Julia allows you to define an `__init__()` function in your module that executes any initialization steps that must occur at runtime. This function will not be called during compilation (`--output-*`). Effectively, you can assume it will be run exactly once in the lifetime of the code. You may, of course, call it manually if necessary, but the default is to assume this function deals with computing state for the local machine, which does not need to be – or even should not be – captured in the compiled image. It will be called after the module is loaded into a process, including if it is being loaded into

an incremental compile (`--output-incremental=yes`), but not if it is being loaded into a full-compilation process.

In particular, if you define a function `__init__()` in a module, then Julia will call `__init__()` immediately after the module is loaded (e.g., by `import`, `using`, or `require`) at runtime for the first time (i.e., `__init__` is only called once, and only after all statements in the module have been executed). Because it is called after the module is fully imported, any submodules or other imported modules have their `__init__` functions called before the `__init__` of the enclosing module.

Two typical uses of `__init__` are calling runtime initialization functions of external C libraries and initializing global constants that involve pointers returned by external libraries. For example, suppose that we are calling a C library `libfoo` that requires us to call a `foo_init()` initialization function at runtime. Suppose that we also want to define a global constant `foo_data_ptr` that holds the return value of a `void *foo_data()` function defined by `libfoo` – this constant must be initialized at runtime (not at compile time) because the pointer address will change from run to run. You could accomplish this by defining the following `__init__` function in your module:

```
const foo_data_ptr = Ref{Ptr{Cvoid}}{0}
function __init__()
    ccall(:foo_init, :libfoo, Cvoid, ())
    foo_data_ptr[] = ccall(:foo_data, :libfoo, Ptr{Cvoid}, ())
    nothing
end
```

Notice that it is perfectly possible to define a global inside a function like `__init__`; this is one of the advantages of using a dynamic language. But by making it a constant at global scope, we can ensure that the type is known to the compiler and allow it to generate better optimized code. Obviously, any other globals in your module that depends on `foo_data_ptr` would also have to be initialized in `__init__`.

Constants involving most Julia objects that are not produced by `ccall` do not need to be placed in `__init__`: their definitions can be precompiled and loaded from the cached module image. This includes complicated heap-allocated objects like arrays. However, any routine that returns a raw pointer value must be called at runtime for precompilation to work (`Ptr` objects will turn into null pointers unless they are hidden inside an `isbits` object). This includes the return values of the Julia functions `@cfunction` and `pointer`.

Dictionary and set types, or in general anything that depends on the output of a `hash(key)` method, are a trickier case. In the common case where the keys are numbers, strings, symbols, ranges, `Expr`, or compositions of these types (via arrays, tuples, sets, pairs, etc.) they are safe to precompile. However, for a few other key types, such as `Function` or `DataType` and generic user-defined types where you haven't defined a hash method, the fallback hash method depends on the memory address of the object (via its `objectid`) and hence may change from run to run. If you have one of these key types, or if you aren't sure, to be safe you can initialize this dictionary from within your `__init__` function. Alternatively, you can use the `IdDict` dictionary type, which is specially handled by precompilation so that it is safe to initialize at compile-time.

When using precompilation, it is important to keep a clear sense of the distinction between the compilation phase and the execution phase. In this mode, it will often be much more clearly apparent that Julia is a compiler which allows execution of arbitrary Julia code, not a standalone interpreter that also generates compiled code.

Other known potential failure scenarios include:

1. Global counters (for example, for attempting to uniquely identify objects). Consider the following code snippet:

```
mutable struct UniquedById
    myid::Int
    let counter = 0
        UniquedById() = new(counter += 1)
    end
end
```

while the intent of this code was to give every instance a unique id, the counter value is recorded at the end of compilation. All subsequent usages of this incrementally compiled module will start from that same counter value.

Note that `objectid` (which works by hashing the memory pointer) has similar issues (see notes on Dict usage below).

One alternative is to use a macro to capture `@__MODULE__` and store it alone with the current counter value, however, it may be better to redesign the code to not depend on this global state.

2. Associative collections (such as Dict and Set) need to be re-hashed in `__init__`. (In the future, a mechanism may be provided to register an initializer function.)
3. Depending on compile-time side-effects persisting through load-time. Example include: modifying arrays or other variables in other Julia modules; maintaining handles to open files or devices; storing pointers to other system resources (including memory);
4. Creating accidental "copies" of global state from another module, by referencing it directly instead of via its lookup path. For example, (in global scope):

```
#mystdout = Base.stdout #= will not work correctly, since this will copy Base.stdout into
↳ this module =#
# instead use accessor functions:
getstdout() = Base.stdout #= best option =#
# or move the assignment into the runtime:
__init__() = global mystdout = Base.stdout #= also works =#
```

Several additional restrictions are placed on the operations that can be done while precompiling code to help the user avoid other wrong-behavior situations:

1. Calling `eval` to cause a side-effect in another module. This will also cause a warning to be emitted when the incremental precompile flag is set.
2. `global` `const` statements from local scope after `__init__()` has been started (see issue #12010 for plans to add an error for this)
3. Replacing a module is a runtime error while doing an incremental precompile.

A few other points to be aware of:

1. No code reload / cache invalidation is performed after changes are made to the source files themselves, (including by `Pkg.update`), and no cleanup is done after `Pkg.rm`

2. The memory sharing behavior of a reshaped array is disregarded by precompilation (each view gets its own copy)
3. Expecting the filesystem to be unchanged between compile-time and runtime e.g. `@__FILE__/source_path()` to find resources at runtime, or the `BinDeps @checked_lib` macro. Sometimes this is unavoidable. However, when possible, it can be good practice to copy resources into the module at compile-time so they won't need to be found at runtime.
4. `WeakRef` objects and finalizers are not currently handled properly by the serializer (this will be fixed in an upcoming release).
5. It is usually best to avoid capturing references to instances of internal metadata objects such as `Method`, `MethodInstance`, `MethodTable`, `TypeMapLevel`, `TypeMapEntry` and fields of those objects, as this can confuse the serializer and may not lead to the outcome you desire. It is not necessarily an error to do this, but you simply need to be prepared that the system will try to copy some of these and to create a single unique instance of others.

It is sometimes helpful during module development to turn off incremental precompilation. The command line flag `--compiled-modules={yes|no}` enables you to toggle module precompilation on and off. When Julia is started with `--compiled-modules=no` the serialized modules in the compile cache are ignored when loading modules and module dependencies. More fine-grained control is available with `--pkgimages=no`, which suppresses only native-code storage during precompilation. `Base.compilecache` can still be called manually. The state of this command line flag is passed to `Pkg.build` to disable automatic precompilation triggering when installing, updating, and explicitly building packages.

You can also debug some precompilation failures with environment variables. Setting `JULIA_VERBOSE_LINKING=true` may help resolve failures in linking shared libraries of compiled native code. See the **Developer Documentation** part of the Julia manual, where you will find further details in the section documenting Julia's internals under "Package Images".

Chapter 17

Documentation

17.1 Accessing Documentation

Documentation can be accessed at the REPL or in [IJulia](#) by typing `?` followed by the name of a function or macro, and pressing Enter. For example,

```
?cos
?@time
?r"""
```

will show documentation for the relevant function, macro or string macro respectively. Most Julia environments provide a way to access documentation directly:

- [VS Code](#) shows documentation when you hover over a function name. You can also use the Julia panel in the sidebar to search for documentation.
- In [Pluto](#), open the "Live Docs" panel on the bottom right.
- In [Juno](#) using `Ctrl-J`, `Ctrl-D` will show the documentation for the object under the cursor.

17.2 Writing Documentation

Julia enables package developers and users to document functions, types and other objects easily via a built-in documentation system.

The basic syntax is simple: any string appearing just before an object (function, macro, type or instance) will be interpreted as documenting it (these are called docstrings). Note that no blank lines or comments may intervene between a docstring and the documented object. Here is a basic example:

```
"Tell whether there are too foo items in the array."
foo(xs::Array) = ...
```

Documentation is interpreted as [Markdown](#), so you can use indentation and code fences to delimit code examples from text. Technically, any object can be associated with any other as metadata; Markdown happens to be the default, but one can construct other string macros and pass them to the `@doc` macro just as well.

Note

Markdown support is implemented in the Markdown standard library and for a full list of supported syntax see the [documentation](#).

Here is a more complex example, still using Markdown:

```
"""
    bar(x[, y])

Compute the Bar index between `x` and `y`.

If `y` is unspecified, compute the Bar index between all pairs of columns of `x`.

# Examples
```julia-repl
julia> bar([1, 2], [1, 2])
1
```
"""
function bar(x, y) ...
```

As in the example above, we recommend following some simple conventions when writing documentation:

1. Always show the signature of a function at the top of the documentation, with a four-space indent so that it is printed as Julia code.

This can be identical to the signature present in the Julia code (like `mean(x::AbstractArray)`), or a simplified form. Optional arguments should be represented with their default values (i.e. `f(x, y=1)`) when possible, following the actual Julia syntax. Optional arguments which do not have a default value should be put in brackets (i.e. `f(x[, y])` and `f(x[, y[, z]])`). An alternative solution is to use several lines: one without optional arguments, the other(s) with them. This solution can also be used to document several related methods of a given function. When a function accepts many keyword arguments, only include a `<keyword arguments>` placeholder in the signature (i.e. `f(x; <keyword arguments>)`), and give the complete list under an `# Arguments` section (see point 4 below).

2. Include a single one-line sentence describing what the function does or what the object represents after the simplified signature block. If needed, provide more details in a second paragraph, after a blank line.

The one-line sentence should use the imperative form ("Do this", "Return that") instead of the third person (do not write "Returns the length...") when documenting functions. It should end with a period. If the meaning of a function cannot be summarized easily, splitting it into separate composable parts could be beneficial (this should not be taken as an absolute requirement for every single case though).

3. Do not repeat yourself.

Since the function name is given by the signature, there is no need to start the documentation with "The function `bar`...": go straight to the point. Similarly, if the signature specifies the types of the arguments, mentioning them in the description is redundant.

4. Only provide an argument list when really necessary.

For simple functions, it is often clearer to mention the role of the arguments directly in the description of the function's purpose. An argument list would only repeat information already provided elsewhere. However, providing an argument list can be a good idea for complex functions with many arguments (in particular keyword arguments). In that case, insert it after the general description of the function, under an `# Arguments` header, with one - bullet for each argument. The list should mention the types and default values (if any) of the arguments:

```
"""
...
# Arguments
- `n::Integer`: the number of elements to compute.
- `dim::Integer=1`: the dimensions along which to perform the computation.
...
"""
```

5. Provide hints to related functions.

Sometimes there are functions of related functionality. To increase discoverability please provide a short list of these in a `See also` paragraph.

```
| See also [bar!](@ref), [baz](@ref), [baaz](@ref).
```

6. Include any code examples in an `# Examples` section.

Examples should, whenever possible, be written as doctests. A doctest is a fenced code block (see [Code blocks](#)) starting with ```jldoctest` and contains any number of `julia>` prompts together with inputs and expected outputs that mimic the Julia REPL.

Note

Doctests are enabled by `Documenter.jl`. For more detailed documentation see Documenter's [manual](#).

For example in the following docstring a variable `a` is defined and the expected result, as printed in a Julia REPL, appears afterwards:

```
"""
Some nice documentation here.

# Examples
``jldoctest
julia> a = [1 2; 3 4]
2×2 Array{Int64,2}:
 1  2
 3  4
...
"""
```

Warning

Calling `rand` and other RNG-related functions should be avoided in doctests since they will not produce consistent outputs during different Julia sessions. If you would like to show some random number generation related functionality, one option is to explicitly

construct and seed your own RNG object (see [Random](#)) and pass it to the functions you are doctesting.

Operating system word size ([Int32](#) or [Int64](#)) as well as path separator differences (/ or \) will also affect the reproducibility of some doctests.

Note that whitespace in your doctest is significant! The doctest will fail if you misalign the output of pretty-printing an array, for example.

You can then run `make -C doc doctest=true` to run all the doctests in the Julia Manual and API documentation, which will ensure that your example works.

To indicate that the output result is truncated, you may write `[...]` at the line where checking should stop. This is useful to hide a `stacktrace` (which contains non-permanent references to lines of Julia code) when the doctest shows that an exception is thrown, for example:

```
```jldoctest
julia> div(1, 0)
ERROR: DivideError: integer division error
[...]
```
```

Examples that are untestable should be written within fenced code blocks starting with ````julia` so that they are highlighted correctly in the generated documentation.

Tip

Wherever possible examples should be **self-contained** and **runnable** so that readers are able to try them out without having to include any dependencies.

7. Use backticks to identify code and equations.

Julia identifiers and code excerpts should always appear between backticks ``` to enable highlighting. Equations in the LaTeX syntax can be inserted between double backticks ````. Use Unicode characters rather than their LaTeX escape sequence, i.e. ```α = 1``` rather than ```\alpha = 1```.

8. Place the starting and ending `"""` characters on lines by themselves.

That is, write:

```
"""
...

...
"""
f(x, y) = ...
```

rather than:

```
""" ...
... """
f(x, y) = ...
```

This makes it clearer where docstrings start and end.

9. Respect the line length limit used in the surrounding code.

Docstrings are edited using the same tools as code. Therefore, the same conventions should apply. It is recommended that lines are at most 92 characters wide.

10. Provide information allowing custom types to implement the function in an `# Implementation` section. These implementation details are intended for developers rather than users, explaining e.g. which functions should be overridden and which functions automatically use appropriate fallbacks. Such details are best kept separate from the main description of the function's behavior.
11. For long docstrings, consider splitting the documentation with an `# Extended help` header. The typical help-mode will show only the material above the header; you can access the full help by adding a `'?` at the beginning of the expression (i.e., `"??foo"` rather than `"?foo"`).

17.3 Functions & Methods

Functions in Julia may have multiple implementations, known as methods. While it's good practice for generic functions to have a single purpose, Julia allows methods to be documented individually if necessary. In general, only the most generic method should be documented, or even the function itself (i.e. the object created without any methods by `function bar end`). Specific methods should only be documented if their behaviour differs from the more generic ones. In any case, they should not repeat the information provided elsewhere. For example:

```
"""
    *(x, y, z...)

Multiplication operator. `x * y * z *...` calls this function with multiple
arguments, i.e. `*(x, y, z...)`.
"""
function *(x, y, z...)
    # ... [implementation sold separately] ...
end

"""
    *(x::AbstractString, y::AbstractString, z::AbstractString...)

When applied to strings, concatenates them.
"""
function *(x::AbstractString, y::AbstractString, z::AbstractString...)
    # ... [insert secret sauce here] ...
end

help?> *
search: * .*

*(x, y, z...)

Multiplication operator. x * y * z *... calls this function with multiple
arguments, i.e. *(x,y,z...).

*(x::AbstractString, y::AbstractString, z::AbstractString...)

When applied to strings, concatenates them.
```

When retrieving documentation for a generic function, the metadata for each method is concatenated with the `catdoc` function, which can of course be overridden for custom types.

17.4 Advanced Usage

The `@doc` macro associates its first argument with its second in a per-module dictionary called `META`.

To make it easier to write documentation, the parser treats the macro name `@doc` specially: if a call to `@doc` has one argument, but another expression appears after a single line break, then that additional expression is added as an argument to the macro. Therefore the following syntax is parsed as a 2-argument call to `@doc`:

```
@doc raw"""
...
"""
f(x) = x
```

This makes it possible to use expressions other than normal string literals (such as the `raw"""` string macro) as a docstring.

When used for retrieving documentation, the `@doc` macro (or equally, the `doc` function) will search all `META` dictionaries for metadata relevant to the given object and return it. The returned object (some Markdown content, for example) will by default display itself intelligently. This design also makes it easy to use the doc system in a programmatic way; for example, to re-use documentation between different versions of a function:

```
@doc "... " foo!
@doc (@doc foo!) foo
```

Or for use with Julia's metaprogramming functionality:

```
for (f, op) in (:(add, :+), (:(subtract, :-), (:(multiply, :*), (:(divide, :/))
    @eval begin
        $f(a,b) = $op(a,b)
    end
end
@doc "`add(a,b)` adds `a` and `b` together" add
@doc "`subtract(a,b)` subtracts `b` from `a`" subtract
```

Documentation in non-toplevel blocks, such as `begin`, `if`, `for`, and `let`, should be added to the documentation system via `@doc` as well. For example:

```
if condition()
    @doc "... "
    f(x) = x
end
```

will add documentation to `f(x)` when `condition()` is true. Note that even if `f(x)` goes out of scope at the end of a block, its documentation will remain.

It is possible to make use of metaprogramming to assist in the creation of documentation. When using string-interpolation within the docstring you will need to use an extra `$` as shown with `$($name)`:

```
for func in (:day, :dayofmonth)
    name = string(func)
    @eval begin
        @doc """
            $( $name )(dt::TimeType) -> Int64

            The day of month of a `Date` or `DateTime` as an `Int64`.
            """ $func(dt::Dates.TimeType)
        end
    end
end
```

Dynamic documentation

Sometimes the appropriate documentation for an instance of a type depends on the field values of that instance, rather than just on the type itself. In these cases, you can add a method to `Docs.getdoc` for your custom type that returns the documentation on a per-instance basis. For instance,

```
struct MyType
    value::Int
end

Docs.getdoc(t::MyType) = "Documentation for MyType with value $(t.value)"

x = MyType(1)
y = MyType(2)
```

`?x` will display "Documentation for MyType with value 1" while `?y` will display "Documentation for MyType with value 2".

17.5 Syntax Guide

This guide provides a comprehensive overview of how to attach documentation to all Julia syntax constructs for which providing documentation is possible.

In the following examples "..." is used to illustrate an arbitrary docstring.

\$ and \ characters

The `$` and `\` characters are still parsed as string interpolation or start of an escape sequence in docstrings too. The `raw""` string macro together with the `@doc` macro can be used to avoid having to escape them. This is handy when the docstrings include LaTeX or Julia source code examples containing interpolation:

```
@doc raw"""
    ``math
    \LaTeX
```

```

| """
| """
| function f end

```

Functions and Methods

```

| """
| """
| function f end
|
| """
| f

```

Adds docstring "... " to the function `f`. The first version is the preferred syntax, however both are equivalent.

```

| """
| """
| f(x) = x
|
| """
| function f(x)
|     x
| end
|
| """
| f(x)

```

Adds docstring "... " to the method `f(::Any)`.

```

| """
| """
| f(x, y = 1) = x + y

```

Adds docstring "... " to two Methods, namely `f(::Any)` and `f(::Any, ::Any)`.

Macros

```

| """
| """
| macro m(x) end

```

Adds docstring "... " to the `@m(::Any)` macro definition.

```

| """
| """
| :(@m)

```

Adds docstring "... " to the macro named `@m`.

Types

```
"..."
abstract type T1 end

"..."
mutable struct T2
    ...
end

"..."
struct T3
    ...
end
```

Adds the docstring "..." to types T1, T2, and T3.

```
"..."
struct T
    "x"
    x
    "y"
    y
end
```

Adds docstring "..." to type T, "x" to field T.x and "y" to field T.y. Also applicable to mutable struct types.

Modules

```
"..."
module M end

module M

"..."
M

end
```

Adds docstring "..." to the Module M. Adding the docstring above the Module is the preferred syntax, however both are equivalent.

```
"..."
baremodule M
# ...
end

baremodule M

import Base: @doc

"..."
```

```
f(x) = x
end
```

Documenting a baremodule by placing a docstring above the expression automatically imports @doc into the module. These imports must be done manually when the module expression is not documented.

Global Variables

```
"..."
const a = 1

"..."
b = 2

"..."
global c = 3
```

Adds docstring "..." to the Bindings a, b, and c.

Bindings are used to store a reference to a particular Symbol in a Module without storing the referenced value itself.

Note

When a const definition is only used to define an alias of another definition, such as is the case with the function div and its alias ÷ in Base, do not document the alias and instead document the actual function.

If the alias is documented and not the real definition then the docsystem (? mode) will not return the docstring attached to the alias when the real definition is searched for.

For example you should write

```
"..."
f(x) = x + 1
const alias = f
```

rather than

```
f(x) = x + 1
"..."
const alias = f
```

```
"..."
sym
```

Adds docstring "..." to the value associated with sym. However, it is preferred that sym is documented where it is defined.

Multiple Objects

```
| "..."  
| a, b
```

Adds docstring `"..."` to `a` and `b` each of which should be a documentable expression. This syntax is equivalent to

```
| "..."  
| a  
  
| "..."  
| b
```

Any number of expressions may be documented together in this way. This syntax can be useful when two functions are related, such as non-mutating and mutating versions `f` and `f!`.

Macro-generated code

```
| "..."  
| @m expression
```

Adds docstring `"..."` to the expression generated by expanding `@m expression`. This allows for expressions decorated with `@inline`, `@noinline`, `@generated`, or any other macro to be documented in the same way as undecorated expressions.

Macro authors should take note that only macros that generate a single expression will automatically support docstrings. If a macro returns a block containing multiple subexpressions then the subexpression that should be documented must be marked using the `@__doc__` macro.

The `@enum` macro makes use of `@__doc__` to allow for documenting `Enums`. Examining its definition should serve as an example of how to use `@__doc__` correctly.

Core.`@__doc__` - Macro.

```
| @__doc__(ex)
```

Low-level macro used to mark expressions returned by a macro that should be documented. If more than one expression is marked then the same docstring is applied to each expression.

```
| macro example(f)  
|   quote  
|     $(f)() = 0  
|     @__doc__ $(f)(x) = 1  
|     $(f)(x, y) = 2  
|   end |> esc  
| end
```

`@__doc__` has no effect when a macro that uses it is not documented.

Chapter 18

Metaprogramming

The strongest legacy of Lisp in the Julia language is its metaprogramming support. Like Lisp, Julia represents its own code as a data structure of the language itself. Since code is represented by objects that can be created and manipulated from within the language, it is possible for a program to transform and generate its own code. This allows sophisticated code generation without extra build steps, and also allows true Lisp-style macros operating at the level of [abstract syntax trees](#). In contrast, preprocessor "macro" systems, like that of C and C++, perform textual manipulation and substitution before any actual parsing or interpretation occurs. Because all data types and code in Julia are represented by Julia data structures, powerful [reflection](#) capabilities are available to explore the internals of a program and its types just like any other data.

Warning

Metaprogramming is a powerful tool, but it introduces complexity that can make code more difficult to understand. For example, it can be surprisingly hard to get scope rules correct. Metaprogramming should typically be used only when other approaches such as [higher order functions](#) and [closures](#) cannot be applied.

`eval` and defining new macros should be typically used as a last resort. It is almost never a good idea to use `Meta.parse` or convert an arbitrary string into Julia code. For manipulating Julia code, use the `Expr` data structure directly to avoid the complexity of how Julia syntax is parsed.

The best uses of metaprogramming often implement most of their functionality in runtime helper functions, striving to minimize the amount of code they generate.

18.1 Program representation

Every Julia program starts life as a string:

```
julia> prog = "1 + 1"
"1 + 1"
```

What happens next?

The next step is to [parse](#) each string into an object called an expression, represented by the Julia type [Expr](#):

```
julia> ex1 = Meta.parse(prog)
:(1 + 1)

julia> typeof(ex1)
Expr
```

Expr objects contain two parts:

- a [Symbol](#) identifying the kind of expression. A symbol is an [interned string](#) identifier (more discussion below).

```
julia> ex1.head
:call
```

- the expression arguments, which may be symbols, other expressions, or literal values:

```
julia> ex1.args
3-element Vector{Any}:
 :+
 1
 1
```

Expressions may also be constructed directly in [prefix notation](#):

```
julia> ex2 = Expr(:call, :+, 1, 1)
:(1 + 1)
```

The two expressions constructed above – by parsing and by direct construction – are equivalent:

```
julia> ex1 == ex2
true
```

The key point here is that Julia code is internally represented as a data structure that is accessible from the language itself.

The [dump](#) function provides indented and annotated display of Expr objects:

```
julia> dump(ex2)
Expr
 head: Symbol call
 args: Array{Any}((3,))
   1: Symbol +
   2: Int64 1
   3: Int64 1
```

Expr objects may also be nested:

```
julia> ex3 = Meta.parse("(4 + 4) / 2")
:((4 + 4) / 2)
```

Another way to view expressions is with `Meta.show_sexpr`, which displays the *S-expression* form of a given Expr, which may look very familiar to users of Lisp. Here's an example illustrating the display on a nested Expr:

```
julia> Meta.show_sexpr(ex3)
(:call, :/, (:call, :+, 4, 4), 2)
```

Symbols

The `:` character has two syntactic purposes in Julia. The first form creates a *Symbol*, an *interned string* used as one building-block of expressions, from valid identifiers:

```
julia> s = :foo
:foo

julia> typeof(s)
Symbol
```

The *Symbol* constructor takes any number of arguments and creates a new symbol by concatenating their string representations together:

```
julia> :foo === Symbol("foo")
true

julia> Symbol("lfoo") # `:lfoo` would not work, as `lfoo` is not a valid identifier
Symbol("lfoo")

julia> Symbol("func", 10)
:func10

julia> Symbol(:var, '_', "sym")
:var_sym
```

In the context of an expression, symbols are used to indicate access to variables; when an expression is evaluated, a symbol is replaced with the value bound to that symbol in the appropriate *scope*.

Sometimes extra parentheses around the argument to `:` are needed to avoid ambiguity in parsing:

```
julia> :( )
:( )

julia> :( :: )
:( :: )
```

18.2 Expressions and evaluation

Quoting

The second syntactic purpose of the `:` character is to create expression objects without using the explicit `Expr` constructor. This is referred to as quoting. The `:` character, followed by paired parentheses around a single statement of Julia code, produces an `Expr` object based on the enclosed code. Here is an example of the short form used to quote an arithmetic expression:

```
julia> ex = :(a+b*c+1)
:(a + b * c + 1)

julia> typeof(ex)
Expr
```

(to view the structure of this expression, try `ex.head` and `ex.args`, or use `dump` as above or `Meta.@dump`)

Note that equivalent expressions may be constructed using `Meta.parse` or the direct `Expr` form:

```
julia>      :(a + b*c + 1)      ==
      Meta.parse("a + b*c + 1") ==
      Expr(:call, :+, :a, Expr(:call, :*, :b, :c), 1)
true
```

Expressions provided by the parser generally only have symbols, other expressions, and literal values as their args, whereas expressions constructed by Julia code can have arbitrary run-time values without literal forms as args. In this specific example, `+` and `a` are symbols, `*(b, c)` is a subexpression, and `1` is a literal 64-bit signed integer.

There is a second syntactic form of quoting for multiple expressions: blocks of code enclosed in `quote . . . end`.

```
julia> ex = quote
      x = 1
      y = 2
      x + y
    end
quote
  #=: none:2 =#
  x = 1
  #=: none:3 =#
  y = 2
  #=: none:4 =#
  x + y
end

julia> typeof(ex)
Expr
```

Interpolation

Direct construction of `Expr` objects with value arguments is powerful, but `Expr` constructors can be tedious compared to "normal" Julia syntax. As an alternative, Julia allows interpolation of literals or expressions into quoted expressions. Interpolation is indicated by a prefix `$`.

In this example, the value of variable `a` is interpolated:

```
julia> a = 1;

julia> ex = :($a + b)
:(1 + b)
```

Interpolating into an unquoted expression is not supported and will cause a compile-time error:

```
julia> $a + b
ERROR: syntax: "$" expression outside quote
```

In this example, the tuple `(1,2,3)` is interpolated as an expression into a conditional test:

```
julia> ex = :(a in $(1,2,3))
:(a in (1, 2, 3))
```

The use of `$` for expression interpolation is intentionally reminiscent of [string interpolation](#) and [command interpolation](#). Expression interpolation allows convenient, readable programmatic construction of complex Julia expressions.

Splatting interpolation

Notice that the `$` interpolation syntax allows inserting only a single expression into an enclosing expression. Occasionally, you have an array of expressions and need them all to become arguments of the surrounding expression. This can be done with the syntax `$(xs...)`. For example, the following code generates a function call where the number of arguments is determined programmatically:

```
julia> args = [:x, :y, :z];

julia> :(f(1, $(args...)))
:(f(1, x, y, z))
```

Nested quote

Naturally, it is possible for quote expressions to contain other quote expressions. Understanding how interpolation works in these cases can be a bit tricky. Consider this example:

```
julia> x = :(1 + 2);

julia> e = quote quote $x end end
quote
  #= none:1 =#
```

```

    $(Expr(:quote, quote
      #= none:1 =#
      $(Expr(:$, :x))
    end))
  end
end

```

Notice that the result contains `$x`, which means that `x` has not been evaluated yet. In other words, the `$` expression "belongs to" the inner quote expression, and so its argument is only evaluated when the inner quote expression is:

```

julia> eval(e)
quote
  #= none:1 =#
  1 + 2
end

```

However, the outer quote expression is able to interpolate values inside the `$` in the inner quote. This is done with multiple `$$`:

```

julia> e = quote quote $$x end end
quote
  #= none:1 =#
  $(Expr(:quote, quote
    #= none:1 =#
    $(Expr(:$, :(1 + 2)))
  end))
end

```

Notice that `(1 + 2)` now appears in the result instead of the symbol `x`. Evaluating this expression yields an interpolated 3:

```

julia> eval(e)
quote
  #= none:1 =#
  3
end

```

The intuition behind this behavior is that `x` is evaluated once for each `$`: one `$` works similarly to `eval(:x)`, giving `x`'s value, while two `$$`s do the equivalent of `eval(eval(:x))`.

QuoteNode

The usual representation of a quote form in an AST is an `Expr` with head `:quote`:

```

julia> dump(Meta.parse(":(1+2)"))
Expr
  head: Symbol quote
  args: Array{Any}{(1,)}
    1: Expr

```

```

head: Symbol call
args: Array{Any}{(3,)}
  1: Symbol +
  2: Int64 1
  3: Int64 2

```

As we have seen, such expressions support interpolation with `$`. However, in some situations it is necessary to quote code without performing interpolation. This kind of quoting does not yet have syntax, but is represented internally as an object of type `QuoteNode`:

```

julia> eval(Meta.quot(Expr(:$, :(1+2))))
3

julia> eval(QuoteNode(Expr(:$, :(1+2))))
:($(Expr(:$, :(1 + 2))))

```

The parser yields `QuoteNodes` for simple quoted items like symbols:

```

julia> dump(Meta.parse(":x"))
QuoteNode
 value: Symbol x

```

`QuoteNode` can also be used for certain advanced metaprogramming tasks.

Evaluating expressions

Given an expression object, one can cause Julia to evaluate (execute) it at global scope using `eval`:

```

julia> ex1 = :(1 + 2)
:(1 + 2)

julia> eval(ex1)
3

julia> ex = :(a + b)
:(a + b)

julia> eval(ex)
ERROR: UndefVarError: `b` not defined
[...]

julia> a = 1; b = 2;

julia> eval(ex)
3

```

Every `module` has its own `eval` function that evaluates expressions in its global scope. Expressions passed to `eval` are not limited to returning values – they can also have side-effects that alter the state of the enclosing module's environment:

```
julia> ex = :(x = 1)
:(x = 1)

julia> x
ERROR: UndefVarError: `x` not defined

julia> eval(ex)
1

julia> x
1
```

Here, the evaluation of an expression object causes a value to be assigned to the global variable `x`.

Since expressions are just `Expr` objects which can be constructed programmatically and then evaluated, it is possible to dynamically generate arbitrary code which can then be run using `eval`. Here is a simple example:

```
julia> a = 1;

julia> ex = Expr(:call, :+, a, :b)
:(1 + b)

julia> a = 0; b = 2;

julia> eval(ex)
3
```

The value of `a` is used to construct the expression `ex` which applies the `+` function to the value `1` and the variable `b`. Note the important distinction between the way `a` and `b` are used:

- The value of the variable `a` at expression construction time is used as an immediate value in the expression. Thus, the value of `a` when the expression is evaluated no longer matters: the value in the expression is already `1`, independent of whatever the value of `a` might be.
- On the other hand, the symbol `:b` is used in the expression construction, so the value of the variable `b` at that time is irrelevant – `:b` is just a symbol and the variable `b` need not even be defined. At expression evaluation time, however, the value of the symbol `:b` is resolved by looking up the value of the variable `b`.

Functions on Expressions

As hinted above, one extremely useful feature of Julia is the capability to generate and manipulate Julia code within Julia itself. We have already seen one example of a function returning `Expr` objects: the `Meta.parse` function, which takes a string of Julia code and returns the corresponding `Expr`. A function can also take one or more `Expr` objects as arguments, and return another `Expr`. Here is a simple, motivating example:

```
julia> function math_expr(op, op1, op2)
    expr = Expr(:call, op, op1, op2)
    return expr
end
```

```

        end
math_expr (generic function with 1 method)

julia> ex = math_expr(:+, 1, Expr(:call, :*, 4, 5))
:(1 + 4 * 5)

julia> eval(ex)
21

```

As another example, here is a function that doubles any numeric argument, but leaves expressions alone:

```

julia> function make_expr2(op, opr1, opr2)
    opr1f, opr2f = map(x -> isa(x, Number) ? 2*x : x, (opr1, opr2))
    retexpr = Expr(:call, op, opr1f, opr2f)
    return retexpr
end
make_expr2 (generic function with 1 method)

julia> make_expr2(:+, 1, 2)
:(2 + 4)

julia> ex = make_expr2(:+, 1, Expr(:call, :*, 5, 8))
:(2 + 5 * 8)

julia> eval(ex)
42

```

18.3 Macros

Macros provide a mechanism to include generated code in the final body of a program. A macro maps a tuple of arguments to a returned expression, and the resulting expression is compiled directly rather than requiring a runtime `eval` call. Macro arguments may include expressions, literal values, and symbols.

Basics

Here is an extraordinarily simple macro:

```

julia> macro sayhello()
    return :( println("Hello, world!") )
end
@sayhello (macro with 1 method)

```

Macros have a dedicated character in Julia's syntax: the `@` (at-sign), followed by the unique name declared in a macro `NAME ... end` block. In this example, the compiler will replace all instances of `@sayhello` with:

```

:( println("Hello, world!") )

```

When `@sayhello` is entered in the REPL, the expression executes immediately, thus we only see the evaluation result:

```
julia> @sayhello()
Hello, world!
```

Now, consider a slightly more complex macro:

```
julia> macro sayhello(name)
    return :( println("Hello, ", $name) )
end
@sayhello (macro with 1 method)
```

This macro takes one argument: `name`. When `@sayhello` is encountered, the quoted expression is expanded to interpolate the value of the argument into the final expression:

```
julia> @sayhello("human")
Hello, human
```

We can view the quoted return expression using the function `macroexpand` (**important note:** this is an extremely useful tool for debugging macros):

```
julia> ex = macroexpand(Main, :(@sayhello("human")))
:(Main.println("Hello, ", "human"))

julia> typeof(ex)
Expr
```

We can see that the `"human"` literal has been interpolated into the expression.

There also exists a macro `@macroexpand` that is perhaps a bit more convenient than the `macroexpand` function:

```
julia> @macroexpand @sayhello "human"
:(println("Hello, ", "human"))
```

Hold up: why macros?

We have already seen a function `f(::Expr...) -> Expr` in a previous section. In fact, `macroexpand` is also such a function. So, why do macros exist?

Macros are necessary because they execute when code is parsed, therefore, macros allow the programmer to generate and include fragments of customized code before the full program is run. To illustrate the difference, consider the following example:

```
julia> macro twostep(arg)
    println("I execute at parse time. The argument is: ", arg)
    return :(println("I execute at runtime. The argument is: ", $arg))
end
@twostep (macro with 1 method)

julia> ex = macroexpand(Main, :(@twostep (1, 2, 3)) );
I execute at parse time. The argument is: :((1, 2, 3))
```

The first call to `println` is executed when `macroexpand` is called. The resulting expression contains only the second `println`:

```
julia> typeof(ex)
Expr

julia> ex
:(println("I execute at runtime. The argument is: ", $(Expr(:copyast, :($(QuoteNode(:((1, 2,
↪ 3))))))))))

julia> eval(ex)
I execute at runtime. The argument is: (1, 2, 3)
```

Macro invocation

Macros are invoked with the following general syntax:

```
@name expr1 expr2 ...
@name(expr1, expr2, ...)
```

Note the distinguishing `@` before the macro name and the lack of commas between the argument expressions in the first form, and the lack of whitespace after `@name` in the second form. The two styles should not be mixed. For example, the following syntax is different from the examples above; it passes the tuple `(expr1, expr2, ...)` as one argument to the macro:

```
@name (expr1, expr2, ...)
```

An alternative way to invoke a macro over an array literal (or comprehension) is to juxtapose both without using parentheses. In this case, the array will be the only expression fed to the macro. The following syntax is equivalent (and different from `@name [a b] * v`):

```
@name[a b] * v
@name([a b]) * v
```

It is important to emphasize that macros receive their arguments as expressions, literals, or symbols. One way to explore macro arguments is to call the `show` function within the macro body:

```
julia> macro showarg(x)
    show(x)
    # ... remainder of macro, returning an expression
end
@showarg (macro with 1 method)

julia> @showarg(a)
:a

julia> @showarg(1+1)
:(1 + 1)

julia> @showarg(println("Yo!"))
:(println("Yo!"))
```

In addition to the given argument list, every macro is passed extra arguments named `__source__` and `__module__`.

The argument `__source__` provides information (in the form of a `LineNumberNode` object) about the parser location of the `@` sign from the macro invocation. This allows macros to include better error diagnostic information, and is commonly used by logging, string-parser macros, and docs, for example, as well as to implement the `@__LINE__`, `@__FILE__`, and `@__DIR__` macros.

The location information can be accessed by referencing `__source__.line` and `__source__.file`:

```
julia> macro __LOCATION__(); return QuoteNode(__source__); end
@__LOCATION__ (macro with 1 method)

julia> dump(
    @__LOCATION__(
    ))
LineNumberNode
  line: Int64 2
  file: Symbol none
```

The argument `__module__` provides information (in the form of a `Module` object) about the expansion context of the macro invocation. This allows macros to look up contextual information, such as existing bindings, or to insert the value as an extra argument to a runtime function call doing self-reflection in the current module.

Building an advanced macro

Here is a simplified definition of Julia's `@assert` macro:

```
julia> macro assert(ex)
    return :( $ex ? nothing : throw(AssertionError($(string(ex)))) )
end
@assert (macro with 1 method)
```

This macro can be used like this:

```
julia> @assert 1 == 1.0

julia> @assert 1 == 0
ERROR: AssertionError: 1 == 0
```

In place of the written syntax, the macro call is expanded at parse time to its returned result. This is equivalent to writing:

```
1 == 1.0 ? nothing : throw(AssertionError("1 == 1.0"))
1 == 0 ? nothing : throw(AssertionError("1 == 0"))
```

That is, in the first call, the expression `:(1 == 1.0)` is spliced into the test condition slot, while the value of `string:(1 == 1.0)` is spliced into the assertion message slot. The entire expression, thus constructed,

is placed into the syntax tree where the `@assert` macro call occurs. Then at execution time, if the test expression evaluates to true, then `nothing` is returned, whereas if the test is false, an error is raised indicating the asserted expression that was false. Notice that it would not be possible to write this as a function, since only the value of the condition is available and it would be impossible to display the expression that computed it in the error message.

The actual definition of `@assert` in Julia Base is more complicated. It allows the user to optionally specify their own error message, instead of just printing the failed expression. Just like in functions with a variable number of arguments ([Varargs Functions](#)), this is specified with an ellipsis following the last argument:

```
julia> macro assert(ex, msgs...)
    msg_body = isempty(msgs) ? ex : msgs[1]
    msg = string(msg_body)
    return :($ex ? nothing : throw(AssertionError($msg)))
end
@assert (macro with 1 method)
```

Now `@assert` has two modes of operation, depending upon the number of arguments it receives! If there's only one argument, the tuple of expressions captured by `msgs` will be empty and it will behave the same as the simpler definition above. But now if the user specifies a second argument, it is printed in the message body instead of the failing expression. You can inspect the result of a macro expansion with the aptly named `@macroexpand` macro:

```
julia> @macroexpand @assert a == b
:(if Main.a == Main.b
    Main.nothing
else
    Main.throw(Main.AssertionError("a == b"))
end)

julia> @macroexpand @assert a==b "a should equal b!"
:(if Main.a == Main.b
    Main.nothing
else
    Main.throw(Main.AssertionError("a should equal b!"))
end)
```

There is yet another case that the actual `@assert` macro handles: what if, in addition to printing "a should equal b," we wanted to print their values? One might naively try to use string interpolation in the custom message, e.g., `@assert a==b "a ($a) should equal b ($b)!"`, but this won't work as expected with the above macro. Can you see why? Recall from [string interpolation](#) that an interpolated string is rewritten to a call to `string`. Compare:

```
julia> typeof(:("a should equal b"))
String

julia> typeof(:("a ($a) should equal b ($b)!"))
Expr

julia> dump(:("a ($a) should equal b ($b)!"))
```

```
Expr
  head: Symbol string
  args: Array{Any}{(5,)}
    1: String "a ("
    2: Symbol a
    3: String ") should equal b ("
    4: Symbol b
    5: String ")!"
```

So now instead of getting a plain string in `msg_body`, the macro is receiving a full expression that will need to be evaluated in order to display as expected. This can be spliced directly into the returned expression as an argument to the `string` call; see `error.jl` for the complete implementation.

The `@assert` macro makes great use of splicing into quoted expressions to simplify the manipulation of expressions inside the macro body.

Hygiene

An issue that arises in more complex macros is that of [hygiene](#). In short, macros must ensure that the variables they introduce in their returned expressions do not accidentally clash with existing variables in the surrounding code they expand into. Conversely, the expressions that are passed into a macro as arguments are often expected to evaluate in the context of the surrounding code, interacting with and modifying the existing variables. Another concern arises from the fact that a macro may be called in a different module from where it was defined. In this case we need to ensure that all global variables are resolved to the correct module. Julia already has a major advantage over languages with textual macro expansion (like C) in that it only needs to consider the returned expression. All the other variables (such as `msg` in `@assert` above) follow the [normal scoping block behavior](#).

To demonstrate these issues, let us consider writing a `@time` macro that takes an expression as its argument, records the time, evaluates the expression, records the time again, prints the difference between the before and after times, and then has the value of the expression as its final value. The macro might look like this:

```
macro time(ex)
    return quote
        local t0 = time_ns()
        local val = $ex
        local t1 = time_ns()
        println("elapsed time: ", (t1-t0)/1e9, " seconds")
        val
    end
end
```

Here, we want `t0`, `t1`, and `val` to be private temporary variables, and we want `time_ns` to refer to the `time_ns` function in Julia Base, not to any `time_ns` variable the user might have (the same applies to `println`). Imagine the problems that could occur if the user expression `ex` also contained assignments to a variable called `t0`, or defined its own `time_ns` variable. We might get errors, or mysteriously incorrect behavior.

Julia's macro expander solves these problems in the following way. First, variables within a macro result are classified as either local or global. A variable is considered local if it is assigned to (and not declared global), declared local, or used as a function argument name. Otherwise, it is considered global. Local variables

are then renamed to be unique (using the `gensym` function, which generates new symbols), and global variables are resolved within the macro definition environment. Therefore both of the above concerns are handled; the macro's locals will not conflict with any user variables, and `time_ns` and `println` will refer to the Julia Base definitions.

One problem remains however. Consider the following use of this macro:

```
module MyModule
import Base.@time

time_ns() = ... # compute something

@time time_ns()
end
```

Here the user expression `ex` is a call to `time_ns`, but not the same `time_ns` function that the macro uses. It clearly refers to `MyModule.time_ns`. Therefore we must arrange for the code in `ex` to be resolved in the macro call environment. This is done by "escaping" the expression with `esc`:

```
macro time(ex)
    ...
    local val = $(esc(ex))
    ...
end
```

An expression wrapped in this manner is left alone by the macro expander and simply pasted into the output verbatim. Therefore it will be resolved in the macro call environment.

This escaping mechanism can be used to "violate" hygiene when necessary, in order to introduce or manipulate user variables. For example, the following macro sets `x` to zero in the call environment:

```
julia> macro zerox()
    return esc(:(x = 0))
end
@zerox (macro with 1 method)

julia> function foo()
    x = 1
    @zerox
    return x # is zero
end
foo (generic function with 1 method)

julia> foo()
0
```

This kind of manipulation of variables should be used judiciously, but is occasionally quite handy.

Getting the hygiene rules correct can be a formidable challenge. Before using a macro, you might want to consider whether a function closure would be sufficient. Another useful strategy is to defer as much work as possible to runtime. For example, many macros simply wrap their arguments in a `QuoteNode` or

other similar `Expr`. Some examples of this include `@task body` which simply returns `schedule(Task(() -> $body))`, and `@eval expr`, which simply returns `eval(QuoteNode(expr))`.

To demonstrate, we might rewrite the `@time` example above as:

```
macro time(expr)
    return :(timeit(() -> $(esc(expr))))
end
function timeit(f)
    t0 = time_ns()
    val = f()
    t1 = time_ns()
    println("elapsed time: ", (t1-t0)/1e9, " seconds")
    return val
end
```

However, we don't do this for a good reason: wrapping the `expr` in a new scope block (the anonymous function) also slightly changes the meaning of the expression (the scope of any variables in it), while we want `@time` to be usable with minimum impact on the wrapped code.

Macros and dispatch

Macros, just like Julia functions, are generic. This means they can also have multiple method definitions, thanks to multiple dispatch:

```
julia> macro m end
@m (macro with 0 methods)

julia> macro m(args...)
    println("$(length(args)) arguments")
end
@m (macro with 1 method)

julia> macro m(x,y)
    println("Two arguments")
end
@m (macro with 2 methods)

julia> @m "asd"
1 arguments

julia> @m 1 2
Two arguments
```

However one should keep in mind, that macro dispatch is based on the types of AST that are handed to the macro, not the types that the AST evaluates to at runtime:

```
julia> macro m(::Int)
    println("An Integer")
end
@m (macro with 3 methods)
```

```
julia> @m 2
An Integer

julia> x = 2
2

julia> @m x
1 arguments
```

18.4 Code Generation

When a significant amount of repetitive boilerplate code is required, it is common to generate it programmatically to avoid redundancy. In most languages, this requires an extra build step, and a separate program to generate the repetitive code. In Julia, expression interpolation and `eval` allow such code generation to take place in the normal course of program execution. For example, consider the following custom type

```
struct MyNumber
    x::Float64
end
# output
```

for which we want to add a number of methods to. We can do this programmatically in the following loop:

```
for op = (:sin, :cos, :tan, :log, :exp)
    eval(quote
        Base.$op(a::MyNumber) = MyNumber($op(a.x))
    end)
end
# output
```

and we can now use those functions with our custom type:

```
julia> x = MyNumber(π)
MyNumber(3.141592653589793)

julia> sin(x)
MyNumber(1.2246467991473532e-16)

julia> cos(x)
MyNumber(-1.0)
```

In this manner, Julia acts as its own `preprocessor`, and allows code generation from inside the language. The above code could be written slightly more tersely using the `:` prefix quoting form:

```
for op = (:sin, :cos, :tan, :log, :exp)
    eval(:(Base.$op(a::MyNumber) = MyNumber($op(a.x))))
end
```

This sort of in-language code generation, however, using the `eval(quote(...))` pattern, is common enough that Julia comes with a macro to abbreviate this pattern:

```
for op = (:sin, :cos, :tan, :log, :exp)
    @eval Base.$op(a::MyNumber) = MyNumber($op(a.x))
end
```

The `@eval` macro rewrites this call to be precisely equivalent to the above longer versions. For longer blocks of generated code, the expression argument given to `@eval` can be a block:

```
@eval begin
    # multiple lines
end
```

18.5 Non-Standard String Literals

Recall from [Strings](#) that string literals prefixed by an identifier are called non-standard string literals, and can have different semantics than un-prefixed string literals. For example:

- `r"\s*(?:#|$)"` produces a [regular expression object](#) rather than a string
- `b"DATA\xff\u2200"` is a [byte array literal](#) for `[68,65,84,65,255,226,136,128]`.

Perhaps surprisingly, these behaviors are not hard-coded into the Julia parser or compiler. Instead, they are custom behaviors provided by a general mechanism that anyone can use: prefixed string literals are parsed as calls to specially-named macros. For example, the regular expression macro is just the following:

```
macro r_str(p)
    Regex(p)
end
```

That's all. This macro says that the literal contents of the string literal `r"\s*(?:#|$)"` should be passed to the `@r_str` macro and the result of that expansion should be placed in the syntax tree where the string literal occurs. In other words, the expression `r"\s*(?:#|$)"` is equivalent to placing the following object directly into the syntax tree:

```
Regex("\s*(?:#|$)")
```

Not only is the string literal form shorter and far more convenient, but it is also more efficient: since the regular expression is compiled and the `Regex` object is actually created when the code is compiled, the compilation occurs only once, rather than every time the code is executed. Consider if the regular expression occurs in a loop:

```
for line = lines
    m = match(r"\s*(?:#|$)", line)
    if m == nothing
        # non-comment
    end
end
```

```

    else
        # comment
    end
end

```

Since the regular expression `r"^\\s*(?:#|\\$)"` is compiled and inserted into the syntax tree when this code is parsed, the expression is only compiled once instead of each time the loop is executed. In order to accomplish this without macros, one would have to write this loop like this:

```

re = Regex("\\s*(?:#|\\$)")
for line = lines
    m = match(re, line)
    if m == nothing
        # non-comment
    else
        # comment
    end
end

```

Moreover, if the compiler could not determine that the regex object was constant over all loops, certain optimizations might not be possible, making this version still less efficient than the more convenient literal form above. Of course, there are still situations where the non-literal form is more convenient: if one needs to interpolate a variable into the regular expression, one must take this more verbose approach; in cases where the regular expression pattern itself is dynamic, potentially changing upon each loop iteration, a new regular expression object must be constructed on each iteration. In the vast majority of use cases, however, regular expressions are not constructed based on run-time data. In this majority of cases, the ability to write regular expressions as compile-time values is invaluable.

The mechanism for user-defined string literals is deeply, profoundly powerful. Not only are Julia's non-standard literals implemented using it, but the command literal syntax (``echo "Hello, $person"``) is also implemented using the following innocuous-looking macro:

```

macro cmd(str)
    :(cmd_gen($(shell_parse(str)[1])))
end

```

Of course, a large amount of complexity is hidden in the functions used in this macro definition, but they are just functions, written entirely in Julia. You can read their source and see precisely what they do – and all they do is construct expression objects to be inserted into your program's syntax tree.

Like string literals, command literals can also be prefixed by an identifier to form what are called non-standard command literals. These command literals are parsed as calls to specially-named macros. For example, the syntax `custom`literal`` is parsed as `@custom_cmd "literal"`. Julia itself does not contain any non-standard command literals, but packages can make use of this syntax. Aside from the different syntax and the `_cmd` suffix instead of the `_str` suffix, non-standard command literals behave exactly like non-standard string literals.

In the event that two modules provide non-standard string or command literals with the same name, it is possible to qualify the string or command literal with a module name. For instance, if both `Foo` and `Bar` provide non-standard string literal `@x_str`, then one can write `Foo.x"literal"` or `Bar.x"literal"` to disambiguate between the two.

Another way to define a macro would be like this:

```
macro foo_str(str, flag)
  # do stuff
end
```

This macro can then be called with the following syntax:

```
foo"str"flag
```

The type of flag in the above mentioned syntax would be a String with contents of whatever trails after the string literal.

18.6 Generated functions

A very special macro is `@generated`, which allows you to define so-called generated functions. These have the capability to generate specialized code depending on the types of their arguments with more flexibility and/or less code than what can be achieved with multiple dispatch. While macros work with expressions at parse time and cannot access the types of their inputs, a generated function gets expanded at a time when the types of the arguments are known, but the function is not yet compiled.

Instead of performing some calculation or action, a generated function declaration returns a quoted expression which then forms the body for the method corresponding to the types of the arguments. When a generated function is called, the expression it returns is compiled and then run. To make this efficient, the result is usually cached. And to make this inferable, only a limited subset of the language is usable. Thus, generated functions provide a flexible way to move work from run time to compile time, at the expense of greater restrictions on allowed constructs.

When defining generated functions, there are five main differences to ordinary functions:

1. You annotate the function declaration with the `@generated` macro. This adds some information to the AST that lets the compiler know that this is a generated function.
2. In the body of the generated function you only have access to the types of the arguments – not their values.
3. Instead of calculating something or performing some action, you return a quoted expression which, when evaluated, does what you want.
4. Generated functions are only permitted to call functions that were defined before the definition of the generated function. (Failure to follow this may result in getting `MethodErrors` referring to functions from a future world-age.)
5. Generated functions must not mutate or observe any non-constant global state (including, for example, IO, locks, non-local dictionaries, or using `hasmethod`). This means they can only read global constants, and cannot have any side effects. In other words, they must be completely pure. Due to an implementation limitation, this also means that they currently cannot define a closure or generator.

It's easiest to illustrate this with an example. We can declare a generated function `foo` as

```
julia> @generated function foo(x)
    Core.println(x)
    return :(x * x)
end
foo (generic function with 1 method)
```

Note that the body returns a quoted expression, namely `:(x * x)`, rather than just the value of `x * x`.

From the caller's perspective, this is identical to a regular function; in fact, you don't have to know whether you're calling a regular or generated function. Let's see how `foo` behaves:

```
julia> x = foo(2); # note: output is from println() statement in the body
Int64

julia> x          # now we print x
4

julia> y = foo("bar");
String

julia> y
"barbar"
```

So, we see that in the body of the generated function, `x` is the type of the passed argument, and the value returned by the generated function, is the result of evaluating the quoted expression we returned from the definition, now with the value of `x`.

What happens if we evaluate `foo` again with a type that we have already used?

```
julia> foo(4)
16
```

Note that there is no printout of `Int64`. We can see that the body of the generated function was only executed once here, for the specific set of argument types, and the result was cached. After that, for this example, the expression returned from the generated function on the first invocation was re-used as the method body. However, the actual caching behavior is an implementation-defined performance optimization, so it is invalid to depend too closely on this behavior.

The number of times a generated function is generated might be only once, but it might also be more often, or appear to not happen at all. As a consequence, you should never write a generated function with side effects - when, and how often, the side effects occur is undefined. (This is true for macros too - and just like for macros, the use of `eval` in a generated function is a sign that you're doing something the wrong way.) However, unlike macros, the runtime system cannot correctly handle a call to `eval`, so it is disallowed.

It is also important to see how `@generated` functions interact with method redefinition. Following the principle that a correct `@generated` function must not observe any mutable state or cause any mutation of global state, we see the following behavior. Observe that the generated function cannot call any method that was not defined prior to the definition of the generated function itself.

Initially `f(x)` has one definition

```
julia> f(x) = "original definition";
```

Define other operations that use `f(x)`:

```
julia> g(x) = f(x);

julia> @generated gen1(x) = f(x);

julia> @generated gen2(x) = :(f(x));
```

We now add some new definitions for `f(x)`:

```
julia> f(x::Int) = "definition for Int";

julia> f(x::Type{Int}) = "definition for Type{Int}";
```

and compare how these results differ:

```
julia> f(1)
"definition for Int"

julia> g(1)
"definition for Int"

julia> gen1(1)
"original definition"

julia> gen2(1)
"definition for Int"
```

Each method of a generated function has its own view of defined functions:

```
julia> @generated gen1(x::Real) = f(x);

julia> gen1(1)
"definition for Type{Int}"
```

The example generated function `foo` above did not do anything a normal function `foo(x) = x * x` could not do (except printing the type on the first invocation, and incurring higher overhead). However, the power of a generated function lies in its ability to compute different quoted expressions depending on the types passed to it:

```
julia> @generated function bar(x)
    if x <: Integer
        return :(x ^ 2)
    else
        return :(x)
    end
end

bar (generic function with 1 method)
```

```
julia> bar(4)
16

julia> bar("baz")
"baz"
```

(although of course this contrived example would be more easily implemented using multiple dispatch...)

Abusing this will corrupt the runtime system and cause undefined behavior:

```
julia> @generated function baz(x)
    if rand() < .9
        return :(x^2)
    else
        return :( "boo!" )
    end
end
baz (generic function with 1 method)
```

Since the body of the generated function is non-deterministic, its behavior, and the behavior of all subsequent code is undefined.

Don't copy these examples!

These examples are hopefully helpful to illustrate how generated functions work, both in the definition end and at the call site; however, don't copy them, for the following reasons:

- the foo function has side-effects (the call to `Core.println`), and it is undefined exactly when, how often or how many times these side-effects will occur
- the bar function solves a problem that is better solved with multiple dispatch - defining `bar(x) = x` and `bar(x::Integer) = x ^ 2` will do the same thing, but it is both simpler and faster.
- the baz function is pathological

Note that the set of operations that should not be attempted in a generated function is unbounded, and the runtime system can currently only detect a subset of the invalid operations. There are many other operations that will simply corrupt the runtime system without notification, usually in subtle ways not obviously connected to the bad definition. Because the function generator is run during inference, it must respect all of the limitations of that code.

Some operations that should not be attempted include:

1. Caching of native pointers.
2. Interacting with the contents or methods of `Core.Compiler` in any way.
3. Observing any mutable state.
 - Inference on the generated function may be run at any time, including while your code is attempting to observe or mutate this state.

4. Taking any locks: C code you call out to may use locks internally, (for example, it is not problematic to call `malloc`, even though most implementations require locks internally) but don't attempt to hold or acquire any while executing Julia code.
5. Calling any function that is defined after the body of the generated function. This condition is relaxed for incrementally-loaded precompiled modules to allow calling any function in the module.

Alright, now that we have a better understanding of how generated functions work, let's use them to build some more advanced (and valid) functionality...

An advanced example

Julia's base library has an internal `sub2ind` function to calculate a linear index into an n-dimensional array, based on a set of n multilinear indices - in other words, to calculate the index `i` that can be used to index into an array `A` using `A[i]`, instead of `A[x,y,z,...]`. One possible implementation is the following:

```
julia> function sub2ind_loop(dims::NTuple{N}, I::Integer...) where N
    ind = I[N] - 1
    for i = N-1:-1:1
        ind = I[i]-1 + dims[i]*ind
    end
    return ind + 1
end
sub2ind_loop (generic function with 1 method)
```

```
julia> sub2ind_loop((3, 5), 1, 2)
4
```

The same thing can be done using recursion:

```
julia> sub2ind_rec(dims::Tuple{}) = 1;

julia> sub2ind_rec(dims::Tuple{}, i1::Integer, I::Integer...) =
    i1 == 1 ? sub2ind_rec(dims, I...) : throw(BoundsError());

julia> sub2ind_rec(dims::Tuple{Integer, Vararg{Integer}}, i1::Integer) = i1;

julia> sub2ind_rec(dims::Tuple{Integer, Vararg{Integer}}, i1::Integer, I::Integer...) =
    i1 + dims[1] * (sub2ind_rec(Base.tail(dims), I...) - 1);

julia> sub2ind_rec((3, 5), 1, 2)
4
```

Both these implementations, although different, do essentially the same thing: a runtime loop over the dimensions of the array, collecting the offset in each dimension into the final index.

However, all the information we need for the loop is embedded in the type information of the arguments. This allows the compiler to move the iteration to compile time and eliminate the runtime loops altogether. We can utilize generated functions to achieve a similar effect; in compiler parlance, we use generated functions to manually unroll the loop. The body becomes almost identical, but instead of calculating the linear index, we build up an expression that calculates the index:

```
julia> @generated function sub2ind_gen(dims::NTuple{N}, I::Integer...) where N
    ex = :(I[$N] - 1)
    for i = (N - 1):-1:1
        ex = :(I[$i] - 1 + dims[$i] * $ex)
    end
    return :($ex + 1)
end
sub2ind_gen (generic function with 1 method)

julia> sub2ind_gen((3, 5), 1, 2)
4
```

What code will this generate?

An easy way to find out is to extract the body into another (regular) function:

```
julia> @generated function sub2ind_gen(dims::NTuple{N}, I::Integer...) where N
    return sub2ind_gen_impl(dims, I...)
end
sub2ind_gen (generic function with 1 method)

julia> function sub2ind_gen_impl(dims::Type{T}, I...) where T <: NTuple{N,Any} where N
    length(I) == N || return :(error("partial indexing is unsupported"))
    ex = :(I[$N] - 1)
    for i = (N - 1):-1:1
        ex = :(I[$i] - 1 + dims[$i] * $ex)
    end
    return :($ex + 1)
end
sub2ind_gen_impl (generic function with 1 method)
```

We can now execute `sub2ind_gen_impl` and examine the expression it returns:

```
julia> sub2ind_gen_impl(Tuple{Int,Int}, Int, Int)
:(((I[1] - 1) + dims[1] * (I[2] - 1)) + 1)
```

So, the method body that will be used here doesn't include a loop at all - just indexing into the two tuples, multiplication and addition/subtraction. All the looping is performed compile-time, and we avoid looping during execution entirely. Thus, we only loop once per type, in this case once per `N` (except in edge cases where the function is generated more than once - see disclaimer above).

Optionally-generated functions

Generated functions can achieve high efficiency at run time, but come with a compile time cost: a new function body must be generated for every combination of concrete argument types. Typically, Julia is able to compile "generic" versions of functions that will work for any arguments, but with generated functions this is impossible. This means that programs making heavy use of generated functions might be impossible to statically compile.

To solve this problem, the language provides syntax for writing normal, non-generated alternative implementations of generated functions. Applied to the `sub2ind` example above, it would look like this:

```

function sub2ind_gen(dims::NTuple{N}, I::Integer...) where N
    if N != length(I)
        throw(ArgumentError("Number of dimensions must match number of indices."))
    end
    if @generated
        ex = :(I[$N] - 1)
        for i = (N - 1):-1:1
            ex = :(I[$i] - 1 + dims[$i] * $ex)
        end
        return :($ex + 1)
    else
        ind = I[N] - 1
        for i = (N - 1):-1:1
            ind = I[i] - 1 + dims[i]*ind
        end
        return ind + 1
    end
end
end

```

Internally, this code creates two implementations of the function: a generated one where the first block in `if @generated` is used, and a normal one where the `else` block is used. Inside the then part of the `if @generated` block, code has the same semantics as other generated functions: argument names refer to types, and the code should return an expression. Multiple `if @generated` blocks may occur, in which case the generated implementation uses all of the then blocks and the alternate implementation uses all of the `else` blocks.

Notice that we added an error check to the top of the function. This code will be common to both versions, and is run-time code in both versions (it will be quoted and returned as an expression from the generated version). That means that the values and types of local variables are not available at code generation time -- the code-generation code can only see the types of arguments.

In this style of definition, the code generation feature is essentially an optional optimization. The compiler will use it if convenient, but otherwise may choose to use the normal implementation instead. This style is preferred, since it allows the compiler to make more decisions and compile programs in more ways, and since normal code is more readable than code-generating code. However, which implementation is used depends on compiler implementation details, so it is essential for the two implementations to behave identically.

Chapter 19

Single- and multi-dimensional Arrays

Julia, like most technical computing languages, provides a first-class array implementation. Most technical computing languages pay a lot of attention to their array implementation at the expense of other containers. Julia does not treat arrays in any special way. The array library is implemented almost completely in Julia itself, and derives its performance from the compiler, just like any other code written in Julia. As such, it's also possible to define custom array types by inheriting from [AbstractArray](#). See the [manual section on the AbstractArray interface](#) for more details on implementing a custom array type.

An array is a collection of objects stored in a multi-dimensional grid. Zero-dimensional arrays are allowed, see [this FAQ entry](#). In the most general case, an array may contain objects of type [Any](#). For most computational purposes, arrays should contain objects of a more specific type, such as [Float64](#) or [Int32](#).

In general, unlike many other technical computing languages, Julia does not expect programs to be written in a vectorized style for performance. Julia's compiler uses type inference and generates optimized code for scalar array indexing, allowing programs to be written in a style that is convenient and readable, without sacrificing performance, and using less memory at times.

In Julia, all arguments to functions are [passed by sharing](#) (i.e. by pointers). Some technical computing languages pass arrays by value, and while this prevents accidental modification by callees of a value in the caller, it makes avoiding unwanted copying of arrays difficult. By convention, a function name ending with a `!` indicates that it will mutate or destroy the value of one or more of its arguments (compare, for example, [sort](#) and [sort!](#)). Callees must make explicit copies to ensure that they don't modify inputs that they don't intend to change. Many non-mutating functions are implemented by calling a function of the same name with an added `!` at the end on an explicit copy of the input, and returning that copy.

19.1 Basic Functions

19.2 Construction and Initialization

Many functions for constructing and initializing arrays are provided. In the following list of such functions, calls with a `dims...` argument can either take a single tuple of dimension sizes or a series of dimension sizes passed as a variable number of arguments. Most of these functions also accept a first input `T`, which is the element type of the array. If the type `T` is omitted it will default to [Float64](#).

To see the various ways we can pass dimensions to these functions, consider the following examples:

¹iid, independently and identically distributed.

| Function | Description |
|---------------------------|--|
| <code>eltype(A)</code> | the type of the elements contained in A |
| <code>length(A)</code> | the number of elements in A |
| <code>ndims(A)</code> | the number of dimensions of A |
| <code>size(A)</code> | a tuple containing the dimensions of A |
| <code>size(A,n)</code> | the size of A along dimension n |
| <code>axes(A)</code> | a tuple containing the valid indices of A |
| <code>axes(A,n)</code> | a range expressing the valid indices along dimension n |
| <code>eachindex(A)</code> | an efficient iterator for visiting each position in A |
| <code>stride(A,k)</code> | the stride (linear index distance between adjacent elements) along dimension k |
| <code>strides(A)</code> | a tuple of the strides in each dimension |

```
julia> zeros{Int8, 2, 3}
2×3 Matrix{Int8}:
 0  0  0
 0  0  0

julia> zeros{Int8, (2, 3)}
2×3 Matrix{Int8}:
 0  0  0
 0  0  0

julia> zeros((2, 3))
2×3 Matrix{Float64}:
 0.0  0.0  0.0
 0.0  0.0  0.0
```

Here, `(2, 3)` is a [Tuple](#) and the first argument — the element type — is optional, defaulting to `Float64`.

19.3 Array literals

Arrays can also be directly constructed with square braces; the syntax `[A, B, C, ...]` creates a one-dimensional array (i.e., a vector) containing the comma-separated arguments as its elements. The element type (`eltype`) of the resulting array is automatically determined by the types of the arguments inside the braces. If all the arguments are the same type, then that is its `eltype`. If they all have a common [promotion type](#) then they get converted to that type using `convert` and that type is the array's `eltype`. Otherwise, a heterogeneous array that can hold anything — a `Vector{Any}` — is constructed; this includes the literal `[]` where no arguments are given. [Array literal can be typed](#) with the syntax `T[A, B, C, ...]` where `T` is a type.

```
julia> [1, 2, 3] # An array of `Int`s
3-element Vector{Int64}:
 1
 2
 3

julia> promote(1, 2.3, 4//5) # This combination of Int, Float64 and Rational promotes to Float64
(1.0, 2.3, 0.8)
```

| Function | Description |
|---------------------------------------|--|
| <code>Array{T}(undef, dims...)</code> | an uninitialized dense <code>Array</code> |
| <code>zeros(T, dims...)</code> | an <code>Array</code> of all zeros |
| <code>ones(T, dims...)</code> | an <code>Array</code> of all ones |
| <code>trues(dims...)</code> | a <code>BitArray</code> with all values true |
| <code>false(dims...)</code> | a <code>BitArray</code> with all values false |
| <code>reshape(A, dims...)</code> | an array containing the same data as <code>A</code> , but with different dimensions |
| <code>copy(A)</code> | copy <code>A</code> |
| <code>deepcopy(A)</code> | copy <code>A</code> , recursively copying its elements |
| <code>similar(A, T, dims...)</code> | an uninitialized array of the same type as <code>A</code> (dense, sparse, etc.), but with the specified element type and dimensions. The second and third arguments are both optional, defaulting to the element type and dimensions of <code>A</code> if omitted. |
| <code>reinterpret{T}(A)</code> | an array with the same binary data as <code>A</code> , but with element type <code>T</code> |
| <code>rand(T, dims...)</code> | an <code>Array</code> with random, iid ¹ and uniformly distributed values. For floating point types <code>T</code> , the values lie in the half-open interval $[0, 1)$. |
| <code>randn(T, dims...)</code> | an <code>Array</code> with random, iid and standard normally distributed values |
| <code>Matrix{T}(I, m, n)</code> | m-by-n identity matrix. Requires using <code>LinearAlgebra</code> for <code>I</code> . |
| <code>range(start, stop, n)</code> | a range of <code>n</code> linearly spaced elements from <code>start</code> to <code>stop</code> |
| <code>fill!(A, x)</code> | fill the array <code>A</code> with the value <code>x</code> |
| <code>fill(x, dims...)</code> | an <code>Array</code> filled with the value <code>x</code> . In particular, <code>fill(x)</code> constructs a zero-dimensional <code>Array</code> containing <code>x</code> . |

```

julia> [1, 2.3, 4//5] # Thus that's the element type of this Array
3-element Vector{Float64}:
 1.0
 2.3
 0.8

julia> Float32[1, 2.3, 4//5] # Specify element type manually
3-element Vector{Float32}:
 1.0
 2.3
 0.8

julia> []
Any[]

```

Concatenation

If the arguments inside the square brackets are separated by single semicolons (;) or newlines instead of commas, then their contents are vertically concatenated together instead of the arguments being used as

elements themselves.

```
julia> [1:2, 4:5] # Has a comma, so no concatenation occurs. The ranges are themselves the
↔ elements
2-element Vector{UnitRange{Int64}}:
 1:2
 4:5

julia> [1:2; 4:5]
4-element Vector{Int64}:
 1
 2
 4
 5

julia> [1:2
        4:5
        6]
5-element Vector{Int64}:
 1
 2
 4
 5
 6
```

Similarly, if the arguments are separated by tabs or spaces or double semicolons, then their contents are horizontally concatenated together.

```
julia> [1:2 4:5 7:8]
2×3 Matrix{Int64}:
 1  4  7
 2  5  8

julia> [[1,2] [4,5] [7,8]]
2×3 Matrix{Int64}:
 1  4  7
 2  5  8

julia> [1 2 3] # Numbers can also be horizontally concatenated
1×3 Matrix{Int64}:
 1  2  3

julia> [1;; 2;; 3;; 4]
1×4 Matrix{Int64}:
 1  2  3  4
```

Single semicolons (or newlines) and spaces (or tabs) can be combined to concatenate both horizontally and vertically at the same time.

```
julia> [1 2
        3 4]
```

```

2×2 Matrix{Int64}:
 1  2
 3  4

julia> [zeros{Int, 2, 2} [1; 2]
      [3 4]           5]
3×3 Matrix{Int64}:
 0  0  1
 0  0  2
 3  4  5

julia> [[1 1]; 2 3; [4 4]]
3×2 Matrix{Int64}:
 1  1
 2  3
 4  4

```

Spaces (and tabs) have a higher precedence than semicolons, performing any horizontal concatenations first and then concatenating the result. Using double semicolons for the horizontal concatenation, on the other hand, performs any vertical concatenations before horizontally concatenating the result.

```

julia> [zeros{Int, 2, 2} ; [3 4] ;; [1; 2] ; 5]
3×3 Matrix{Int64}:
 0  0  1
 0  0  2
 3  4  5

julia> [1:2; 4;; 1; 3:4]
3×2 Matrix{Int64}:
 1  1
 2  3
 4  4

```

Just as `;` and `;;` concatenate in the first and second dimension, using more semicolons extends this same general scheme. The number of semicolons in the separator specifies the particular dimension, so `;;;` concatenates in the third dimension, `;;;;` in the 4th, and so on. Fewer semicolons take precedence, so the lower dimensions are generally concatenated first.

```

julia> [1; 2;; 3; 4;; 5; 6;;;
      7; 8;; 9; 10;; 11; 12]
2×3×2 Array{Int64, 3}:
[:, :, 1] =
 1  3  5
 2  4  6

[:, :, 2] =
 7  9  11
 8  10 12

```

Like before, spaces (and tabs) for horizontal concatenation have a higher precedence than any number of semicolons. Thus, higher-dimensional arrays can also be written by specifying their rows first, with their elements textually arranged in a manner similar to their layout:

```

julia> [1 3 5
        2 4 6;;;
        7 9 11
        8 10 12]
2×3×2 Array{Int64, 3}:
[:, :, 1] =
 1 3 5
 2 4 6

[:, :, 2] =
 7 9 11
 8 10 12

julia> [1 2;;; 3 4;;; 5 6;;; 7 8]
1×2×2×2 Array{Int64, 4}:
[:, :, 1, 1] =
 1 2

[:, :, 2, 1] =
 3 4

[:, :, 1, 2] =
 5 6

[:, :, 2, 2] =
 7 8

julia> [[1 2;;; 3 4];; [5 6];; [7 8]]
1×2×2×2 Array{Int64, 4}:
[:, :, 1, 1] =
 1 2

[:, :, 2, 1] =
 3 4

[:, :, 1, 2] =
 5 6

[:, :, 2, 2] =
 7 8

```

Although they both mean concatenation in the second dimension, spaces (or tabs) and `;;` cannot appear in the same array expression unless the double semicolon is simply serving as a "line continuation" character. This allows a single horizontal concatenation to span multiple lines (without the line break being interpreted as a vertical concatenation).

```

julia> [1 2 ;;
        3 4]
1×4 Matrix{Int64}:
 1 2 3 4

```

Terminating semicolons may also be used to add trailing length 1 dimensions.

```
julia> [1;;]
1×1 Matrix{Int64}:
 1

julia> [2; 3;;;]
2×1×1 Array{Int64, 3}:
[:, :, 1] =
 2
 3
```

More generally, concatenation can be accomplished through the `cat` function. These syntaxes are short-hands for function calls that themselves are convenience functions:

| Syntax | Function | Description |
|-----------------------------------|----------------------|--|
| | <code>cat</code> | concatenate input arrays along dimension(s) <code>k</code> |
| <code>[A; B; C; ...]</code> | <code>vcat</code> | shorthand for <code>cat(A...; dims=1)</code> |
| <code>[A B C ...]</code> | <code>hcat</code> | shorthand for <code>cat(A...; dims=2)</code> |
| <code>[A B; C D; ...]</code> | <code>hvcats</code> | simultaneous vertical and horizontal concatenation |
| <code>[A; C;; B; D;;; ...]</code> | <code>hvncats</code> | simultaneous n-dimensional concatenation, where number of semicolons indicate the dimension to concatenate |

Typed array literals

An array with a specific element type can be constructed using the syntax `T[A, B, C, ...]`. This will construct a 1-d array with element type `T`, initialized to contain elements `A, B, C`, etc. For example, `Any[x, y, z]` constructs a heterogeneous array that can contain any values.

Concatenation syntax can similarly be prefixed with a type to specify the element type of the result.

```
julia> [[1 2] [3 4]]
1×4 Matrix{Int64}:
 1  2  3  4

julia> Int8[[1 2] [3 4]]
1×4 Matrix{Int8}:
 1  2  3  4
```

19.4 Comprehensions

Comprehensions provide a general and powerful way to construct arrays. Comprehension syntax is similar to set construction notation in mathematics:

```
A = [ F(x, y, ...) for x=rx, y=ry, ... ]
```

The meaning of this form is that `F(x, y, ...)` is evaluated with the variables `x, y`, etc. taking on each value in their given list of values. Values can be specified as any iterable object, but will commonly be ranges like `1:n` or `2:(n-1)`, or explicit arrays of values like `[1.2, 3.4, 5.7]`. The result is an N-d dense array

with dimensions that are the concatenation of the dimensions of the variable ranges rx , ry , etc. and each $F(x, y, \dots)$ evaluation returns a scalar.

The following example computes a weighted average of the current element and its left and right neighbor along a 1-d grid. :

```
julia> x = rand(8)
8-element Array{Float64,1}:
 0.843025
 0.869052
 0.365105
 0.699456
 0.977653
 0.994953
 0.41084
 0.809411

julia> [ 0.25*x[i-1] + 0.5*x[i] + 0.25*x[i+1] for i=2:length(x)-1 ]
6-element Array{Float64,1}:
 0.736559
 0.57468
 0.685417
 0.912429
 0.8446
 0.656511
```

The resulting array type depends on the types of the computed elements just like [array literals](#) do. In order to control the type explicitly, a type can be prepended to the comprehension. For example, we could have requested the result in single precision by writing:

```
Float32[ 0.25*x[i-1] + 0.5*x[i] + 0.25*x[i+1] for i=2:length(x)-1 ]
```

19.5 Generator Expressions

Comprehensions can also be written without the enclosing square brackets, producing an object known as a generator. This object can be iterated to produce values on demand, instead of allocating an array and storing them in advance (see [Iteration](#)). For example, the following expression sums a series without allocating memory:

```
julia> sum(1/n^2 for n=1:1000)
1.6439345666815615
```

When writing a generator expression with multiple dimensions inside an argument list, parentheses are needed to separate the generator from subsequent arguments:

```
julia> map(tuple, 1/(i+j) for i=1:2, j=1:2, [1:4;])
ERROR: syntax: invalid iteration specification
```

All comma-separated expressions after `for` are interpreted as ranges. Adding parentheses lets us add a third argument to `map`:

```
julia> map(tuple, (1/(i+j) for i=1:2, j=1:2), [1 3; 2 4])
2×2 Matrix{Tuple{Float64, Int64}}:
 (0.5, 1)      (0.333333, 3)
 (0.333333, 2) (0.25, 4)
```

Generators are implemented via inner functions. Just like inner functions used elsewhere in the language, variables from the enclosing scope can be "captured" in the inner function. For example, `sum(p[i] - q[i] for i=1:n)` captures the three variables `p`, `q` and `n` from the enclosing scope. Captured variables can present performance challenges; see [performance tips](#).

Ranges in generators and comprehensions can depend on previous ranges by writing multiple `for` keywords:

```
julia> [(i, j) for i=1:3 for j=1:i]
6-element Vector{Tuple{Int64, Int64}}:
 (1, 1)
 (2, 1)
 (2, 2)
 (3, 1)
 (3, 2)
 (3, 3)
```

In such cases, the result is always 1-d.

Generated values can be filtered using the `if` keyword:

```
julia> [(i, j) for i=1:3 for j=1:i if i+j == 4]
2-element Vector{Tuple{Int64, Int64}}:
 (2, 2)
 (3, 1)
```

19.6 Indexing

The general syntax for indexing into an n -dimensional array `A` is:

```
X = A[I_1, I_2, ..., I_n]
```

where each `I_k` may be a scalar integer, an array of integers, or any other [supported index](#). This includes [Colon](#) (`:`) to select all indices within the entire dimension, ranges of the form `a:c` or `a:b:c` to select contiguous or strided subsections, and arrays of booleans to select elements at their `true` indices.

If all the indices are scalars, then the result `X` is a single element from the array `A`. Otherwise, `X` is an array with the same number of dimensions as the sum of the dimensionalities of all the indices.

If all indices `I_k` are vectors, for example, then the shape of `X` would be `(length(I_1), length(I_2), ..., length(I_n))`, with location `i_1`, `i_2`, ..., `i_n` of `X` containing the value `A[I_1[i_1], I_2[i_2], ..., I_n[i_n]]`.

Example:

```
julia> A = reshape(collect(1:16), (2, 2, 2, 2))
2×2×2×2 Array{Int64, 4}:
```

```

[:, :, 1, 1] =
 1  3
 2  4

[:, :, 2, 1] =
 5  7
 6  8

[:, :, 1, 2] =
 9 11
10 12

[:, :, 2, 2] =
13 15
14 16

julia> A[1, 2, 1, 1] # all scalar indices
3

julia> A[[1, 2], [1], [1, 2], [1]] # all vector indices
2×1×2×1 Array{Int64, 4}:
[:, :, 1, 1] =
 1
 2

[:, :, 2, 1] =
 5
 6

julia> A[[1, 2], [1], [1, 2], 1] # a mix of index types
2×1×2 Array{Int64, 3}:
[:, :, 1] =
 1
 2

[:, :, 2] =
 5
 6

```

Note how the size of the resulting array is different in the last two cases.

If `I_1` is changed to a two-dimensional matrix, then `X` becomes an $n+1$ -dimensional array of shape `(size(I_1, 1), size(I_1, 2), length(I_2), ..., length(I_n))`. The matrix adds a dimension.

Example:

```

julia> A = reshape(collect(1:16), (2, 2, 2, 2));

julia> A[[1 2; 1 2]]
2×2 Matrix{Int64}:
 1  2
 1  2

```

```
julia> A[[1 2; 1 2], 1, 2, 1]
2×2 Matrix{Int64}:
 5  6
 5  6
```

The location $i_1, i_2, i_3, \dots, i_{n+1}$ contains the value at $A[I_1[i_1, i_2], I_2[i_3], \dots, I_n[i_{n+1}]]$. All dimensions indexed with scalars are dropped. For example, if J is an array of indices, then the result of $A[2, J, 3]$ is an array with size $\text{size}(J)$. Its j th element is populated by $A[2, J[j], 3]$.

As a special part of this syntax, the end keyword may be used to represent the last index of each dimension within the indexing brackets, as determined by the size of the innermost array being indexed. Indexing syntax without the end keyword is equivalent to a call to `getindex`:

```
X = getindex(A, I_1, I_2, ..., I_n)
```

Example:

```
julia> x = reshape(1:16, 4, 4)
4×4 reshape{::UnitRange{Int64}, 4, 4} with eltype Int64:
 1  5  9 13
 2  6 10 14
 3  7 11 15
 4  8 12 16

julia> x[2:3, 2:end-1]
2×2 Matrix{Int64}:
 6 10
 7 11

julia> x[1, [2 3; 4 1]]
2×2 Matrix{Int64}:
 5  9
13  1
```

19.7 Indexed Assignment

The general syntax for assigning values in an n -dimensional array A is:

```
A[I_1, I_2, ..., I_n] = X
```

where each I_k may be a scalar integer, an array of integers, or any other [supported index](#). This includes `Colon` (`:`) to select all indices within the entire dimension, ranges of the form $a:c$ or $a:b:c$ to select contiguous or strided subsections, and arrays of booleans to select elements at their true indices.

If all indices I_k are integers, then the value in location I_1, I_2, \dots, I_n of A is overwritten with the value of X , [converting](#) to the [eltype](#) of A if necessary.

If any index I_k is itself an array, then the right hand side X must also be an array with the same shape as the result of indexing $A[I_1, I_2, \dots, I_n]$ or a vector with the same number of elements. The value in location $I_1[i_1], I_2[i_2], \dots, I_n[i_n]$ of A is overwritten with the value $X[I_1, I_2, \dots, I_n]$, converting if necessary. The element-wise assignment operator `.=` may be used to [broadcast](#) X across the selected locations:

```
| A[I_1, I_2, ..., I_n] .= X
```

Just as in [Indexing](#), the end keyword may be used to represent the last index of each dimension within the indexing brackets, as determined by the size of the array being assigned into. Indexed assignment syntax without the end keyword is equivalent to a call to [setindex!](#):

```
| setindex!(A, X, I_1, I_2, ..., I_n)
```

Example:

```
julia> x = collect(reshape(1:9, 3, 3))
3×3 Matrix{Int64}:
 1  4  7
 2  5  8
 3  6  9

julia> x[3, 3] = -9;

julia> x[1:2, 1:2] = [-1 -4; -2 -5];

julia> x
3×3 Matrix{Int64}:
-1  -4   7
-2  -5   8
 3   6  -9
```

19.8 Supported index types

In the expression `A[I_1, I_2, ..., I_n]`, each `I_k` may be a scalar index, an array of scalar indices, or an object that represents an array of scalar indices and can be converted to such by [to_indices](#):

1. A scalar index. By default this includes:
 - Non-boolean integers
 - [CartesianIndex{N}](#)s, which behave like an N-tuple of integers spanning multiple dimensions (see below for more details)
2. An array of scalar indices. This includes:
 - Vectors and multidimensional arrays of integers
 - Empty arrays like `[]`, which select no elements e.g. `A[]` (not to be confused with `A[]`)
 - Ranges like `a:c` or `a:b:c`, which select contiguous or strided subsections from `a` to `c` (inclusive)
 - Any custom array of scalar indices that is a subtype of `AbstractArray`
 - Arrays of [CartesianIndex{N}](#) (see below for more details)
3. An object that represents an array of scalar indices and can be converted to such by [to_indices](#). By default this includes:
 - [Colon\(\)](#) `(:)`, which represents all indices within an entire dimension or across the entire array

- Arrays of booleans, which select elements at their true indices (see below for more details)

Some examples:

```
julia> A = reshape(collect(1:2:18), (3, 3))
3×3 Matrix{Int64}:
 1  7 13
 3  9 15
 5 11 17

julia> A[4]
7

julia> A[[2, 5, 8]]
3-element Vector{Int64}:
 3
 9
15

julia> A[[1 4; 3 8]]
2×2 Matrix{Int64}:
 1  7
 5 15

julia> A[[]]
Int64[]

julia> A[1:2:5]
3-element Vector{Int64}:
 1
 5
 9

julia> A[2, :]
3-element Vector{Int64}:
 3
 9
15

julia> A[:, 3]
3-element Vector{Int64}:
13
15
17

julia> A[:, 3:3]
3×1 Matrix{Int64}:
13
15
17
```

Cartesian indices

The special `CartesianIndex{N}` object represents a scalar index that behaves like an N-tuple of integers spanning multiple dimensions. For example:

```
julia> A = reshape(1:32, 4, 4, 2);

julia> A[3, 2, 1]
7

julia> A[CartesianIndex(3, 2, 1)] == A[3, 2, 1] == 7
true
```

Considered alone, this may seem relatively trivial; `CartesianIndex` simply gathers multiple integers together into one object that represents a single multidimensional index. When combined with other indexing forms and iterators that yield `CartesianIndex`s, however, this can produce very elegant and efficient code. See [iteration](#) below, and for some more advanced examples, see [this blog post on multidimensional algorithms and iteration](#).

Arrays of `CartesianIndex{N}` are also supported. They represent a collection of scalar indices that each span N dimensions, enabling a form of indexing that is sometimes referred to as pointwise indexing. For example, it enables accessing the diagonal elements from the first "page" of A from above:

```
julia> page = A[:, :, 1]
4×4 Matrix{Int64}:
 1  5  9 13
 2  6 10 14
 3  7 11 15
 4  8 12 16

julia> page[[CartesianIndex(1, 1),
              CartesianIndex(2, 2),
              CartesianIndex(3, 3),
              CartesianIndex(4, 4)]]
4-element Vector{Int64}:
 1
 6
11
16
```

This can be expressed much more simply with [dot broadcasting](#) and by combining it with a normal integer index (instead of extracting the first page from A as a separate step). It can even be combined with a `:` to extract both diagonals from the two pages at the same time:

```
julia> A[CartesianIndex.(axes(A, 1), axes(A, 2)), 1]
4-element Vector{Int64}:
 1
 6
11
16
```

```
julia> A[CartesianIndex.(axes(A, 1), axes(A, 2)), :]
4×2 Matrix{Int64}:
 1  17
 6  22
11  27
16  32
```

Warning

`CartesianIndex` and arrays of `CartesianIndex` are not compatible with the `end` keyword to represent the last index of a dimension. Do not use `end` in indexing expressions that may contain either `CartesianIndex` or arrays thereof.

Logical indexing

Often referred to as logical indexing or indexing with a logical mask, indexing by a boolean array selects elements at the indices where its values are `true`. Indexing by a boolean vector `B` is effectively the same as indexing by the vector of integers that is returned by `findall(B)`. Similarly, indexing by a N-dimensional boolean array is effectively the same as indexing by the vector of `CartesianIndex{N}`s where its values are `true`. A logical index must be a vector of the same length as the dimension it indexes into, or it must be the only index provided and match the size and dimensionality of the array it indexes into. It is generally more efficient to use boolean arrays as indices directly instead of first calling `findall`.

```
julia> x = reshape(1:16, 4, 4)
4×4 reshape{::UnitRange{Int64}, 4, 4} with eltype Int64:
 1  5  9 13
 2  6 10 14
 3  7 11 15
 4  8 12 16

julia> x[[false, true, true, false], :]
2×4 Matrix{Int64}:
 2  6 10 14
 3  7 11 15

julia> mask = map(ispow2, x)
4×4 Matrix{Bool}:
 1  0  0  0
 1  0  0  0
 0  0  0  0
 1  1  0  1

julia> x[mask]
5-element Vector{Int64}:
 1
 2
 4
 8
16
```

Number of indices

Cartesian indexing

The ordinary way to index into an N-dimensional array is to use exactly N indices; each index selects the position(s) in its particular dimension. For example, in the three-dimensional array `A = rand(4, 3, 2)`, `A[2, 3, 1]` will select the number in the second row of the third column in the first "page" of the array. This is often referred to as cartesian indexing.

Linear indexing

When exactly one index `i` is provided, that index no longer represents a location in a particular dimension of the array. Instead, it selects the *i*th element using the column-major iteration order that linearly spans the entire array. This is known as linear indexing. It essentially treats the array as though it had been reshaped into a one-dimensional vector with `vec`.

```
julia> A = [2 6; 4 7; 3 1]
3×2 Matrix{Int64}:
 2  6
 4  7
 3  1

julia> A[5]
7

julia> vec(A)[5]
7
```

A linear index into the array `A` can be converted to a `CartesianIndex` for cartesian indexing with `CartesianIndices(A)[i]` (see [CartesianIndices](#)), and a set of *N* cartesian indices can be converted to a linear index with `LinearIndices(A)[i_1, i_2, ..., i_N]` (see [LinearIndices](#)).

```
julia> CartesianIndices(A)[5]
CartesianIndex{2, 2}

julia> LinearIndices(A)[2, 2]
5
```

It's important to note that there's a very large asymmetry in the performance of these conversions. Converting a linear index to a set of cartesian indices requires dividing and taking the remainder, whereas going the other way is just multiplies and adds. In modern processors, integer division can be 10-50 times slower than multiplication. While some arrays — like `Array` itself — are implemented using a linear chunk of memory and directly use a linear index in their implementations, other arrays — like `Diagonal` — need the full set of cartesian indices to do their lookup (see [IndexStyle](#) to introspect which is which).

Warnings

When iterating over all the indices for an array, it is better to iterate over `eachindex(A)` instead of `1:length(A)`. Not only will this be faster in cases where `A` is `IndexCartesian`, but it will also support arrays with custom indexing, such as `OffsetArrays`. If only the values are needed, then is better to just iterate the array directly, i.e. `for a in A`.

Omitted and extra indices

In addition to linear indexing, an N-dimensional array may be indexed with fewer or more than N indices in certain situations.

Indices may be omitted if the trailing dimensions that are not indexed into are all length one. In other words, trailing indices can be omitted only if there is only one possible value that those omitted indices could be for an in-bounds indexing expression. For example, a four-dimensional array with size (3, 4, 2, 1) may be indexed with only three indices as the dimension that gets skipped (the fourth dimension) has length one. Note that linear indexing takes precedence over this rule.

```
julia> A = reshape(1:24, 3, 4, 2, 1)
3×4×2×1 reshape{::UnitRange{Int64}, 3, 4, 2, 1} with eltype Int64:
[:, :, 1, 1] =
 1  4  7 10
 2  5  8 11
 3  6  9 12

[:, :, 2, 1] =
13 16 19 22
14 17 20 23
15 18 21 24

julia> A[1, 3, 2] # Omits the fourth dimension (length 1)
19

julia> A[1, 3] # Attempts to omit dimensions 3 & 4 (lengths 2 and 1)
ERROR: BoundsError: attempt to access 3×4×2×1 reshape{::UnitRange{Int64}, 3, 4, 2, 1} with eltype
↪ Int64 at index [1, 3]

julia> A[19] # Linear indexing
19
```

When omitting all indices with `A[]`, this semantic provides a simple idiom to retrieve the only element in an array and simultaneously ensure that there was only one element.

Similarly, more than N indices may be provided if all the indices beyond the dimensionality of the array are 1 (or more generally are the first and only element of axes(A, d) where d is that particular dimension number). This allows vectors to be indexed like one-column matrices, for example:

```
julia> A = [8,6,7]
3-element Vector{Int64}:
 8
 6
 7

julia> A[2,1]
6
```

19.9 Iteration

The recommended ways to iterate over a whole array are

```

for a in A
    # Do something with the element a
end

for i in eachindex(A)
    # Do something with i and/or A[i]
end

```

The first construct is used when you need the value, but not index, of each element. In the second construct, `i` will be an `Int` if `A` is an array type with fast linear indexing; otherwise, it will be a `CartesianIndex`:

```

julia> A = rand(4, 3);

julia> B = view(A, 1:3, 2:3);

julia> for i in eachindex(B)
           @show i
       end
i = CartesianIndex(1, 1)
i = CartesianIndex(2, 1)
i = CartesianIndex(3, 1)
i = CartesianIndex(1, 2)
i = CartesianIndex(2, 2)
i = CartesianIndex(3, 2)

```

Note

In contrast with `for i = 1:length(A)`, iterating with `eachindex` provides an efficient way to iterate over any array type. Besides, this also supports generic arrays with custom indexing such as `OffsetArrays`.

19.10 Array traits

If you write a custom `AbstractArray` type, you can specify that it has fast linear indexing using

```
Base.IndexStyle{::Type{<:MyArray}} = IndexLinear()
```

This setting will cause `eachindex` iteration over a `MyArray` to use integers. If you don't specify this trait, the default value `IndexCartesian()` is used.

19.11 Array and Vectorized Operators and Functions

The following operators are supported for arrays:

1. Unary arithmetic – `-`, `+`
2. Binary arithmetic – `-`, `+`, `*`, `/`, `\`, `^`
3. Comparison – `==`, `!=`, `≈` (`isapprox`), `≠`

To enable convenient vectorization of mathematical and other operations, Julia [provides the dot syntax](#) `f.(args...)`, e.g. `sin.(x)` or `min.(x,y)`, for elementwise operations over arrays or mixtures of arrays and scalars (a [Broadcasting](#) operation); these have the additional advantage of "fusing" into a single loop when combined with other dot calls, e.g. `sin.(cos.(x))`.

Also, every binary operator supports a [dot version](#) that can be applied to arrays (and combinations of arrays and scalars) in such [fused broadcasting operations](#), e.g. `z .= sin.(x .* y)`.

Note that comparisons such as `==` operate on whole arrays, giving a single boolean answer. Use dot operators like `==` for elementwise comparisons. (For comparison operations like `<`, only the elementwise `.<` version is applicable to arrays.)

Also notice the difference between `max.(a,b)`, which [broadcasts](#) `max` elementwise over `a` and `b`, and `maximum(a)`, which finds the largest value within `a`. The same relationship holds for `min.(a,b)` and `minimum(a)`.

19.12 Broadcasting

It is sometimes useful to perform element-by-element binary operations on arrays of different sizes, such as adding a vector to each column of a matrix. An inefficient way to do this would be to replicate the vector to the size of the matrix:

```
julia> a = rand(2, 1); A = rand(2, 3);

julia> repeat(a, 1, 3) + A
2×3 Array{Float64,2}:
 1.20813  1.82068  1.25387
 1.56851  1.86401  1.67846
```

This is wasteful when dimensions get large, so Julia provides [broadcast](#), which expands singleton dimensions in array arguments to match the corresponding dimension in the other array without using extra memory, and applies the given function elementwise:

```
julia> broadcast(+, a, A)
2×3 Array{Float64,2}:
 1.20813  1.82068  1.25387
 1.56851  1.86401  1.67846

julia> b = rand(1,2)
1×2 Array{Float64,2}:
 0.867535  0.00457906

julia> broadcast(+, a, b)
2×2 Array{Float64,2}:
 1.71056  0.847604
 1.73659  0.873631
```

[Dotted operators](#) such as `.+` and `.*` are equivalent to broadcast calls (except that they fuse, as [described above](#)). There is also a [broadcast!](#) function to specify an explicit destination (which can also be accessed in a fusing fashion by `.=` assignment). In fact, `f.(args...)` is equivalent to `broadcast(f, args...)`,

providing a convenient syntax to broadcast any function ([dot syntax](#)). Nested "dot calls" `f.(...)` (including calls to `.+` etcetera) [automatically fuse](#) into a single broadcast call.

Additionally, [broadcast](#) is not limited to arrays (see the function documentation); it also handles scalars, tuples and other collections. By default, only some argument types are considered scalars, including (but not limited to) Numbers, Strings, Symbols, Types, Functions and some common singletons like `missing` and `nothing`. All other arguments are iterated over or indexed into elementwise.

```
julia> convert.(Float32, [1, 2])
2-element Vector{Float32}:
 1.0
 2.0

julia> ceil.(UInt8, [1.2 3.4; 5.6 6.7])
2x2 Matrix{UInt8}:
 0x02  0x04
 0x06  0x07

julia> string.(1:3, ". ", ["First", "Second", "Third"])
3-element Vector{String}:
 "1. First"
 "2. Second"
 "3. Third"
```

Sometimes, you want a container (like an array) that would normally participate in broadcast to be "protected" from broadcast's behavior of iterating over all of its elements. By placing it inside another container (like a single element [Tuple](#)) broadcast will treat it as a single value.

```
julia> ([1, 2, 3], [4, 5, 6]) .+ ([1, 2, 3],)
([2, 4, 6], [5, 7, 9])

julia> ([1, 2, 3], [4, 5, 6]) .+ tuple([1, 2, 3])
([2, 4, 6], [5, 7, 9])
```

19.13 Implementation

The base array type in Julia is the abstract type [AbstractArray{T,N}](#). It is parameterized by the number of dimensions `N` and the element type `T`. [AbstractVector](#) and [AbstractMatrix](#) are aliases for the 1-d and 2-d cases. Operations on [AbstractArray](#) objects are defined using higher level operators and functions, in a way that is independent of the underlying storage. These operations generally work correctly as a fallback for any specific array implementation.

The [AbstractArray](#) type includes anything vaguely array-like, and implementations of it might be quite different from conventional arrays. For example, elements might be computed on request rather than stored. However, any concrete [AbstractArray{T,N}](#) type should generally implement at least [size\(A\)](#) (returning an `Int` tuple), [getindex\(A,i\)](#) and [getindex\(A,i1,...,iN\)](#); mutable arrays should also implement [setindex!](#). It is recommended that these operations have nearly constant time complexity, as otherwise some array functions may be unexpectedly slow. Concrete types should also typically provide a [similar\(A,T=eltype\(A\),dims=size\(A\)\)](#) method, which is used to allocate a similar array for [copy](#) and other out-of-place operations. No matter how an [AbstractArray{T,N}](#) is represented internally, `T` is the type of object returned by integer indexing (`A[1, ..., 1]`, when `A` is not empty) and `N` should be the length

of the tuple returned by `size`. For more details on defining custom `AbstractArray` implementations, see the [array interface guide in the interfaces chapter](#).

`DenseArray` is an abstract subtype of `AbstractArray` intended to include all arrays where elements are stored contiguously in column-major order (see [additional notes in Performance Tips](#)). The `Array` type is a specific instance of `DenseArray`; `Vector` and `Matrix` are aliases for the 1-d and 2-d cases. Very few operations are implemented specifically for `Array` beyond those that are required for all `AbstractArrays`; much of the array library is implemented in a generic manner that allows all custom arrays to behave similarly.

`SubArray` is a specialization of `AbstractArray` that performs indexing by sharing memory with the original array rather than by copying it. A `SubArray` is created with the `view` function, which is called the same way as `getindex` (with an array and a series of index arguments). The result of `view` looks the same as the result of `getindex`, except the data is left in place. `view` stores the input index vectors in a `SubArray` object, which can later be used to index the original array indirectly. By putting the `@views` macro in front of an expression or block of code, any `array[...]` slice in that expression will be converted to create a `SubArray` view instead.

`BitArrays` are space-efficient "packed" boolean arrays, which store one bit per boolean value. They can be used similarly to `Array{Bool}` arrays (which store one byte per boolean value), and can be converted to/from the latter via `Array{Bool}(bitarray)` and `BitArray(array)`, respectively.

An array is "strided" if it is stored in memory with well-defined spacings (strides) between its elements. A strided array with a supported element type may be passed to an external (non-Julia) library like BLAS or LAPACK by simply passing its `pointer` and the stride for each dimension. The `stride(A, d)` is the distance between elements along dimension `d`. For example, the builtin `Array` returned by `rand(5,7,2)` has its elements arranged contiguously in column major order. This means that the stride of the first dimension — the spacing between elements in the same column — is 1:

```
julia> A = rand(5, 7, 2);

julia> stride(A, 1)
1
```

The stride of the second dimension is the spacing between elements in the same row, skipping as many elements as there are in a single column (5). Similarly, jumping between the two "pages" (in the third dimension) requires skipping $5 \times 7 = 35$ elements. The `strides` of this array is the tuple of these three numbers together:

```
julia> strides(A)
(1, 5, 35)
```

In this particular case, the number of elements skipped in memory matches the number of linear indices skipped. This is only the case for contiguous arrays like `Array` (and other `DenseArray` subtypes) and is not true in general. Views with range indices are a good example of non-contiguous strided arrays; consider `V = @view A[1:3:4, 2:2:6, 2:-1:1]`. This view `V` refers to the same memory as `A` but is skipping and re-arranging some of its elements. The stride of the first dimension of `V` is 3 because we're only selecting every third row from our original array:

```
julia> V = @view A[1:3:4, 2:2:6, 2:-1:1];
```

```
julia> stride(V, 1)
3
```

This view is similarly selecting every other column from our original A — and thus it needs to skip the equivalent of two five-element columns when moving between indices in the second dimension:

```
julia> stride(V, 2)
10
```

The third dimension is interesting because its order is reversed! Thus to get from the first "page" to the second one it must go backwards in memory, and so its stride in this dimension is negative!

```
julia> stride(V, 3)
-35
```

This means that the pointer for V is actually pointing into the middle of A's memory block, and it refers to elements both backwards and forwards in memory. See the [interface guide for strided arrays](#) for more details on defining your own strided arrays. [StridedVector](#) and [StridedMatrix](#) are convenient aliases for many of the builtin array types that are considered strided arrays, allowing them to dispatch to select specialized implementations that call highly tuned and optimized BLAS and LAPACK functions using just the pointer and strides.

It is worth emphasizing that strides are about offsets in memory rather than indexing. If you are looking to convert between linear (single-index) indexing and cartesian (multi-index) indexing, see [LinearIndices](#) and [CartesianIndices](#).

Chapter 20

Missing Values

Julia provides support for representing missing values in the statistical sense. This is for situations where no value is available for a variable in an observation, but a valid value theoretically exists. Missing values are represented via the `missing` object, which is the singleton instance of the type `Missing`. `missing` is equivalent to `NULL` in `SQL` and `NA` in `R`, and behaves like them in most situations.

20.1 Propagation of Missing Values

`missing` values propagate automatically when passed to standard mathematical operators and functions. For these functions, uncertainty about the value of one of the operands induces uncertainty about the result. In practice, this means a math operation involving a missing value generally returns `missing`:

```
julia> missing + 1
missing

julia> "a" * missing
missing

julia> abs(missing)
missing
```

Since `missing` is a normal Julia object, this propagation rule only works for functions which have opted in to implement this behavior. This can be achieved by:

- adding a specific method defined for arguments of type `Missing`,
- accepting arguments of this type, and passing them to functions which propagate them (like standard math operators).

Packages should consider whether it makes sense to propagate missing values when defining new functions, and define methods appropriately if this is the case. Passing a missing value to a function which does not have a method accepting arguments of type `Missing` throws a `MethodError`, just like for any other type.

Functions that do not propagate missing values can be made to do so by wrapping them in the `passmissing` function provided by the `Missings.jl` package. For example, `f(x)` becomes `passmissing(f)(x)`.

20.2 Equality and Comparison Operators

Standard equality and comparison operators follow the propagation rule presented above: if any of the operands is missing, the result is missing. Here are a few examples:

```
julia> missing == 1
missing

julia> missing == missing
missing

julia> missing < 1
missing

julia> 2 >= missing
missing
```

In particular, note that `missing == missing` returns `missing`, so `==` cannot be used to test whether a value is missing. To test whether `x` is missing, use `ismissing(x)`.

Special comparison operators `isequal` and `===` are exceptions to the propagation rule. They will always return a `Bool` value, even in the presence of missing values, considering missing as equal to missing and as different from any other value. They can therefore be used to test whether a value is missing:

```
julia> missing === 1
false

julia> isequal(missing, 1)
false

julia> missing === missing
true

julia> isequal(missing, missing)
true
```

The `isless` operator is another exception: missing is considered as greater than any other value. This operator is used by `sort!`, which therefore places missing values after all other values:

```
julia> isless(1, missing)
true

julia> isless(missing, Inf)
false

julia> isless(missing, missing)
false
```

20.3 Logical operators

Logical (or boolean) operators `|`, `&` and `xor` are another special case since they only propagate missing values when it is logically required. For these operators, whether or not the result is uncertain, depends on the particular operation. This follows the well-established rules of *three-valued logic* which are implemented by e.g. NULL in SQL and NA in R. This abstract definition corresponds to a relatively natural behavior which is best explained via concrete examples.

Let us illustrate this principle with the logical "or" operator `|`. Following the rules of boolean logic, if one of the operands is true, the value of the other operand does not have an influence on the result, which will always be true:

```
julia> true | true
true

julia> true | false
true

julia> false | true
true
```

Based on this observation, we can conclude if one of the operands is true and the other missing, we know that the result is true in spite of the uncertainty about the actual value of one of the operands. If we had been able to observe the actual value of the second operand, it could only be true or false, and in both cases the result would be true. Therefore, in this particular case, missingness does not propagate:

```
julia> true | missing
true

julia> missing | true
true
```

On the contrary, if one of the operands is false, the result could be either true or false depending on the value of the other operand. Therefore, if that operand is missing, the result has to be missing too:

```
julia> false | true
true

julia> true | false
true

julia> false | false
false

julia> false | missing
missing

julia> missing | false
missing
```

The behavior of the logical "and" operator `&` is similar to that of the `|` operator, with the difference that missingness does not propagate when one of the operands is `false`. For example, when that is the case of the first operand:

```
julia> false & false
false

julia> false & true
false

julia> false & missing
false
```

On the other hand, missingness propagates when one of the operands is `true`, for example the first one:

```
julia> true & true
true

julia> true & false
false

julia> true & missing
missing
```

Finally, the "exclusive or" logical operator `xor` always propagates missing values, since both operands always have an effect on the result. Also note that the negation operator `!` returns missing when the operand is missing, just like other unary operators.

20.4 Control Flow and Short-Circuiting Operators

Control flow operators including `if`, `while` and the `ternary operator` `x ? y : z` do not allow for missing values. This is because of the uncertainty about whether the actual value would be `true` or `false` if we could observe it. This implies we do not know how the program should behave. In this case, a `TypeError` is thrown as soon as a missing value is encountered in this context:

```
julia> if missing
    println("here")
end
ERROR: TypeError: non-boolean (Missing) used in boolean context
```

For the same reason, contrary to logical operators presented above, the short-circuiting boolean operators `&&` and `||` do not allow for missing values in situations where the value of the operand determines whether the next operand is evaluated or not. For example:

```
julia> missing || false
ERROR: TypeError: non-boolean (Missing) used in boolean context

julia> missing && false
ERROR: TypeError: non-boolean (Missing) used in boolean context
```

```
julia> true && missing && false
ERROR: TypeError: non-boolean (Missing) used in boolean context
```

In contrast, there is no error thrown when the result can be determined without the missing values. This is the case when the code short-circuits before evaluating the missing operand, and when the missing operand is the last one:

```
julia> true && missing
missing

julia> false && missing
false
```

20.5 Arrays With Missing Values

Arrays containing missing values can be created like other arrays:

```
julia> [1, missing]
2-element Vector{Union{Missing, Int64}}:
 1
missing
```

As this example shows, the element type of such arrays is `Union{Missing, T}`, with `T` the type of the non-missing values. This reflects the fact that array entries can be either of type `T` (here, `Int64`) or of type `Missing`. This kind of array uses an efficient memory storage equivalent to an `Array{T}` holding the actual values combined with an `Array{UInt8}` indicating the type of the entry (i.e. whether it is `Missing` or `T`).

Arrays allowing for missing values can be constructed with the standard syntax. Use `Array{Union{Missing, T}}(missing, dims)` to create arrays filled with missing values:

```
julia> Array{Union{Missing, String}}(missing, 2, 3)
2×3 Matrix{Union{Missing, String}}:
missing missing missing
missing missing missing
```

Note

Using `undef` or `similar` may currently give an array filled with `missing`, but this is not the correct way to obtain such an array. Use a missing constructor as shown above instead.

An array with element type allowing missing entries (e.g. `Vector{Union{Missing, T}}`) which does not contain any missing entries can be converted to an array type that does not allow for missing entries (e.g. `Vector{T}`) using `convert`. If the array contains missing values, a `MethodError` is thrown during conversion:

```
julia> x = Union{Missing, String}["a", "b"]
2-element Vector{Union{Missing, String}}:
 "a"
```

```

"b"

julia> convert{Array{String}, x}
2-element Vector{String}:
 "a"
 "b"

julia> y = Union{Missing, String}[missing, "b"]
2-element Vector{Union{Missing, String}}:
 missing
 "b"

julia> convert{Array{String}, y}
ERROR: MethodError: Cannot `convert` an object of type Missing to an object of type String

```

20.6 Skipping Missing Values

Since missing values propagate with standard mathematical operators, reduction functions return missing when called on arrays which contain missing values:

```

julia> sum([1, missing])
missing

```

In this situation, use the `skipmissing` function to skip missing values:

```

julia> sum(skipmissing([1, missing]))
1

```

This convenience function returns an iterator which filters out missing values efficiently. It can therefore be used with any function which supports iterators:

```

julia> x = skipmissing([3, missing, 2, 1])
skipmissing{Union{Missing, Int64}}{3, missing, 2, 1}

julia> maximum(x)
3

julia> sum(x)
6

julia> mapreduce(sqrt, +, x)
4.146264369941973

```

Objects created by calling `skipmissing` on an array can be indexed using indices from the parent array. Indices corresponding to missing values are not valid for these objects, and an error is thrown when trying to use them (they are also skipped by `keys` and `eachindex`):

```

julia> x[1]
3

```

```
julia> x[2]
ERROR: MissingException: the value at index (2,) is missing
[...]
```

This allows functions which operate on indices to work in combination with `skipmissing`. This is notably the case for search and find functions. These functions return indices valid for the object returned by `skipmissing`, and are also the indices of the matching entries in the parent array:

```
julia> findall(==(1), x)
1-element Vector{Int64}:
 4

julia> findfirst(!iszero, x)
1

julia> argmax(x)
1
```

Use `collect` to extract non-missing values and store them in an array:

```
julia> collect(x)
3-element Vector{Int64}:
 3
 2
 1
```

20.7 Logical Operations on Arrays

The three-valued logic described above for logical operators is also used by logical functions applied to arrays. Thus, array equality tests using the `==` operator return missing whenever the result cannot be determined without knowing the actual value of the missing entry. In practice, this means missing is returned if all non-missing values of the compared arrays are equal, but one or both arrays contain missing values (possibly at different positions):

```
julia> [1, missing] == [2, missing]
false

julia> [1, missing] == [1, missing]
missing

julia> [1, 2, missing] == [1, missing, 2]
missing
```

As for single values, use `isequal` to treat missing values as equal to other missing values, but different from non-missing values:

```
julia> isequal([1, missing], [1, missing])
true
```

```
julia> isequal([1, 2, missing], [1, missing, 2])  
false
```

Functions `any` and `all` also follow the rules of three-valued logic. Thus, returning `missing` when the result cannot be determined:

```
julia> all([true, missing])  
missing  
  
julia> all([false, missing])  
false  
  
julia> any([true, missing])  
true  
  
julia> any([false, missing])  
missing
```

Chapter 21

Networking and Streams

Julia provides a rich interface to deal with streaming I/O objects such as terminals, pipes and TCP sockets. This interface, though asynchronous at the system level, is presented in a synchronous manner to the programmer and it is usually unnecessary to think about the underlying asynchronous operation. This is achieved by making heavy use of Julia cooperative threading ([coroutine](#)) functionality.

21.1 Basic Stream I/O

All Julia streams expose at least a [read](#) and a [write](#) method, taking the stream as their first argument, e.g.:

```
julia> write(stdout, "Hello World"); # suppress return value 11 with ;
Hello World
julia> read(stdin, Char)

'\n': ASCII/Unicode U+000a (category Cc: Other, control)
```

Note that [write](#) returns 11, the number of bytes (in "Hello World") written to [stdout](#), but this return value is suppressed with the `;`.

Here Enter was pressed again so that Julia would read the newline. Now, as you can see from this example, [write](#) takes the data to write as its second argument, while [read](#) takes the type of the data to be read as the second argument.

For example, to read a simple byte array, we could do:

```
julia> x = zeros{UInt8, 4}
4-element Array{UInt8,1}:
 0x00
 0x00
 0x00
 0x00

julia> read!(stdin, x)
abcd
4-element Array{UInt8,1}:
 0x61
```

```
0x62
0x63
0x64
```

However, since this is slightly cumbersome, there are several convenience methods provided. For example, we could have written the above as:

```
julia> read(stdin, 4)
abcd
4-element Array{UInt8,1}:
 0x61
 0x62
 0x63
 0x64
```

or if we had wanted to read the entire line instead:

```
julia> readline(stdin)
abcd
"abcd"
```

Note that depending on your terminal settings, your TTY may be line buffered and might thus require an additional enter before the data is sent to Julia.

To read every line from `stdin` you can use `eachline`:

```
for line in eachline(stdin)
    print("Found $line")
end
```

or `read` if you wanted to read by character instead:

```
while !eof(stdin)
    x = read(stdin, Char)
    println("Found: $x")
end
```

21.2 Text I/O

Note that the `write` method mentioned above operates on binary streams. In particular, values do not get converted to any canonical text representation but are written out as is:

```
julia> write(stdout, 0x61); # suppress return value 1 with ;
a
```

Note that a is written to `stdout` by the `write` function and that the returned value is 1 (since 0x61 is one byte).

For text I/O, use the `print` or `show` methods, depending on your needs (see the documentation for these two methods for a detailed discussion of the difference between them):

```
julia> print(stdout, 0x61)
97
```

See [Custom pretty-printing](#) for more information on how to implement display methods for custom types.

21.3 IO Output Contextual Properties

Sometimes IO output can benefit from the ability to pass contextual information into show methods. The [IOContext](#) object provides this framework for associating arbitrary metadata with an IO object. For example, `:compact => true` adds a hinting parameter to the IO object that the invoked show method should print a shorter output (if applicable). See the [IOContext](#) documentation for a list of common properties.

21.4 Working with Files

You can write content to a file with the `write(filename::String, content)` method:

```
julia> write("hello.txt", "Hello, World!")
13
```

(13 is the number of bytes written.)

You can read the contents of a file with the `read(filename::String)` method, or `read(filename::String, String)` to the contents as a string:

```
julia> read("hello.txt", String)
"Hello, World!"
```

Advanced: streaming files

The read and write methods above allow you to read and write file contents. Like many other environments, Julia also has an [open](#) function, which takes a filename and returns an [IOStream](#) object that you can use to read and write things from the file. For example, if we have a file, `hello.txt`, whose contents are `Hello, World!`:

```
julia> f = open("hello.txt")
IOStream(<file hello.txt>)

julia> readlines(f)
1-element Array{String,1}:
"Hello, World!"
```

If you want to write to a file, you can open it with the `write ("w")` flag:

```
julia> f = open("hello.txt", "w")
IOStream(<file hello.txt>)

julia> write(f, "Hello again.")
12
```

If you examine the contents of `hello.txt` at this point, you will notice that it is empty; nothing has actually been written to disk yet. This is because the `IOStream` must be closed before the write is actually flushed to disk:

```
julia> close(f)
```

Examining `hello.txt` again will show its contents have been changed.

Opening a file, doing something to its contents, and closing it again is a very common pattern. To make this easier, there exists another invocation of `open` which takes a function as its first argument and filename as its second, opens the file, calls the function with the file as an argument, and then closes it again. For example, given a function:

```
function read_and_capitalize(f::IOStream)
    return uppercase(read(f, String))
end
```

You can call:

```
julia> open(read_and_capitalize, "hello.txt")
"HELLO AGAIN."
```

to open `hello.txt`, call `read_and_capitalize` on it, close `hello.txt` and return the capitalized contents.

To avoid even having to define a named function, you can use the `do` syntax, which creates an anonymous function on the fly:

```
julia> open("hello.txt") do f
    uppercase(read(f, String))
end
"HELLO AGAIN."
```

21.5 A simple TCP example

Let's jump right in with a simple example involving TCP sockets. This functionality is in a standard library package called `Sockets`. Let's first create a simple server:

```
julia> using Sockets

julia> errormonitor(@async begin
    server = listen(2000)
    while true
        sock = accept(server)
        println("Hello World\n")
    end
end)
Task (runnable) @0x00007fd31dc11ae0
```

To those familiar with the Unix socket API, the method names will feel familiar, though their usage is somewhat simpler than the raw Unix socket API. The first call to `listen` will create a server waiting for incoming connections on the specified port (2000) in this case. The same function may also be used to create various other kinds of servers:

```
julia> listen(2000) # Listens on localhost:2000 (IPv4)
Sockets.TCPServer{active}

julia> listen(ip"127.0.0.1",2000) # Equivalent to the first
Sockets.TCPServer{active}

julia> listen(ip "::1",2000) # Listens on localhost:2000 (IPv6)
Sockets.TCPServer{active}

julia> listen(IPv4{0},2001) # Listens on port 2001 on all IPv4 interfaces
Sockets.TCPServer{active}

julia> listen(IPv6{0},2001) # Listens on port 2001 on all IPv6 interfaces
Sockets.TCPServer{active}

julia> listen("testsocket") # Listens on a UNIX domain socket
Sockets.PipeServer{active}

julia> listen("\\\\.\\pipe\\testsocket") # Listens on a Windows named pipe
Sockets.PipeServer{active}
```

Note that the return type of the last invocation is different. This is because this server does not listen on TCP, but rather on a named pipe (Windows) or UNIX domain socket. Also note that Windows named pipe format has to be a specific pattern such that the name prefix (`\\.\\pipe\\`) uniquely identifies the *file type*. The difference between TCP and named pipes or UNIX domain sockets is subtle and has to do with the `accept` and `connect` methods. The `accept` method retrieves a connection to the client that is connecting on the server we just created, while the `connect` function connects to a server using the specified method. The `connect` function takes the same arguments as `listen`, so, assuming the environment (i.e. host, cwd, etc.) is the same you should be able to pass the same arguments to `connect` as you did to `listen` to establish the connection. So let's try that out (after having created the server above):

```
julia> connect(2000)
TCPSocket{open, 0 bytes waiting}

julia> Hello World
```

As expected we saw "Hello World" printed. So, let's actually analyze what happened behind the scenes. When we called `connect`, we connect to the server we had just created. Meanwhile, the `accept` function returns a server-side connection to the newly created socket and prints "Hello World" to indicate that the connection was successful.

A great strength of Julia is that since the API is exposed synchronously even though the I/O is actually happening asynchronously, we didn't have to worry about callbacks or even making sure that the server gets to run. When we called `connect` the current task waited for the connection to be established and only continued executing after that was done. In this pause, the server task resumed execution (because

a connection request was now available), accepted the connection, printed the message and waited for the next client. Reading and writing works in the same way. To see this, consider the following simple echo server:

```
julia> errormonitor(@async begin
    server = listen(2001)
    while true
        sock = accept(server)
        @async while isopen(sock)
            write(sock, readline(sock, keep=true))
        end
    end
end)
Task (runnable) @0x00007fd31dc12e60

julia> clientside = connect(2001)
TCPSocket(RawFD(28) open, 0 bytes waiting)

julia> errormonitor(@async while isopen(clientside)
    write(stdout, readline(clientside, keep=true))
end)
Task (runnable) @0x00007fd31dc11870

julia> println(clientside,"Hello World from the Echo Server")
Hello World from the Echo Server
```

As with other streams, use `close` to disconnect the socket:

```
julia> close(clientside)
```

21.6 Resolving IP Addresses

One of the `connect` methods that does not follow the `listen` methods is `connect(host::String,port)`, which will attempt to connect to the host given by the `host` parameter on the port given by the `port` parameter. It allows you to do things like:

```
julia> connect("google.com", 80)
TCPSocket(RawFD(30) open, 0 bytes waiting)
```

At the base of this functionality is `getaddrinfo`, which will do the appropriate address resolution:

```
julia> getaddrinfo("google.com")
ip"74.125.226.225"
```

21.7 Asynchronous I/O

All I/O operations exposed by `Base.read` and `Base.write` can be performed asynchronously through the use of `coroutines`. You can create a new coroutine to read from or write to a stream using the `@async` macro:

```
julia> task = @async open("foo.txt", "w") do io
    write(io, "Hello, World!")
end;

julia> wait(task)

julia> readlines("foo.txt")
1-element Array{String,1}:
"Hello, World!"
```

It's common to run into situations where you want to perform multiple asynchronous operations concurrently and wait until they've all completed. You can use the `@sync` macro to cause your program to block until all of the coroutines it wraps around have exited:

```
julia> using Sockets

julia> @sync for hostname in ("google.com", "github.com", "julialang.org")
    @async begin
        conn = connect(hostname, 80)
        write(conn, "GET / HTTP/1.1\r\nHost:$(hostname)\r\n\r\n")
        readline(conn, keep=true)
        println("Finished connection to $(hostname)")
    end
end
Finished connection to google.com
Finished connection to julialang.org
Finished connection to github.com
```

21.8 Multicast

Julia supports **multicast** over IPv4 and IPv6 using the User Datagram Protocol (**UDP**) as transport.

Unlike the Transmission Control Protocol (**TCP**), UDP makes almost no assumptions about the needs of the application. TCP provides flow control (it accelerates and decelerates to maximize throughput), reliability (lost or corrupt packets are automatically retransmitted), sequencing (packets are ordered by the operating system before they are given to the application), segment size, and session setup and teardown. UDP provides no such features.

A common use for UDP is in multicast applications. TCP is a stateful protocol for communication between exactly two devices. UDP can use special multicast addresses to allow simultaneous communication between many devices.

Receiving IP Multicast Packets

To transmit data over UDP multicast, simply `recv` on the socket, and the first packet received will be returned. Note that it may not be the first packet that you sent however!

```
using Sockets
group = ip"228.5.6.7"
socket = Sockets.UDPSocket()
bind(socket, ip"0.0.0.0", 6789)
```

```
join_multicast_group(socket, group)
println(String(recv(socket)))
leave_multicast_group(socket, group)
close(socket)
```

Sending IP Multicast Packets

To transmit data over UDP multicast, simply send to the socket. Notice that it is not necessary for a sender to join the multicast group.

```
using Sockets
group = ip"228.5.6.7"
socket = Sockets.UDPSocket()
send(socket, group, 6789, "Hello over IPv4")
close(socket)
```

IPv6 Example

This example gives the same functionality as the previous program, but uses IPv6 as the network-layer protocol.

Listener:

```
using Sockets
group = Sockets.IPv6("ff05::5:6:7")
socket = Sockets.UDPSocket()
bind(socket, Sockets.IPv6("::"), 6789)
join_multicast_group(socket, group)
println(String(recv(socket)))
leave_multicast_group(socket, group)
close(socket)
```

Sender:

```
using Sockets
group = Sockets.IPv6("ff05::5:6:7")
socket = Sockets.UDPSocket()
send(socket, group, 6789, "Hello over IPv6")
close(socket)
```

Chapter 22

Parallel Computing

Julia supports these four categories of concurrent and parallel programming:

1. **Asynchronous "tasks", or coroutines:**

Julia Tasks allow suspending and resuming computations for I/O, event handling, producer-consumer processes, and similar patterns. Tasks can synchronize through operations like [wait](#) and [fetch](#), and communicate via [Channels](#). While strictly not parallel computing by themselves, Julia lets you schedule [Tasks](#) on several threads.

2. **Multi-threading:**

Julia's [multi-threading](#) provides the ability to schedule Tasks simultaneously on more than one thread or CPU core, sharing memory. This is usually the easiest way to get parallelism on one's PC or on a single large multi-core server. Julia's multi-threading is composable. When one multi-threaded function calls another multi-threaded function, Julia will schedule all the threads globally on available resources, without oversubscribing.

3. **Distributed computing:**

Distributed computing runs multiple Julia processes with separate memory spaces. These can be on the same computer or multiple computers. The [Distributed](#) standard library provides the capability for remote execution of a Julia function. With this basic building block, it is possible to build many different kinds of distributed computing abstractions. Packages like [DistributedArrays.jl](#) are an example of such an abstraction. On the other hand, packages like [MPI.jl](#) and [Elemental.jl](#) provide access to the existing MPI ecosystem of libraries.

4. **GPU computing:**

The Julia GPU compiler provides the ability to run Julia code natively on GPUs. There is a rich ecosystem of Julia packages that target GPUs. The [JuliaGPU.org](#) website provides a list of capabilities, supported GPUs, related packages and documentation.

Chapter 23

Asynchronous Programming

When a program needs to interact with the outside world, for example communicating with another machine over the internet, operations in the program may need to happen in an unpredictable order. Say your program needs to download a file. We would like to initiate the download operation, perform other operations while we wait for it to complete, and then resume the code that needs the downloaded file when it is available. This sort of scenario falls in the domain of asynchronous programming, sometimes also referred to as concurrent programming (since, conceptually, multiple things are happening at once).

To address these scenarios, Julia provides [Tasks](#) (also known by several other names, such as symmetric coroutines, lightweight threads, cooperative multitasking, or one-shot continuations). When a piece of computing work (in practice, executing a particular function) is designated as a [Task](#), it becomes possible to interrupt it by switching to another [Task](#). The original [Task](#) can later be resumed, at which point it will pick up right where it left off. At first, this may seem similar to a function call. However there are two key differences. First, switching tasks does not use any space, so any number of task switches can occur without consuming the call stack. Second, switching among tasks can occur in any order, unlike function calls, where the called function must finish executing before control returns to the calling function.

23.1 Basic Task operations

You can think of a Task as a handle to a unit of computational work to be performed. It has a create-start-run-finish lifecycle. Tasks are created by calling the Task constructor on a 0-argument function to run, or using the [@task](#) macro:

```
julia> t = @task begin; sleep(5); println("done"); end
Task (runnable) @0x00007f13a40c0eb0
```

`@task x` is equivalent to `Task(()->x)`.

This task will wait for five seconds, and then print done. However, it has not started running yet. We can run it whenever we're ready by calling [schedule](#):

```
julia> schedule(t);
```

If you try this in the REPL, you will see that `schedule` returns immediately. That is because it simply adds `t` to an internal queue of tasks to run. Then, the REPL will print the next prompt and wait for more input.

Waiting for keyboard input provides an opportunity for other tasks to run, so at that point `t` will start. `t` calls `sleep`, which sets a timer and stops execution. If other tasks have been scheduled, they could run then. After five seconds, the timer fires and restarts `t`, and you will see `done` printed. `t` is then finished.

The `wait` function blocks the calling task until some other task finishes. So for example if you type

```
julia> schedule(t); wait(t)
```

instead of only calling `schedule`, you will see a five second pause before the next input prompt appears. That is because the REPL is waiting for `t` to finish before proceeding.

It is common to want to create a task and schedule it right away, so the macro `@async` is provided for that purpose -- `@async x` is equivalent to `schedule(@task x)`.

23.2 Communicating with Channels

In some problems, the various pieces of required work are not naturally related by function calls; there is no obvious "caller" or "callee" among the jobs that need to be done. An example is the producer-consumer problem, where one complex procedure is generating values and another complex procedure is consuming them. The consumer cannot simply call a producer function to get a value, because the producer may have more values to generate and so might not yet be ready to return. With tasks, the producer and consumer can both run as long as they need to, passing values back and forth as necessary.

Julia provides a `Channel` mechanism for solving this problem. A `Channel` is a waitable first-in first-out queue which can have multiple tasks reading from and writing to it.

Let's define a producer task, which produces values via the `put!` call. To consume values, we need to schedule the producer to run in a new task. A special `Channel` constructor which accepts a 1-arg function as an argument can be used to run a task bound to a channel. We can then `take!` values repeatedly from the channel object:

```
julia> function producer(c::Channel)
    put!(c, "start")
    for n=1:4
        put!(c, 2n)
    end
    put!(c, "stop")
end;

julia> chnl = Channel(producer);

julia> take!(chnl)
"start"

julia> take!(chnl)
2

julia> take!(chnl)
4

julia> take!(chnl)
6
```

```
julia> take!(chnl)
8
julia> take!(chnl)
"stop"
```

One way to think of this behavior is that producer was able to return multiple times. Between calls to `put!`, the producer's execution is suspended and the consumer has control.

The returned `Channel` can be used as an iterable object in a for loop, in which case the loop variable takes on all the produced values. The loop is terminated when the channel is closed.

```
julia> for x in Channel(producer)
        println(x)
    end
start
2
4
6
8
stop
```

Note that we did not have to explicitly close the channel in the producer. This is because the act of binding a `Channel` to a `Task` associates the open lifetime of a channel with that of the bound task. The channel object is closed automatically when the task terminates. Multiple channels can be bound to a task, and vice-versa.

While the `Task` constructor expects a 0-argument function, the `Channel` method that creates a task-bound channel expects a function that accepts a single argument of type `Channel`. A common pattern is for the producer to be parameterized, in which case a partial function application is needed to create a 0 or 1 argument `anonymous function`.

For `Task` objects this can be done either directly or by use of a convenience macro:

```
function mytask(myarg)
    ...
end

taskHdl = Task() -> mytask(7)
# or, equivalently
taskHdl = @task mytask(7)
```

To orchestrate more advanced work distribution patterns, `bind` and `schedule` can be used in conjunction with `Task` and `Channel` constructors to explicitly link a set of channels with a set of producer/consumer tasks.

More on Channels

A channel can be visualized as a pipe, i.e., it has a write end and a read end :

- Multiple writers in different tasks can write to the same channel concurrently via `put!` calls.
- Multiple readers in different tasks can read data concurrently via `take!` calls.
- As an example:

```
# Given Channels c1 and c2,
c1 = Channel{32}
c2 = Channel{32}

# and a function `foo` which reads items from c1, processes the item read
# and writes a result to c2,
function foo()
    while true
        data = take!(c1)
        [...]          # process data
        put!(c2, result) # write out result
    end
end

# we can schedule `n` instances of `foo` to be active concurrently.
for _ in 1:n
    errormonitor(@async foo())
end
```

- Channels are created via the `Channel{T}(sz)` constructor. The channel will only hold objects of type `T`. If the type is not specified, the channel can hold objects of any type. `sz` refers to the maximum number of elements that can be held in the channel at any time. For example, `Channel{32}` creates a channel that can hold a maximum of 32 objects of any type. A `Channel{MyType}(64)` can hold up to 64 objects of `MyType` at any time.
- If a `Channel` is empty, readers (on a `take!` call) will block until data is available.
- If a `Channel` is full, writers (on a `put!` call) will block until space becomes available.
- `isready` tests for the presence of any object in the channel, while `wait` waits for an object to become available.
- A `Channel` is in an open state initially. This means that it can be read from and written to freely via `take!` and `put!` calls. `close` closes a `Channel`. On a closed `Channel`, `put!` will fail. For example:

```
julia> c = Channel{2};

julia> put!(c, 1) # `put!` on an open channel succeeds
1

julia> close(c);

julia> put!(c, 2) # `put!` on a closed channel throws an exception.
ERROR: InvalidStateException: Channel is closed.
Stacktrace:
[...]

```

- `take!` and `fetch` (which retrieves but does not remove the value) on a closed channel successfully return any existing values until it is emptied. Continuing the above example:

```

julia> fetch(c) # Any number of `fetch` calls succeed.
1

julia> fetch(c)
1

julia> take!(c) # The first `take!` removes the value.
1

julia> take!(c) # No more data available on a closed channel.
ERROR: InvalidStateException: Channel is closed.
Stacktrace:
[...]

```

Consider a simple example using channels for inter-task communication. We start 4 tasks to process data from a single jobs channel. Jobs, identified by an id (`job_id`), are written to the channel. Each task in this simulation reads a `job_id`, waits for a random amount of time and writes back a tuple of `job_id` and the simulated time to the results channel. Finally all the results are printed out.

```

julia> const jobs = Channel{Int}(32);

julia> const results = Channel{Tuple}(32);

julia> function do_work()
    for job_id in jobs
        exec_time = rand()
        sleep(exec_time)                # simulates elapsed time doing actual work
                                        # typically performed externally.
        put!(results, (job_id, exec_time))
    end
end;

julia> function make_jobs(n)
    for i in 1:n
        put!(jobs, i)
    end
end;

julia> n = 12;

julia> errormonitor(@async make_jobs(n)); # feed the jobs channel with "n" jobs

julia> for i in 1:4 # start 4 tasks to process requests in parallel
    errormonitor(@async do_work())
end

julia> @elapsed while n > 0 # print out results
    job_id, exec_time = take!(results)
    println("$job_id finished in $(round(exec_time; digits=2)) seconds")
    global n = n - 1
end
4 finished in 0.22 seconds

```

```

3 finished in 0.45 seconds
1 finished in 0.5 seconds
7 finished in 0.14 seconds
2 finished in 0.78 seconds
5 finished in 0.9 seconds
9 finished in 0.36 seconds
6 finished in 0.87 seconds
8 finished in 0.79 seconds
10 finished in 0.64 seconds
12 finished in 0.5 seconds
11 finished in 0.97 seconds
0.029772311

```

Instead of `errormonitor(t)`, a more robust solution may be to use `bind(results, t)`, as that will not only log any unexpected failures, but also force the associated resources to close and propagate the exception everywhere.

23.3 More task operations

Task operations are built on a low-level primitive called `yieldto`. `yieldto(task, value)` suspends the current task, switches to the specified task, and causes that task's last `yieldto` call to return the specified value. Notice that `yieldto` is the only operation required to use task-style control flow; instead of calling and returning we are always just switching to a different task. This is why this feature is also called "symmetric coroutines"; each task is switched to and from using the same mechanism.

`yieldto` is powerful, but most uses of tasks do not invoke it directly. Consider why this might be. If you switch away from the current task, you will probably want to switch back to it at some point, but knowing when to switch back, and knowing which task has the responsibility of switching back, can require considerable coordination. For example, `put!` and `take!` are blocking operations, which, when used in the context of channels maintain state to remember who the consumers are. Not needing to manually keep track of the consuming task is what makes `put!` easier to use than the low-level `yieldto`.

In addition to `yieldto`, a few other basic functions are needed to use tasks effectively.

- `current_task` gets a reference to the currently-running task.
- `istaskdone` queries whether a task has exited.
- `istaskstarted` queries whether a task has run yet.
- `task_local_storage` manipulates a key-value store specific to the current task.

23.4 Tasks and events

Most task switches occur as a result of waiting for events such as I/O requests, and are performed by a scheduler included in Julia Base. The scheduler maintains a queue of runnable tasks, and executes an event loop that restarts tasks based on external events such as message arrival.

The basic function for waiting for an event is `wait`. Several objects implement `wait`; for example, given a `Process` object, `wait` will wait for it to exit. `wait` is often implicit; for example, a `wait` can happen inside a call to `read` to wait for data to be available.

In all of these cases, `wait` ultimately operates on a `Condition` object, which is in charge of queueing and restarting tasks. When a task calls `wait` on a `Condition`, the task is marked as non-runnable, added to the condition's queue, and switches to the scheduler. The scheduler will then pick another task to run, or block waiting for external events. If all goes well, eventually an event handler will call `notify` on the condition, which causes tasks waiting for that condition to become runnable again.

A task created explicitly by calling `Task` is initially not known to the scheduler. This allows you to manage tasks manually using `yieldto` if you wish. However, when such a task waits for an event, it still gets restarted automatically when the event happens, as you would expect.

Chapter 24

Multi-Threading

Visit this [blog post](#) for a presentation of Julia multi-threading features.

24.1 Starting Julia with multiple threads

By default, Julia starts up with a single thread of execution. This can be verified by using the command `Threads.nthreads()`:

```
julia> Threads.nthreads()  
1
```

The number of execution threads is controlled either by using the `-t/--threads` command line argument or by using the `JULIA_NUM_THREADS` environment variable. When both are specified, then `-t/--threads` takes precedence.

The number of threads can either be specified as an integer (`--threads=4`) or as `auto` (`--threads=auto`), where `auto` tries to infer a useful default number of threads to use (see [Command-line Options](#) for more details).

Julia 1.5

The `-t/--threads` command line argument requires at least Julia 1.5. In older versions you must use the environment variable instead.

Julia 1.7

Using `auto` as value of the environment variable `JULIA_NUM_THREADS` requires at least Julia 1.7. In older versions, this value is ignored.

Lets start Julia with 4 threads:

```
$ julia --threads 4
```

Let's verify there are 4 threads at our disposal.

```
julia> Threads.nthreads()  
4
```

But we are currently on the master thread. To check, we use the function `Threads.threadid`

```
julia> Threads.threadid()
1
```

Note

If you prefer to use the environment variable you can set it as follows in Bash (Linux/macOS):

```
| export JULIA_NUM_THREADS=4
```

C shell on Linux/macOS, CMD on Windows:

```
| set JULIA_NUM_THREADS=4
```

Powershell on Windows:

```
| $env:JULIA_NUM_THREADS=4
```

Note that this must be done before starting Julia.

Note

The number of threads specified with `-t/--threads` is propagated to worker processes that are spawned using the `-p/--procs` or `--machine-file` command line options. For example, `julia -p2 -t2` spawns 1 main process with 2 worker processes, and all three processes have 2 threads enabled. For more fine grained control over worker threads use `addprocs` and pass `-t/--threads` as `exeflags`.

Multiple GC Threads

The Garbage Collector (GC) can use multiple threads. The amount used is either half the number of compute worker threads or configured by either the `--gcthreads` command line argument or by using the `JULIA_NUM_GC_THREADS` environment variable.

Julia 1.10

The `--gcthreads` command line argument requires at least Julia 1.10.

24.2 Threadpools

When a program's threads are busy with many tasks to run, tasks may experience delays which may negatively affect the responsiveness and interactivity of the program. To address this, you can specify that a task is interactive when you `Threads.@spawn` it:

```
using Base.Threads
@spawn :interactive f()
```

Interactive tasks should avoid performing high latency operations, and if they are long duration tasks, should yield frequently.

Julia may be started with one or more threads reserved to run interactive tasks:

```
| $ julia --threads 3,1
```

The environment variable `JULIA_NUM_THREADS` can also be used similarly:

```
| export JULIA_NUM_THREADS=3,1
```

This starts Julia with 3 threads in the `:default` threadpool and 1 thread in the `:interactive` threadpool:

```
julia> using Base.Threads

julia> nthreadpools()
2

julia> threadpool() # the main thread is in the interactive thread pool
:interactive

julia> nthreads(:default)
3

julia> nthreads(:interactive)
1

julia> nthreads()
3
```

Note

The zero-argument version of `nthreads` returns the number of threads in the default pool.

Note

Depending on whether Julia has been started with interactive threads, the main thread is either in the default or interactive thread pool.

Either or both numbers can be replaced with the word `auto`, which causes Julia to choose a reasonable default.

24.3 Communication and synchronization

Although Julia's threads can communicate through shared memory, it is notoriously difficult to write correct and data-race free multi-threaded code. Julia's `Channels` are thread-safe and may be used to communicate safely.

Data-race freedom

You are entirely responsible for ensuring that your program is data-race free, and nothing promised here can be assumed if you do not observe that requirement. The observed results may be highly unintuitive.

The best way to ensure this is to acquire a lock around any access to data that can be observed from multiple threads. For example, in most cases you should use the following code pattern:

```
julia> lock(lk) do
    use(a)
end

julia> begin
    lock(lk)
    try
        use(a)
    finally
        unlock(lk)
    end
end
```

where `lk` is a lock (e.g. `ReentrantLock()`) and `a` data.

Additionally, Julia is not memory safe in the presence of a data race. Be very careful about reading any data if another thread might write to it! Instead, always use the lock pattern above when changing data (such as assigning to a global or closure variable) accessed by other threads.

```
Thread 1:
global b = false
global a = rand()
global b = true

Thread 2:
while !b; end
bad_read1(a) # it is NOT safe to access `a` here!

Thread 3:
while !@isdefined(a); end
bad_read2(a) # it is NOT safe to access `a` here
```

24.4 The @threads Macro

Let's work a simple example using our native threads. Let us create an array of zeros:

```
julia> a = zeros(10)
10-element Vector{Float64}:
 0.0
 0.0
 0.0
 0.0
 0.0
 0.0
 0.0
 0.0
 0.0
 0.0
```

Let us operate on this array simultaneously using 4 threads. We'll have each thread write its thread ID into each location.

Julia supports parallel loops using the `Threads.@threads` macro. This macro is affixed in front of a `for` loop to indicate to Julia that the loop is a multi-threaded region:

```
julia> Threads.@threads for i = 1:10
    a[i] = Threads.threadid()
end
```

The iteration space is split among the threads, after which each thread writes its thread ID to its assigned locations:

```
julia> a
10-element Vector{Float64}:
 1.0
 1.0
 1.0
 2.0
 2.0
 2.0
 3.0
 3.0
 4.0
 4.0
```

Note that `Threads.@threads` does not have an optional reduction parameter like `@distributed`.

Using @threads without data races

Taking the example of a naive sum

```
julia> function sum_single(a)
    s = 0
    for i in a
        s += i
    end
    s
end
sum_single (generic function with 1 method)

julia> sum_single(1:1_000_000)
500000500000
```

Simply adding `@threads` exposes a data race with multiple threads reading and writing `s` at the same time.

```
julia> function sum_multi_bad(a)
    s = 0
    Threads.@threads for i in a
        s += i
    end
    s
end
```

```
sum_multi_bad (generic function with 1 method)

julia> sum_multi_bad(1:1_000_000)
70140554652
```

Note that the result is not 500000500000 as it should be, and will most likely change each evaluation.

To fix this, buffers that are specific to the task may be used to segment the sum into chunks that are race-free. Here `sum_single` is reused, with its own internal buffer `s`, and vector `a` is split into `nthreads()` chunks for parallel work via `nthreads()` @spawn-ed tasks.

```
julia> function sum_multi_good(a)
    chunks = Iterators.partition(a, length(a) ÷ Threads.nthreads())
    tasks = map(chunks) do chunk
        Threads.@spawn sum_single(chunk)
    end
    chunk_sums = fetch.(tasks)
    return sum_single(chunk_sums)
end
sum_multi_good (generic function with 1 method)

julia> sum_multi_good(1:1_000_000)
500000500000
```

Note

Buffers should not be managed based on `threadid()` i.e. `buffers = zeros(Threads.nthreads())` because concurrent tasks can yield, meaning multiple concurrent tasks may use the same buffer on a given thread, introducing risk of data races. Further, when more than one thread is available tasks may change thread at yield points, which is known as [task migration](#).

Another option is the use of atomic operations on variables shared across tasks/threads, which may be more performant depending on the characteristics of the operations.

24.5 Atomic Operations

Julia supports accessing and modifying values atomically, that is, in a thread-safe way to avoid [race conditions](#). A value (which must be of a primitive type) can be wrapped as `Threads.Atomic` to indicate it must be accessed in this way. Here we can see an example:

```
julia> i = Threads.Atomic{Int}();

julia> ids = zeros(4);

julia> old_is = zeros(4);

julia> Threads.@threads for id in 1:4
    old_is[id] = Threads.atomic_add!(i, id)
    ids[id] = id
end
```

```
julia> old_is
4-element Vector{Float64}:
 0.0
 1.0
 7.0
 3.0

julia> i[]
10

julia> ids
4-element Vector{Float64}:
 1.0
 2.0
 3.0
 4.0
```

Had we tried to do the addition without the atomic tag, we might have gotten the wrong answer due to a race condition. An example of what would happen if we didn't avoid the race:

```
julia> using Base.Threads

julia> Threads.nthreads()
4

julia> acc = Ref{0}
Base.RefValue{Int64}(0)

julia> @threads for i in 1:1000
    acc[] += 1
end

julia> acc[]
926

julia> acc = Atomic{Int64}(0)
Atomic{Int64}(0)

julia> @threads for i in 1:1000
    atomic_add!(acc, 1)
end

julia> acc[]
1000
```

24.6 Per-field atomics

We can also use atomics on a more granular level using the `@atomic`, `@atomicswap`, and `@atomicreplace` macros.

Specific details of the memory model and other details of the design are written in the [Julia Atomics Manifesto](#), which will later be published formally.

Any field in a struct declaration can be decorated with `@atomic`, and then any write must be marked with `@atomic` also, and must use one of the defined atomic orderings (`:monotonic`, `:acquire`, `:release`, `:acquire_release`, or `:sequentially_consistent`). Any read of an atomic field can also be annotated with an atomic ordering constraint, or will be done with monotonic (relaxed) ordering if unspecified.

Julia 1.7

Per-field atomics requires at least Julia 1.7.

24.7 Side effects and mutable function arguments

When using multi-threading we have to be careful when using functions that are not `pure` as we might get a wrong answer. For instance functions that have a `name ending with !` by convention modify their arguments and thus are not pure.

24.8 @threadcall

External libraries, such as those called via `ccall`, pose a problem for Julia's task-based I/O mechanism. If a C library performs a blocking operation, that prevents the Julia scheduler from executing any other tasks until the call returns. (Exceptions are calls into custom C code that call back into Julia, which may then yield, or C code that calls `jl_yield()`, the C equivalent of `yield`.)

The `@threadcall` macro provides a way to avoid stalling execution in such a scenario. It schedules a C function for execution in a separate thread. A threadpool with a default size of 4 is used for this. The size of the threadpool is controlled via environment variable `UV_THREADPOOL_SIZE`. While waiting for a free thread, and during function execution once a thread is available, the requesting task (on the main Julia event loop) yields to other tasks. Note that `@threadcall` does not return until the execution is complete. From a user point of view, it is therefore a blocking call like other Julia APIs.

It is very important that the called function does not call back into Julia, as it will segfault.

`@threadcall` may be removed/changed in future versions of Julia.

24.9 Caveats

At this time, most operations in the Julia runtime and standard libraries can be used in a thread-safe manner, if the user code is data-race free. However, in some areas work on stabilizing thread support is ongoing. Multi-threaded programming has many inherent difficulties, and if a program using threads exhibits unusual or undesirable behavior (e.g. crashes or mysterious results), thread interactions should typically be suspected first.

There are a few specific limitations and warnings to be aware of when using threads in Julia:

- Base collection types require manual locking if used simultaneously by multiple threads where at least one thread modifies the collection (common examples include `push!` on arrays, or inserting items into a `Dict`).
- The schedule used by `@spawn` is nondeterministic and should not be relied on.
- Compute-bound, non-memory-allocating tasks can prevent garbage collection from running in other threads that are allocating memory. In these cases it may be necessary to insert a manual call to `GC.safepoint()` to allow GC to run. This limitation will be removed in the future.

- Avoid running top-level operations, e.g. `include`, or `eval` of type, method, and module definitions in parallel.
- Be aware that finalizers registered by a library may break if threads are enabled. This may require some transitional work across the ecosystem before threading can be widely adopted with confidence. See the next section for further details.

24.10 Task Migration

After a task starts running on a certain thread it may move to a different thread if the task yields.

Such tasks may have been started with `@spawn` or `@threads`, although the `:static` schedule option for `@threads` does freeze the threadid.

This means that in most cases `threadid()` should not be treated as constant within a task, and therefore should not be used to index into a vector of buffers or stateful objects.

Julia 1.7

Task migration was introduced in Julia 1.7. Before this tasks always remained on the same thread that they were started on.

24.11 Safe use of Finalizers

Because finalizers can interrupt any code, they must be very careful in how they interact with any global state. Unfortunately, the main reason that finalizers are used is to update global state (a pure function is generally rather pointless as a finalizer). This leads us to a bit of a conundrum. There are a few approaches to dealing with this problem:

1. When single-threaded, code could call the internal `j1_gc_enable_finalizers` C function to prevent finalizers from being scheduled inside a critical region. Internally, this is used inside some functions (such as our C locks) to prevent recursion when doing certain operations (incremental package loading, codegen, etc.). The combination of a lock and this flag can be used to make finalizers safe.
2. A second strategy, employed by Base in a couple places, is to explicitly delay a finalizer until it may be able to acquire its lock non-recursively. The following example demonstrates how this strategy could be applied to `Distributed.finalize_ref`:

```
function finalize_ref(r::AbstractRemoteRef)
    if r.where > 0 # Check if the finalizer is already run
        if islocked(client_refs) || !trylock(client_refs)
            # delay finalizer for later if we aren't free to acquire the lock
            finalizer(finalize_ref, r)
            return nothing
        end
    try # `lock` should always be followed by `try`
        if r.where > 0 # Must check again here
            # Do actual cleanup here
            r.where = 0
        end
    finally
        unlock(client_refs)
    end
end
```

```
        end
    end
    nothing
end
```

3. A related third strategy is to use a yield-free queue. We don't currently have a lock-free queue implemented in Base, but `Base.IntrusiveLinkedListSynchronized{T}` is suitable. This can frequently be a good strategy to use for code with event loops. For example, this strategy is employed by `Gtk.jl` to manage lifetime ref-counting. In this approach, we don't do any explicit work inside the finalizer, and instead add it to a queue to run at a safer time. In fact, Julia's task scheduler already uses this, so defining the finalizer as `x -> @spawn do_cleanup(x)` is one example of this approach. Note however that this doesn't control which thread `do_cleanup` runs on, so `do_cleanup` would still need to acquire a lock. That doesn't need to be true if you implement your own queue, as you can explicitly only drain that queue from your thread.

Chapter 25

Multi-processing and Distributed Computing

An implementation of distributed memory parallel computing is provided by module `Distributed` as part of the standard library shipped with Julia.

Most modern computers possess more than one CPU, and several computers can be combined together in a cluster. Harnessing the power of these multiple CPUs allows many computations to be completed more quickly. There are two major factors that influence performance: the speed of the CPUs themselves, and the speed of their access to memory. In a cluster, it's fairly obvious that a given CPU will have fastest access to the RAM within the same computer (node). Perhaps more surprisingly, similar issues are relevant on a typical multicore laptop, due to differences in the speed of main memory and the `cache`. Consequently, a good multiprocessing environment should allow control over the "ownership" of a chunk of memory by a particular CPU. Julia provides a multiprocessing environment based on message passing to allow programs to run on multiple processes in separate memory domains at once.

Julia's implementation of message passing is different from other environments such as MPI¹. Communication in Julia is generally "one-sided", meaning that the programmer needs to explicitly manage only one process in a two-process operation. Furthermore, these operations typically do not look like "message send" and "message receive" but rather resemble higher-level operations like calls to user functions.

Distributed programming in Julia is built on two primitives: remote references and remote calls. A remote reference is an object that can be used from any process to refer to an object stored on a particular process. A remote call is a request by one process to call a certain function on certain arguments on another (possibly the same) process.

Remote references come in two flavors: `Future` and `RemoteChannel`.

A remote call returns a `Future` to its result. Remote calls return immediately; the process that made the call proceeds to its next operation while the remote call happens somewhere else. You can wait for a remote call to finish by calling `wait` on the returned `Future`, and you can obtain the full value of the result using `fetch`.

On the other hand, `RemoteChannel`s are rewritable. For example, multiple processes can coordinate their processing by referencing the same remote `Channel`.

Each process has an associated identifier. The process providing the interactive Julia prompt always has an id equal to 1. The processes used by default for parallel operations are referred to as "workers". When there is only one process, process 1 is considered a worker. Otherwise, workers are considered to be all processes other than process 1. As a result, adding 2 or more processes is required to gain benefits from parallel processing methods like `pmap`. Adding a single process is beneficial if you just wish to do other things in the main process while a long computation is running on the worker.

Let's try this out. Starting with `julia -p n` provides `n` worker processes on the local machine. Generally it makes sense for `n` to equal the number of CPU threads (logical cores) on the machine. Note that the `-p` argument implicitly loads module `Distributed`.

```
$ julia -p 2

julia> r = remotecall(rand, 2, 2, 2)
Future(2, 1, 4, nothing)

julia> s = @spawnat 2 1 .+ fetch(r)
Future(2, 1, 5, nothing)

julia> fetch(s)
2×2 Array{Float64,2}:
 1.18526  1.50912
 1.16296  1.60607
```

The first argument to `remotecall` is the function to call. Most parallel programming in Julia does not reference specific processes or the number of processes available, but `remotecall` is considered a low-level interface providing finer control. The second argument to `remotecall` is the id of the process that will do the work, and the remaining arguments will be passed to the function being called.

As you can see, in the first line we asked process 2 to construct a 2-by-2 random matrix, and in the second line we asked it to add 1 to it. The result of both calculations is available in the two futures, `r` and `s`. The `@spawnat` macro evaluates the expression in the second argument on the process specified by the first argument.

Occasionally you might want a remotely-computed value immediately. This typically happens when you read from a remote object to obtain data needed by the next local operation. The function `remotecall_fetch` exists for this purpose. It is equivalent to `fetch(remotecall(...))` but is more efficient.

```
julia> remotecall_fetch(r-> fetch(r)[1, 1], 2, r)
0.18526337335308085
```

This fetches the array on worker 2 and returns the first value. Note, that `fetch` doesn't move any data in this case, since it's executed on the worker that owns the array. One can also write:

```
julia> remotecall_fetch(getindex, 2, r, 1, 1)
0.10824216411304866
```

Remember that `getindex(r, 1, 1)` is equivalent to `r[1, 1]`, so this call fetches the first element of the future `r`.

To make things easier, the symbol `:any` can be passed to `@spawnat`, which picks where to do the operation for you:

```
julia> r = @spawnat :any rand(2,2)
Future(2, 1, 4, nothing)

julia> s = @spawnat :any 1 .+ fetch(r)
```

```
Future(3, 1, 5, nothing)
```

```
julia> fetch(s)
2×2 Array{Float64,2}:
 1.38854  1.9098
 1.20939  1.57158
```

Note that we used `1 .+ fetch(r)` instead of `1 .+ r`. This is because we do not know where the code will run, so in general a `fetch` might be required to move `r` to the process doing the addition. In this case, `@spawnat` is smart enough to perform the computation on the process that owns `r`, so the `fetch` will be a no-op (no work is done).

(It is worth noting that `@spawnat` is not built-in but defined in Julia as a `macro`. It is possible to define your own such constructs.)

An important thing to remember is that, once fetched, a `Future` will cache its value locally. Further `fetch` calls do not entail a network hop. Once all referencing `Futures` have fetched, the remote stored value is deleted.

`@async` is similar to `@spawnat`, but only runs tasks on the local process. We use it to create a "feeder" task for each process. Each task picks the next index that needs to be computed, then waits for its process to finish, then repeats until we run out of indices. Note that the feeder tasks do not begin to execute until the main task reaches the end of the `@sync` block, at which point it surrenders control and waits for all the local tasks to complete before returning from the function. As for v0.7 and beyond, the feeder tasks are able to share state via `nextidx` because they all run on the same process. Even if Tasks are scheduled cooperatively, locking may still be required in some contexts, as in [asynchronous I/O](#). This means context switches only occur at well-defined points: in this case, when `remotecall_fetch` is called. This is the current state of implementation and it may change for future Julia versions, as it is intended to make it possible to run up to N Tasks on M Process, aka [M:N Threading](#). Then a lock acquiring\releasing model for `nextidx` will be needed, as it is not safe to let multiple processes read-write a resource at the same time.

25.1 Code Availability and Loading Packages

Your code must be available on any process that runs it. For example, type the following into the Julia prompt:

```
julia> function rand2(dims...)
           return 2*rand(dims...)
       end

julia> rand2(2,2)
2×2 Array{Float64,2}:
 0.153756  0.368514
 1.15119   0.918912

julia> fetch(@spawnat :any rand2(2,2))
ERROR: RemoteException(2, CapturedException(UndefVarError(Symbol("#rand2")))
Stacktrace:
[...]
```

Process 1 knew about the function `rand2`, but process 2 did not.

Most commonly you'll be loading code from files or packages, and you have a considerable amount of flexibility in controlling which processes load code. Consider a file, `DummyModule.jl`, containing the following code:

```
module DummyModule

export MyType, f

mutable struct MyType
    a::Int
end

f(x) = x^2+1

println("loaded")

end
```

In order to refer to `MyType` across all processes, `DummyModule.jl` needs to be loaded on every process. Calling `include("DummyModule.jl")` loads it only on a single process. To load it on every process, use the `@everywhere` macro (starting Julia with `julia -p 2`):

```
julia> @everywhere include("DummyModule.jl")
loaded
      From worker 3:    loaded
      From worker 2:    loaded
```

As usual, this does not bring `DummyModule` into scope on any of the process, which requires `using` or `import`. Moreover, when `DummyModule` is brought into scope on one process, it is not on any other:

```
julia> using .DummyModule

julia> MyType(7)
MyType(7)

julia> fetch(@spawnat 2 MyType(7))
ERROR: On worker 2:
UndefVarError: `MyType` not defined

julia> fetch(@spawnat 2 DummyModule.MyType(7))
MyType(7)
```

However, it's still possible, for instance, to send a `MyType` to a process which has loaded `DummyModule` even if it's not in scope:

```
julia> put!(RemoteChannel{2}, MyType(7))
RemoteChannel{Channel{Any}}{2, 1, 13}
```

A file can also be preloaded on multiple processes at startup with the `-L` flag, and a driver script can be used to drive the computation:

```
| julia -p <n> -L file1.jl -L file2.jl driver.jl
```

The Julia process running the driver script in the example above has an `id` equal to 1, just like a process providing an interactive prompt.

Finally, if `DummyModule.jl` is not a standalone file but a package, then using `DummyModule` will load `DummyModule.jl` on all processes, but only bring it into scope on the process where `using` was called.

25.2 Starting and managing worker processes

The base Julia installation has in-built support for two types of clusters:

- A local cluster specified with the `-p` option as shown above.
- A cluster spanning machines using the `--machine-file` option. This uses a passwordless ssh login to start Julia worker processes (from the same path as the current host) on the specified machines. Each machine definition takes the form `[count*][user@]host[:port] [bind_addr[:port]]`. `user` defaults to current user, `port` to the standard ssh port. `count` is the number of workers to spawn on the node, and defaults to 1. The optional `bind-to bind_addr[:port]` specifies the IP address and port that other workers should use to connect to this worker.

Note

While Julia generally strives for backward compatibility, distribution of code to worker processes relies on `Serialization.serialize`. As pointed out in the corresponding documentation, this can not be guaranteed to work across different Julia versions, so it is advised that all workers on all machines use the same version.

Functions `addprocs`, `rmprocs`, `workers`, and others are available as a programmatic means of adding, removing and querying the processes in a cluster.

```
| julia> using Distributed
|
| julia> addprocs(2)
| 2-element Array{Int64,1}:
|  2
|  3
```

Module `Distributed` must be explicitly loaded on the master process before invoking `addprocs`. It is automatically made available on the worker processes.

Note that workers do not run a `~/.julia/config/startup.jl` startup script, nor do they synchronize their global state (such as global variables, new method definitions, and loaded modules) with any of the other running processes. You may use `addprocs(exeflags="--project")` to initialize a worker with a particular environment, and then `@everywhere using <modulename>` or `@everywhere include("file.jl")`.

Other types of clusters can be supported by writing your own custom `ClusterManager`, as described below in the `ClusterManagers` section.

25.3 Data Movement

Sending messages and moving data constitute most of the overhead in a distributed program. Reducing the number of messages and the amount of data sent is critical to achieving performance and scalability. To this end, it is important to understand the data movement performed by Julia's various distributed programming constructs.

`fetch` can be considered an explicit data movement operation, since it directly asks that an object be moved to the local machine. `@spawnat` (and a few related constructs) also moves data, but this is not as obvious, hence it can be called an implicit data movement operation. Consider these two approaches to constructing and squaring a random matrix:

Method 1:

```
julia> A = rand(1000,1000);
julia> Bref = @spawnat :any A^2;
[...]
julia> fetch(Bref);
```

Method 2:

```
julia> Bref = @spawnat :any rand(1000,1000)^2;
[...]
julia> fetch(Bref);
```

The difference seems trivial, but in fact is quite significant due to the behavior of `@spawnat`. In the first method, a random matrix is constructed locally, then sent to another process where it is squared. In the second method, a random matrix is both constructed and squared on another process. Therefore the second method sends much less data than the first.

In this toy example, the two methods are easy to distinguish and choose from. However, in a real program designing data movement might require more thought and likely some measurement. For example, if the first process needs matrix A then the first method might be better. Or, if computing A is expensive and only the current process has it, then moving it to another process might be unavoidable. Or, if the current process has very little to do between the `@spawnat` and `fetch(Bref)`, it might be better to eliminate the parallelism altogether. Or imagine `rand(1000,1000)` is replaced with a more expensive operation. Then it might make sense to add another `@spawnat` statement just for this step.

25.4 Global variables

Expressions executed remotely via `@spawnat`, or closures specified for remote execution using `remotecall` may refer to global variables. Global bindings under module `Main` are treated a little differently compared to global bindings in other modules. Consider the following code snippet:

```
A = rand(10,10)
remotecall_fetch(()->sum(A), 2)
```

In this case `sum` MUST be defined in the remote process. Note that `A` is a global variable defined in the local workspace. Worker 2 does not have a variable called `A` under `Main`. The act of shipping the closure `()->sum(A)` to worker 2 results in `Main.A` being defined on 2. `Main.A` continues to exist on worker 2 even after the call `remotecall_fetch` returns. Remote calls with embedded global references (under `Main` module only) manage globals as follows:

- New global bindings are created on destination workers if they are referenced as part of a remote call.
- Global constants are declared as constants on remote nodes too.
- Globals are re-sent to a destination worker only in the context of a remote call, and then only if its value has changed. Also, the cluster does not synchronize global bindings across nodes. For example:

```
A = rand(10,10)
remotecall_fetch(()->sum(A), 2) # worker 2
A = rand(10,10)
remotecall_fetch(()->sum(A), 3) # worker 3
A = nothing
```

Executing the above snippet results in `Main.A` on worker 2 having a different value from `Main.A` on worker 3, while the value of `Main.A` on node 1 is set to `nothing`.

As you may have realized, while memory associated with globals may be collected when they are reassigned on the master, no such action is taken on the workers as the bindings continue to be valid. `clear!` can be used to manually reassign specific globals on remote nodes to `nothing` once they are no longer required. This will release any memory associated with them as part of a regular garbage collection cycle.

Thus programs should be careful referencing globals in remote calls. In fact, it is preferable to avoid them altogether if possible. If you must reference globals, consider using `let` blocks to localize global variables.

For example:

```
julia> A = rand(10,10);

julia> remotecall_fetch(()->A, 2);

julia> B = rand(10,10);

julia> let B = B
    remotecall_fetch(()->B, 2)
end;

julia> @fetchfrom 2 InteractiveUtils.varinfo()
name      size summary
-----
A          800 bytes 10×10 Array{Float64,2}
Base
Core
Main
```

As can be seen, global variable `A` is defined on worker 2, but `B` is captured as a local variable and hence a binding for `B` does not exist on worker 2.

25.5 Parallel Map and Loops

Fortunately, many useful parallel computations do not require data movement. A common example is a Monte Carlo simulation, where multiple processes can handle independent simulation trials simultaneously. We can use `@spawnat` to flip coins on two processes. First, write the following function in `count_heads.jl`:

```
function count_heads(n)
    c::Int = 0
    for i = 1:n
        c += rand{Bool}
    end
    c
end
```

The function `count_heads` simply adds together `n` random bits. Here is how we can perform some trials on two machines, and add together the results:

```
julia> @everywhere include_string(Main, $(read("count_heads.jl", String)), "count_heads.jl")

julia> a = @spawnat :any count_heads(100000000)
Future(2, 1, 6, nothing)

julia> b = @spawnat :any count_heads(100000000)
Future(3, 1, 7, nothing)

julia> fetch(a)+fetch(b)
100001564
```

This example demonstrates a powerful and often-used parallel programming pattern. Many iterations run independently over several processes, and then their results are combined using some function. The combination process is called a reduction, since it is generally tensor-rank-reducing: a vector of numbers is reduced to a single number, or a matrix is reduced to a single row or column, etc. In code, this typically looks like the pattern `x = f(x, v[i])`, where `x` is the accumulator, `f` is the reduction function, and the `v[i]` are the elements being reduced. It is desirable for `f` to be associative, so that it does not matter what order the operations are performed in.

Notice that our use of this pattern with `count_heads` can be generalized. We used two explicit `@spawnat` statements, which limits the parallelism to two processes. To run on any number of processes, we can use a parallel for loop, running in distributed memory, which can be written in Julia using `@distributed` like this:

```
nheads = @distributed (+) for i = 1:200000000
    Int(rand{Bool})
end
```

This construct implements the pattern of assigning iterations to multiple processes, and combining them with a specified reduction (in this case `(+)`). The result of each iteration is taken as the value of the last expression inside the loop. The whole parallel loop expression itself evaluates to the final answer.

Note that although parallel for loops look like serial for loops, their behavior is dramatically different. In particular, the iterations do not happen in a specified order, and writes to variables or arrays will not be

globally visible since iterations run on different processes. Any variables used inside the parallel loop will be copied and broadcast to each process.

For example, the following code will not work as intended:

```
a = zeros(100000)
@distributed for i = 1:100000
    a[i] = i
end
```

This code will not initialize all of `a`, since each process will have a separate copy of it. Parallel for loops like these must be avoided. Fortunately, [Shared Arrays](#) can be used to get around this limitation:

```
using SharedArrays

a = SharedArray{Float64}(10)
@distributed for i = 1:10
    a[i] = i
end
```

Using "outside" variables in parallel loops is perfectly reasonable if the variables are read-only:

```
a = randn(1000)
@distributed (+) for i = 1:100000
    f(a[rand(1:end)])
end
```

Here each iteration applies `f` to a randomly-chosen sample from a vector `a` shared by all processes.

As you could see, the reduction operator can be omitted if it is not needed. In that case, the loop executes asynchronously, i.e. it spawns independent tasks on all available workers and returns an array of [Future](#) immediately without waiting for completion. The caller can wait for the [Future](#) completions at a later point by calling [fetch](#) on them, or wait for completion at the end of the loop by prefixing it with [@sync](#), like `@sync @distributed for`.

In some cases no reduction operator is needed, and we merely wish to apply a function to all integers in some range (or, more generally, to all elements in some collection). This is another useful operation called parallel map, implemented in Julia as the [pmap](#) function. For example, we could compute the singular values of several large random matrices in parallel as follows:

```
julia> M = Matrix{Float64}(rand(1000,1000) for i = 1:10);
julia> pmap(svdvals, M);
```

Julia's [pmap](#) is designed for the case where each function call does a large amount of work. In contrast, `@distributed for` can handle situations where each iteration is tiny, perhaps merely summing two numbers. Only worker processes are used by both [pmap](#) and `@distributed for` for the parallel computation. In case of `@distributed for`, the final reduction is done on the calling process.

25.6 Remote References and AbstractChannels

Remote references always refer to an implementation of an `AbstractChannel`.

A concrete implementation of an `AbstractChannel` (like `Channel`), is required to implement `put!`, `take!`, `fetch`, `isready` and `wait`. The remote object referred to by a `Future` is stored in a `Channel{Any}(1)`, i.e., a `Channel` of size 1 capable of holding objects of Any type.

`RemoteChannel`, which is rewritable, can point to any type and size of channels, or any other implementation of an `AbstractChannel`.

The constructor `RemoteChannel(f::Function, pid)()` allows us to construct references to channels holding more than one value of a specific type. `f` is a function executed on `pid` and it must return an `AbstractChannel`.

For example, `RemoteChannel(()->Channel{Int}(10), pid)`, will return a reference to a channel of type `Int` and size 10. The channel exists on worker `pid`.

Methods `put!`, `take!`, `fetch`, `isready` and `wait` on a `RemoteChannel` are proxied onto the backing store on the remote process.

`RemoteChannel` can thus be used to refer to user implemented `AbstractChannel` objects. A simple example of this is provided in `dictchannel.jl` in the [Examples repository](#), which uses a dictionary as its remote store.

25.7 Channels and RemoteChannels

- A `Channel` is local to a process. Worker 2 cannot directly refer to a `Channel` on worker 3 and vice-versa. A `RemoteChannel`, however, can put and take values across workers.
- A `RemoteChannel` can be thought of as a handle to a `Channel`.
- The process id, `pid`, associated with a `RemoteChannel` identifies the process where the backing store, i.e., the backing `Channel` exists.
- Any process with a reference to a `RemoteChannel` can put and take items from the channel. Data is automatically sent to (or retrieved from) the process a `RemoteChannel` is associated with.
- Serializing a `Channel` also serializes any data present in the channel. Deserializing it therefore effectively makes a copy of the original object.
- On the other hand, serializing a `RemoteChannel` only involves the serialization of an identifier that identifies the location and instance of `Channel` referred to by the handle. A deserialized `RemoteChannel` object (on any worker), therefore also points to the same backing store as the original.

The channels example from above can be modified for interprocess communication, as shown below.

We start 4 workers to process a single jobs remote channel. Jobs, identified by an id (`job_id`), are written to the channel. Each remotely executing task in this simulation reads a `job_id`, waits for a random amount of time and writes back a tuple of `job_id`, time taken and its own `pid` to the results channel. Finally all the results are printed out on the master process.

```
julia> addprocs(4); # add worker processes
julia> const jobs = RemoteChannel(()->Channel{Int}(32));
```

```

julia> const results = RemoteChannel{()->Channel{Tuple}}(32));

julia> @everywhere function do_work(jobs, results) # define work function everywhere
    while true
        job_id = take!(jobs)
        exec_time = rand()
        sleep(exec_time) # simulates elapsed time doing actual work
        put!(results, (job_id, exec_time, myid()))
    end
end

julia> function make_jobs(n)
    for i in 1:n
        put!(jobs, i)
    end
end;

julia> n = 12;

julia> errormonitor(@async make_jobs(n)); # feed the jobs channel with "n" jobs

julia> for p in workers() # start tasks on the workers to process requests in parallel
    remote_do(do_work, p, jobs, results)
end

julia> @elapsed while n > 0 # print out results
    job_id, exec_time, where = take!(results)
    println("$job_id finished in $(round(exec_time; digits=2)) seconds on worker $where")
    global n = n - 1
end
1 finished in 0.18 seconds on worker 4
2 finished in 0.26 seconds on worker 5
6 finished in 0.12 seconds on worker 4
7 finished in 0.18 seconds on worker 4
5 finished in 0.35 seconds on worker 5
4 finished in 0.68 seconds on worker 2
3 finished in 0.73 seconds on worker 3
11 finished in 0.01 seconds on worker 3
12 finished in 0.02 seconds on worker 3
9 finished in 0.26 seconds on worker 5
8 finished in 0.57 seconds on worker 4
10 finished in 0.58 seconds on worker 2
0.055971741

```

Remote References and Distributed Garbage Collection

Objects referred to by remote references can be freed only when all held references in the cluster are deleted.

The node where the value is stored keeps track of which of the workers have a reference to it. Every time a `RemoteChannel` or a (unfetched) `Future` is serialized to a worker, the node pointed to by the reference is notified. And every time a `RemoteChannel` or a (unfetched) `Future` is garbage collected locally, the node

owning the value is again notified. This is implemented in an internal cluster aware serializer. Remote references are only valid in the context of a running cluster. Serializing and deserializing references to and from regular IO objects is not supported.

The notifications are done via sending of "tracking" messages—an "add reference" message when a reference is serialized to a different process and a "delete reference" message when a reference is locally garbage collected.

Since `Futures` are write-once and cached locally, the act of `fetching` a `Future` also updates reference tracking information on the node owning the value.

The node which owns the value frees it once all references to it are cleared.

With `Futures`, serializing an already fetched `Future` to a different node also sends the value since the original remote store may have collected the value by this time.

It is important to note that when an object is locally garbage collected depends on the size of the object and the current memory pressure in the system.

In case of remote references, the size of the local reference object is quite small, while the value stored on the remote node may be quite large. Since the local object may not be collected immediately, it is a good practice to explicitly call `finalize` on local instances of a `RemoteChannel`, or on unfetched `Futures`. Since calling `fetch` on a `Future` also removes its reference from the remote store, this is not required on fetched `Futures`. Explicitly calling `finalize` results in an immediate message sent to the remote node to go ahead and remove its reference to the value.

Once finalized, a reference becomes invalid and cannot be used in any further calls.

25.8 Local invocations

Data is necessarily copied over to the remote node for execution. This is the case for both remotecalls and when data is stored to a `RemoteChannel` / `Future` on a different node. As expected, this results in a copy of the serialized objects on the remote node. However, when the destination node is the local node, i.e. the calling process id is the same as the remote node id, it is executed as a local call. It is usually (not always) executed in a different task - but there is no serialization/deserialization of data. Consequently, the call refers to the same object instances as passed - no copies are created. This behavior is highlighted below:

```
julia> using Distributed;

julia> rc = RemoteChannel{()->Channel{3}}(); # RemoteChannel created on local node

julia> v = [0];

julia> for i in 1:3
           v[1] = i
           put!(rc, v)
       end; # Reusing `v`

julia> result = [take!(rc) for _ in 1:3];

julia> println(result);
Array{Int64,1}[[3], [3], [3]]

julia> println("Num Unique objects : ", length(unique(map(objectid, result))));
```

```

Num Unique objects : 1

julia> addprocs(1);

julia> rc = RemoteChannel{()->Channel{3}, workers()[1]}; # RemoteChannel created on remote node

julia> v = [0];

julia> for i in 1:3
           v[1] = i
           put!(rc, v)
       end;

julia> result = [take!(rc) for _ in 1:3];

julia> println(result);
Array{Int64,1}[[1], [2], [3]]

julia> println("Num Unique objects : ", length(unique(map(objectid, result))));
Num Unique objects : 3

```

As can be seen, `put!` on a locally owned `RemoteChannel` with the same object `v` modified between calls results in the same single object instance stored. As opposed to copies of `v` being created when the node owning `rc` is a different node.

It is to be noted that this is generally not an issue. It is something to be factored in only if the object is both being stored locally and modified post the call. In such cases it may be appropriate to store a deepcopy of the object.

This is also true for remotecalls on the local node as seen in the following example:

```

julia> using Distributed; addprocs(1);

julia> v = [0];

julia> v2 = remotecall_fetch(x->(x[1] = 1; x), myid(), v); # Executed on local node

julia> println("v=$v, v2=$v2, ", v == v2);
v=[1], v2=[1], true

julia> v = [0];

julia> v2 = remotecall_fetch(x->(x[1] = 1; x), workers()[1], v); # Executed on remote node

julia> println("v=$v, v2=$v2, ", v == v2);
v=[0], v2=[1], false

```

As can be seen once again, a remote call onto the local node behaves just like a direct invocation. The call modifies local objects passed as arguments. In the remote invocation, it operates on a copy of the arguments.

To repeat, in general this is not an issue. If the local node is also being used as a compute node, and the arguments used post the call, this behavior needs to be factored in and if required deep copies of arguments

must be passed to the call invoked on the local node. Calls on remote nodes will always operate on copies of arguments.

25.9 Shared Arrays

Shared Arrays use system shared memory to map the same array across many processes. While there are some similarities to a `DArray`, the behavior of a `SharedArray` is quite different. In a `DArray`, each process has local access to just a chunk of the data, and no two processes share the same chunk; in contrast, in a `SharedArray` each "participating" process has access to the entire array. A `SharedArray` is a good choice when you want to have a large amount of data jointly accessible to two or more processes on the same machine.

Shared Array support is available via module `SharedArrays` which must be explicitly loaded on all participating workers.

`SharedArray` indexing (assignment and accessing values) works just as with regular arrays, and is efficient because the underlying memory is available to the local process. Therefore, most algorithms work naturally on `SharedArrays`, albeit in single-process mode. In cases where an algorithm insists on an `Array` input, the underlying array can be retrieved from a `SharedArray` by calling `sdata`. For other `AbstractArray` types, `sdata` just returns the object itself, so it's safe to use `sdata` on any `Array`-type object.

The constructor for a shared array is of the form:

```
SharedArray{T,N}(dims::NTuple; init=false, pids=Int[])
```

which creates an N-dimensional shared array of a bits type `T` and size `dims` across the processes specified by `pids`. Unlike distributed arrays, a shared array is accessible only from those participating workers specified by the `pids` named argument (and the creating process too, if it is on the same host). Note that only elements that are `isbits` are supported in a `SharedArray`.

If an `init` function, of signature `initfn(S::SharedArray)`, is specified, it is called on all the participating workers. You can specify that each worker runs the `init` function on a distinct portion of the array, thereby parallelizing initialization.

Here's a brief example:

```
julia> using Distributed

julia> addprocs(3)
3-element Array{Int64,1}:
 2
 3
 4

julia> @everywhere using SharedArrays

julia> S = SharedArray{Int,2}((3,4), init = S -> S[localindices(S)] = repeat([myid()],
↪ length(localindices(S))))
3×4 SharedArray{Int64,2}:
 2  2  3  4
 2  3  3  4
 2  3  4  4
```

```
julia> S[3,2] = 7
7

julia> S
3×4 SharedArray{Int64,2}:
 2  2  3  4
 2  3  3  4
 2  7  4  4
```

`SharedArrays.localindices` provides disjoint one-dimensional ranges of indices, and is sometimes convenient for splitting up tasks among processes. You can, of course, divide the work any way you wish:

```
julia> S = SharedArray{Int,2}((3,4), init = S -> S[indexpids(S):length(procs(S)):length(S)] =
↳ repeat([myid()], length( indexpids(S):length(procs(S)):length(S))))
3×4 SharedArray{Int64,2}:
 2  2  2  2
 3  3  3  3
 4  4  4  4
```

Since all processes have access to the underlying data, you do have to be careful not to set up conflicts. For example:

```
@sync begin
    for p in procs(S)
        @async begin
            remotecall_wait(fill!, p, S, p)
        end
    end
end
```

would result in undefined behavior. Because each process fills the entire array with its own pid, whichever process is the last to execute (for any particular element of `S`) will have its pid retained.

As a more extended and complex example, consider running the following "kernel" in parallel:

$$q[i,j,t+1] = q[i,j,t] + u[i,j,t]$$

In this case, if we try to split up the work using a one-dimensional index, we are likely to run into trouble: if $q[i,j,t]$ is near the end of the block assigned to one worker and $q[i,j,t+1]$ is near the beginning of the block assigned to another, it's very likely that $q[i,j,t]$ will not be ready at the time it's needed for computing $q[i,j,t+1]$. In such cases, one is better off chunking the array manually. Let's split along the second dimension. Define a function that returns the $(i\text{range}, j\text{range})$ indices assigned to this worker:

```
julia> @everywhere function myrange(q::SharedArray)
    idx = indexpids(q)
    if idx == 0 # This worker is not assigned a piece
        return 1:0, 1:0
    end
end
```

```

        nchunks = length(procs(q))
        splits = [round{Int, s} for s in range(0, stop=size(q,2), length=nchunks+1)]
        1:size(q,1), splits[idx]+1:splits[idx+1]
    end

```

Next, define the kernel:

```

julia> @everywhere function advection_chunk!(q, u, irange, jrange, trange)
    @show (irange, jrange, trange) # display so we can see what's happening
    for t in trange, j in jrange, i in irange
        q[i,j,t+1] = q[i,j,t] + u[i,j,t]
    end
    q
end

```

We also define a convenience wrapper for a SharedArray implementation

```

julia> @everywhere advection_shared_chunk!(q, u) =
    advection_chunk!(q, u, myrange(q)..., 1:size(q,3)-1)

```

Now let's compare three different versions, one that runs in a single process:

```

julia> advection_serial!(q, u) = advection_chunk!(q, u, 1:size(q,1), 1:size(q,2), 1:size(q,3)-1);

```

one that uses `@distributed`:

```

julia> function advection_parallel!(q, u)
    for t = 1:size(q,3)-1
        @sync @distributed for j = 1:size(q,2)
            for i = 1:size(q,1)
                q[i,j,t+1] = q[i,j,t] + u[i,j,t]
            end
        end
    end
    q
end;

```

and one that delegates in chunks:

```

julia> function advection_shared!(q, u)
    @sync begin
        for p in procs(q)
            @async remotecall_wait(advection_shared_chunk!, p, q, u)
        end
    end
    q
end;

```

If we create SharedArrays and time these functions, we get the following results (with `julia -p 4`):

```
julia> q = SharedArray{Float64,3}((500,500,500));
julia> u = SharedArray{Float64,3}((500,500,500));
```

Run the functions once to JIT-compile and `@time` them on the second run:

```
julia> @time advection_serial!(q, u);
(irange,jrange,trange) = (1:500,1:500,1:499)
830.220 milliseconds (216 allocations: 13820 bytes)

julia> @time advection_parallel!(q, u);
2.495 seconds (3999 k allocations: 289 MB, 2.09% gc time)

julia> @time advection_shared!(q,u);
From worker 2: (irange,jrange,trange) = (1:500,1:125,1:499)
From worker 4: (irange,jrange,trange) = (1:500,251:375,1:499)
From worker 3: (irange,jrange,trange) = (1:500,126:250,1:499)
From worker 5: (irange,jrange,trange) = (1:500,376:500,1:499)
238.119 milliseconds (2264 allocations: 169 KB)
```

The biggest advantage of `advection_shared!` is that it minimizes traffic among the workers, allowing each to compute for an extended time on the assigned piece.

Shared Arrays and Distributed Garbage Collection

Like remote references, shared arrays are also dependent on garbage collection on the creating node to release references from all participating workers. Code which creates many short lived shared array objects would benefit from explicitly finalizing these objects as soon as possible. This results in both memory and file handles mapping the shared segment being released sooner.

25.10 ClusterManagers

The launching, management and networking of Julia processes into a logical cluster is done via cluster managers. A `ClusterManager` is responsible for

- launching worker processes in a cluster environment
- managing events during the lifetime of each worker
- optionally, providing data transport

A Julia cluster has the following characteristics:

- The initial Julia process, also called the master, is special and has an id of 1.
- Only the master process can add or remove worker processes.
- All processes can directly communicate with each other.

Connections between workers (using the in-built TCP/IP transport) is established in the following manner:

- `addprocs` is called on the master process with a `ClusterManager` object.
- `addprocs` calls the appropriate `launch` method which spawns required number of worker processes on appropriate machines.
- Each worker starts listening on a free port and writes out its host and port information to `stdout`.
- The cluster manager captures the `stdout` of each worker and makes it available to the master process.
- The master process parses this information and sets up TCP/IP connections to each worker.
- Every worker is also notified of other workers in the cluster.
- Each worker connects to all workers whose id is less than the worker's own id.
- In this way a mesh network is established, wherein every worker is directly connected with every other worker.

While the default transport layer uses plain `TCPSocket`, it is possible for a Julia cluster to provide its own transport.

Julia provides two in-built cluster managers:

- `LocalManager`, used when `addprocs()` or `addprocs(np::Integer)` are called
- `SSHManager`, used when `addprocs(hostnames::Array)` is called with a list of hostnames

`LocalManager` is used to launch additional workers on the same host, thereby leveraging multi-core and multi-processor hardware.

Thus, a minimal cluster manager would need to:

- be a subtype of the abstract `ClusterManager`
- implement `launch`, a method responsible for launching new workers
- implement `manage`, which is called at various events during a worker's lifetime (for example, sending an interrupt signal)

`addprocs(manager::FooManager)` requires `FooManager` to implement:

```
function launch(manager::FooManager, params::Dict, launched::Array, c::Condition)
    [...]
end

function manage(manager::FooManager, id::Integer, config::WorkerConfig, op::Symbol)
    [...]
end
```

As an example let us see how the `LocalManager`, the manager responsible for starting workers on the same host, is implemented:

```

struct LocalManager <: ClusterManager
    np::Integer
end

function launch(manager::LocalManager, params::Dict, launched::Array, c::Condition)
    [...]
end

function manage(manager::LocalManager, id::Integer, config::WorkerConfig, op::Symbol)
    [...]
end

```

The `launch` method takes the following arguments:

- `manager::ClusterManager`: the cluster manager that `addprocs` is called with
- `params::Dict`: all the keyword arguments passed to `addprocs`
- `launched::Array`: the array to append one or more `WorkerConfig` objects to
- `c::Condition`: the condition variable to be notified as and when workers are launched

The `launch` method is called asynchronously in a separate task. The termination of this task signals that all requested workers have been launched. Hence the `launch` function MUST exit as soon as all the requested workers have been launched.

Newly launched workers are connected to each other and the master process in an all-to-all manner. Specifying the command line argument `--worker[=<cookie>]` results in the launched processes initializing themselves as workers and connections being set up via TCP/IP sockets.

All workers in a cluster share the same `cookie` as the master. When the cookie is unspecified, i.e. with the `--worker` option, the worker tries to read it from its standard input. `LocalManager` and `SSHManager` both pass the cookie to newly launched workers via their standard inputs.

By default a worker will listen on a free port at the address returned by a call to `getipaddr()`. A specific address to listen on may be specified by optional argument `--bind-to bind_addr[:port]`. This is useful for multi-homed hosts.

As an example of a non-TCP/IP transport, an implementation may choose to use MPI, in which case `--worker` must NOT be specified. Instead, newly launched workers should call `init_worker(cookie)` before using any of the parallel constructs.

For every worker launched, the `launch` method must add a `WorkerConfig` object (with appropriate fields initialized) to `launched`

```

mutable struct WorkerConfig
    # Common fields relevant to all cluster managers
    io::Union{IO, Nothing}
    host::Union{AbstractString, Nothing}
    port::Union{Integer, Nothing}

    # Used when launching additional workers at a host
    count::Union{Int, Symbol, Nothing}

```

```

exename::Union{AbstractString, Cmd, Nothing}
exeflags::Union{Cmd, Nothing}

# External cluster managers can use this to store information at a per-worker level
# Can be a dict if multiple fields need to be stored.
userdata::Any

# SSHManager / SSH tunnel connections to workers
tunnel::Union{Bool, Nothing}
bind_addr::Union{AbstractString, Nothing}
sshflags::Union{Cmd, Nothing}
max_parallel::Union{Integer, Nothing}

# Used by Local/SSH managers
connect_at::Any

[...]
end

```

Most of the fields in `WorkerConfig` are used by the inbuilt managers. Custom cluster managers would typically specify only `io` or `host / port`:

- If `io` is specified, it is used to read host/port information. A Julia worker prints out its bind address and port at startup. This allows Julia workers to listen on any free port available instead of requiring worker ports to be configured manually.
- If `io` is not specified, `host` and `port` are used to connect.
- `count`, `exename` and `exeflags` are relevant for launching additional workers from a worker. For example, a cluster manager may launch a single worker per node, and use that to launch additional workers.
 - `count` with an integer value `n` will launch a total of `n` workers.
 - `count` with a value of `:auto` will launch as many workers as the number of CPU threads (logical cores) on that machine.
 - `exename` is the name of the `julia` executable including the full path.
 - `exeflags` should be set to the required command line arguments for new workers.
- `tunnel`, `bind_addr`, `sshflags` and `max_parallel` are used when a `ssh` tunnel is required to connect to the workers from the master process.
- `userdata` is provided for custom cluster managers to store their own worker-specific information.

`manage(manager::FooManager, id::Integer, config::WorkerConfig, op::Symbol)` is called at different times during the worker's lifetime with appropriate `op` values:

- with `:register`/`:deregister` when a worker is added / removed from the Julia worker pool.
- with `:interrupt` when `interrupt(workers)` is called. The `ClusterManager` should signal the appropriate worker with an interrupt signal.
- with `:finalize` for cleanup purposes.

Cluster Managers with Custom Transports

Replacing the default TCP/IP all-to-all socket connections with a custom transport layer is a little more involved. Each Julia process has as many communication tasks as the workers it is connected to. For example, consider a Julia cluster of 32 processes in an all-to-all mesh network:

- Each Julia process thus has 31 communication tasks.
- Each task handles all incoming messages from a single remote worker in a message-processing loop.
- The message-processing loop waits on an I/O object (for example, a [TCP Socket](#) in the default implementation), reads an entire message, processes it and waits for the next one.
- Sending messages to a process is done directly from any Julia task—not just communication tasks—again, via the appropriate I/O object.

Replacing the default transport requires the new implementation to set up connections to remote workers and to provide appropriate I/O objects that the message-processing loops can wait on. The manager-specific callbacks to be implemented are:

```
connect(manager::FooManager, pid::Integer, config::WorkerConfig)
kill(manager::FooManager, pid::Int, config::WorkerConfig)
```

The default implementation (which uses TCP/IP sockets) is implemented as `connect(manager::ClusterManager, pid::Integer, config::WorkerConfig)`.

`connect` should return a pair of I/O objects, one for reading data sent from worker `pid`, and the other to write data that needs to be sent to worker `pid`. Custom cluster managers can use an in-memory `BufferStream` as the plumbing to proxy data between the custom, possibly non-I/O transport and Julia's in-built parallel infrastructure.

A `BufferStream` is an in-memory [IOBuffer](#) which behaves like an I/O—it is a stream which can be handled asynchronously.

The folder `clustermanager/0mq` in the [Examples repository](#) contains an example of using ZeroMQ to connect Julia workers in a star topology with a 0MQ broker in the middle. Note: The Julia processes are still all logically connected to each other—any worker can message any other worker directly without any awareness of 0MQ being used as the transport layer.

When using custom transports:

- Julia workers must NOT be started with `--worker`. Starting with `--worker` will result in the newly launched workers defaulting to the TCP/IP socket transport implementation.
- For every incoming logical connection with a worker, `Base.process_messages(rd::IO, wr::IO)()` must be called. This launches a new task that handles reading and writing of messages from/to the worker represented by the I/O objects.
- `init_worker(cookie, manager::FooManager)` must be called as part of worker process initialization.

- Field `connect_at::Any` in `WorkerConfig` can be set by the cluster manager when `launch` is called. The value of this field is passed in all `connect` callbacks. Typically, it carries information on how to connect to a worker. For example, the TCP/IP socket transport uses this field to specify the (host, port) tuple at which to connect to a worker.

`kill(manager, pid, config)` is called to remove a worker from the cluster. On the master process, the corresponding IO objects must be closed by the implementation to ensure proper cleanup. The default implementation simply executes an `exit()` call on the specified remote worker.

The Examples folder `clustermanager/simple` is an example that shows a simple implementation using UNIX domain sockets for cluster setup.

Network Requirements for LocalManager and SSHManager

Julia clusters are designed to be executed on already secured environments on infrastructure such as local laptops, departmental clusters, or even the cloud. This section covers network security requirements for the inbuilt `LocalManager` and `SSHManager`:

- The master process does not listen on any port. It only connects out to the workers.
- Each worker binds to only one of the local interfaces and listens on an ephemeral port number assigned by the OS.
- `LocalManager`, used by `addprocs(N)`, by default binds only to the loopback interface. This means that workers started later on remote hosts (or by anyone with malicious intentions) are unable to connect to the cluster. An `addprocs(4)` followed by an `addprocs(["remote_host"])` will fail. Some users may need to create a cluster comprising their local system and a few remote systems. This can be done by explicitly requesting `LocalManager` to bind to an external network interface via the `restrict` keyword argument: `addprocs(4; restrict=false)`.
- `SSHManager`, used by `addprocs(list_of_remote_hosts)`, launches workers on remote hosts via SSH. By default SSH is only used to launch Julia workers. Subsequent master-worker and worker-worker connections use plain, unencrypted TCP/IP sockets. The remote hosts must have password-less login enabled. Additional SSH flags or credentials may be specified via keyword argument `sshflags`.
- `addprocs(list_of_remote_hosts; tunnel=true, sshflags=<ssh keys and other flags>)` is useful when we wish to use SSH connections for master-worker too. A typical scenario for this is a local laptop running the Julia REPL (i.e., the master) with the rest of the cluster on the cloud, say on Amazon EC2. In this case only port 22 needs to be opened at the remote cluster coupled with SSH client authenticated via public key infrastructure (PKI). Authentication credentials can be supplied via `sshflags`, for example `sshflags="-i <keyfile>".`

In an all-to-all topology (the default), all workers connect to each other via plain TCP sockets. The security policy on the cluster nodes must thus ensure free connectivity between workers for the ephemeral port range (varies by OS).

Securing and encrypting all worker-worker traffic (via SSH) or encrypting individual messages can be done via a custom `ClusterManager`.

- If you specify `multiplex=true` as an option to `addprocs`, SSH multiplexing is used to create a tunnel between the master and workers. If you have configured SSH multiplexing on your own and the

connection has already been established, SSH multiplexing is used regardless of `multiplex` option. If multiplexing is enabled, forwarding is set by using the existing connection (`-O` forward option in `ssh`). This is beneficial if your servers require password authentication; you can avoid authentication in Julia by logging in to the server ahead of `addprocs`. The control socket will be located at `~/.ssh/julia-%r@%h:%p` during the session unless the existing multiplexing connection is used. Note that bandwidth may be limited if you create multiple processes on a node and enable multiplexing, because in that case processes share a single multiplexing TCP connection.

Cluster Cookie

All processes in a cluster share the same cookie which, by default, is a randomly generated string on the master process:

- `cluster_cookie()` returns the cookie, while `cluster_cookie(cookie)()` sets it and returns the new cookie.
- All connections are authenticated on both sides to ensure that only workers started by the master are allowed to connect to each other.
- The cookie may be passed to the workers at startup via argument `--worker=<cookie>`. If argument `--worker` is specified without the cookie, the worker tries to read the cookie from its standard input (`stdin`). The `stdin` is closed immediately after the cookie is retrieved.
- `ClusterManagers` can retrieve the cookie on the master by calling `cluster_cookie()`. Cluster managers not using the default TCP/IP transport (and hence not specifying `--worker`) must call `init_worker(cookie, manager)` with the same cookie as on the master.

Note that environments requiring higher levels of security can implement this via a custom `ClusterManager`. For example, cookies can be pre-shared and hence not specified as a startup argument.

25.11 Specifying Network Topology (Experimental)

The keyword argument `topology` passed to `addprocs` is used to specify how the workers must be connected to each other:

- `:all_to_all`, the default: all workers are connected to each other.
- `:master_worker`: only the driver process, i.e. `pid 1`, has connections to the workers.
- `:custom`: the `launch` method of the cluster manager specifies the connection topology via the fields `ident` and `connect_idents` in `WorkerConfig`. A worker with a cluster-manager-provided identity `ident` will connect to all workers specified in `connect_idents`.

Keyword argument `lazy=true|false` only affects topology option `:all_to_all`. If `true`, the cluster starts off with the master connected to all workers. Specific worker-worker connections are established at the first remote invocation between two workers. This helps in reducing initial resources allocated for intra-cluster communication. Connections are setup depending on the runtime requirements of a parallel program. Default value for `lazy` is `true`.

Currently, sending a message between unconnected workers results in an error. This behaviour, as with the functionality and interface, should be considered experimental in nature and may change in future releases.

25.12 Noteworthy external packages

Outside of Julia parallelism there are plenty of external packages that should be mentioned. For example [MPI.jl](#) is a Julia wrapper for the MPI protocol, [Dagger.jl](#) provides functionality similar to Python's [Dask](#), and [DistributedArrays.jl](#) provides array operations distributed across workers, as presented in [Shared Arrays](#).

A mention must be made of Julia's GPU programming ecosystem, which includes:

1. [CUDA.jl](#) wraps the various CUDA libraries and supports compiling Julia kernels for Nvidia GPUs.
2. [oneAPI.jl](#) wraps the oneAPI unified programming model, and supports executing Julia kernels on supported accelerators. Currently only Linux is supported.
3. [AMDGPU.jl](#) wraps the AMD ROCm libraries and supports compiling Julia kernels for AMD GPUs. Currently only Linux is supported.
4. High-level libraries like [KernelAbstractions.jl](#), [Tullio.jl](#) and [ArrayFire.jl](#).

In the following example we will use both `DistributedArrays.jl` and `CUDA.jl` to distribute an array across multiple processes by first casting it through `distribute()` and `CuArray()`.

Remember when importing `DistributedArrays.jl` to import it across all processes using [@everywhere](#)

```
$ ./julia -p 4

julia> addprocs()

julia> @everywhere using DistributedArrays

julia> using CUDA

julia> B = ones(10_000) ./ 2;

julia> A = ones(10_000) .* π;

julia> C = 2 .* A ./ B;

julia> all(C .≈ 4*π)
true

julia> typeof(C)
Array{Float64,1}

julia> dB = distribute(B);

julia> dA = distribute(A);

julia> dC = 2 .* dA ./ dB;

julia> all(dC .≈ 4*π)
true

julia> typeof(dC)
```

```

DistributedArrays.DArray{Float64,1,Array{Float64,1}}

julia> cuB = CuArray(B);

julia> cuA = CuArray(A);

julia> cuC = 2 .* cuA ./ cuB;

julia> all(cuC .≈ 4*π);
true

julia> typeof(cuC)
CuArray{Float64,1}

```

In the following example we will use both `DistributedArrays.jl` and `CUDA.jl` to distribute an array across multiple processes and call a generic function on it.

```

function power_method(M, v)
    for i in 1:100
        v = M*v
        v /= norm(v)
    end

    return v, norm(M*v) / norm(v) # or (M*v) ./ v
end

```

`power_method` repeatedly creates a new vector and normalizes it. We have not specified any type signature in function declaration, let's see if it works with the aforementioned datatypes:

```

julia> M = [2. 1; 1 1];

julia> v = rand(2)
2-element Array{Float64,1}:
0.40395
0.445877

julia> power_method(M,v)
([0.850651, 0.525731], 2.618033988749895)

julia> cuM = CuArray(M);

julia> cuv = CuArray(v);

julia> curesult = power_method(cuM, cuv);

julia> typeof(curesult)
CuArray{Float64,1}

julia> dM = distribute(M);

julia> dv = distribute(v);

```

```
julia> dC = power_method(dM, dv);

julia> typeof(dC)
Tuple{DistributedArrays.DArray{Float64,1,Array{Float64,1}},Float64}
```

To end this short exposure to external packages, we can consider `MPI.jl`, a Julia wrapper of the MPI protocol. As it would take too long to consider every inner function, it would be better to simply appreciate the approach used to implement the protocol.

Consider this toy script which simply calls each subprocess, instantiate its rank and when the master process is reached, performs the ranks' sum

```
import MPI

MPI.Init()

comm = MPI.COMM_WORLD
MPI.Barrier(comm)

root = 0
r = MPI.Comm_rank(comm)

sr = MPI.Reduce(r, MPI.SUM, root, comm)

if(MPI.Comm_rank(comm) == root)
    @printf("sum of ranks: %s\n", sr)
end

MPI.Finalize()

mpirun -np 4 ./julia example.jl
```

¹In this context, MPI refers to the MPI-1 standard. Beginning with MPI-2, the MPI standards committee introduced a new set of communication mechanisms, collectively referred to as Remote Memory Access (RMA). The motivation for adding rma to the MPI standard was to facilitate one-sided communication patterns. For additional information on the latest MPI standard, see <https://mpi-forum.org/docs>.

Chapter 26

Running External Programs

Julia borrows backtick notation for commands from the shell, Perl, and Ruby. However, in Julia, writing

```
julia> `echo hello`  
`echo hello`
```

differs in several aspects from the behavior in various shells, Perl, or Ruby:

- Instead of immediately running the command, backticks create a `Cmd` object to represent the command. You can use this object to connect the command to others via pipes, `run` it, and `read` or `write` to it.
- When the command is run, Julia does not capture its output unless you specifically arrange for it to. Instead, the output of the command by default goes to `stdout` as it would using `libc`'s system call.
- The command is never run with a shell. Instead, Julia parses the command syntax directly, appropriately interpolating variables and splitting on words as the shell would, respecting shell quoting syntax. The command is run as Julia's immediate child process, using `fork` and `exec` calls.

Note

The following assumes a Posix environment as on Linux or MacOS. On Windows, many similar commands, such as `echo` and `dir`, are not external programs and instead are built into the shell `cmd.exe` itself. One option to run these commands is to invoke `cmd.exe`, for example `cmd /C echo hello`. Alternatively Julia can be run inside a Posix environment such as Cygwin.

Here's a simple example of running an external program:

```
julia> mycommand = `echo hello`  
`echo hello`  
  
julia> typeof(mycommand)  
Cmd  
  
julia> run(mycommand);  
hello
```

The `hello` is the output of the `echo` command, sent to `stdout`. If the external command fails to run successfully, the `run` method throws an `ProcessFailedException`.

If you want to read the output of the external command, `read` or `readchomp` can be used instead:

```
julia> read(`echo hello`, String)
"hello\n"

julia> readchomp(`echo hello`)
"hello"
```

More generally, you can use `open` to read from or write to an external command.

```
julia> open(`less`, "w", stdout) do io
    for i = 1:3
        println(io, i)
    end
end

1
2
3
```

The program name and the individual arguments in a command can be accessed and iterated over as if the command were an array of strings:

```
julia> collect(`echo "foo bar"`)
2-element Vector{String}:
"echo"
"foo bar"

julia> `echo "foo bar"`[2]
"foo bar"
```

26.1 Interpolation

Suppose you want to do something a bit more complicated and use the name of a file in the variable `file` as an argument to a command. You can use `$` for interpolation much as you would in a string literal (see [Strings](#)):

```
julia> file = "/etc/passwd"
"/etc/passwd"

julia> `sort $file`
`sort /etc/passwd`
```

A common pitfall when running external programs via a shell is that if a file name contains characters that are special to the shell, they may cause undesirable behavior. Suppose, for example, rather than `/etc/passwd`, we wanted to sort the contents of the file `/Volumes/External HD/data.csv`. Let's try it:

```
julia> file = "/Volumes/External HD/data.csv"
"/Volumes/External HD/data.csv"

julia> `sort $file`
`sort '/Volumes/External HD/data.csv'`
```

How did the file name get quoted? Julia knows that `file` is meant to be interpolated as a single argument, so it quotes the word for you. Actually, that is not quite accurate: the value of `file` is never interpreted by a shell, so there's no need for actual quoting; the quotes are inserted only for presentation to the user. This will even work if you interpolate a value as part of a shell word:

```
julia> path = "/Volumes/External HD"
"/Volumes/External HD"

julia> name = "data"
"data"

julia> ext = "csv"
"csv"

julia> `sort $path/$name.$ext`
`sort '/Volumes/External HD/data.csv'`
```

As you can see, the space in the path variable is appropriately escaped. But what if you want to interpolate multiple words? In that case, just use an array (or any other iterable container):

```
julia> files = ["/etc/passwd", "/Volumes/External HD/data.csv"]
2-element Vector{String}:
"/etc/passwd"
"/Volumes/External HD/data.csv"

julia> `grep foo $files`
`grep foo /etc/passwd '/Volumes/External HD/data.csv'`
```

If you interpolate an array as part of a shell word, Julia emulates the shell's `{a,b,c}` argument generation:

```
julia> names = ["foo", "bar", "baz"]
3-element Vector{String}:
"foo"
"bar"
"baz"

julia> `grep xylophone $names.txt`
`grep xylophone foo.txt bar.txt baz.txt`
```

Moreover, if you interpolate multiple arrays into the same word, the shell's Cartesian product generation behavior is emulated:

```
julia> names = ["foo", "bar", "baz"]
3-element Vector{String}:
"foo"
"bar"
"baz"

julia> exts = ["aux", "log"]
2-element Vector{String}:
"aux"
"log"

julia> `rm -f $names.$exts`
`rm -f foo.aux foo.log bar.aux bar.log baz.aux baz.log`
```

Since you can interpolate literal arrays, you can use this generative functionality without needing to create temporary array objects first:

```
julia> `rm -rf ${"foo", "bar", "baz", "qux"}.${"aux", "log", "pdf"}`
`rm -rf foo.aux foo.log foo.pdf bar.aux bar.log bar.pdf baz.aux baz.log baz.pdf qux.aux qux.log`
↪ qux.pdf`
```

26.2 Quoting

Inevitably, one wants to write commands that aren't quite so simple, and it becomes necessary to use quotes. Here's a simple example of a Perl one-liner at a shell prompt:

```
sh$ perl -le '$|=1; for (0..3) { print }'
0
1
2
3
```

The Perl expression needs to be in single quotes for two reasons: so that spaces don't break the expression into multiple shell words, and so that uses of Perl variables like `$|` (yes, that's the name of a variable in Perl), don't cause interpolation. In other instances, you may want to use double quotes so that interpolation does occur:

```
sh$ first="A"
sh$ second="B"
sh$ perl -le '$|=1; print for @ARGV' "1: $first" "2: $second"
1: A
2: B
```

In general, the Julia backtick syntax is carefully designed so that you can just cut-and-paste shell commands as is into backticks and they will work: the escaping, quoting, and interpolation behaviors are the same as the shell's. The only difference is that the interpolation is integrated and aware of Julia's notion of what is a single string value, and what is a container for multiple values. Let's try the above two examples in Julia:

```
julia> A = `perl -le '$|=1; for (0..3) { print }'`
`perl -le '$|=1; for (0..3) { print }'`

julia> run(A);
```

```

0
1
2
3
julia> first = "A"; second = "B";

julia> B = `perl -le 'print for @ARGV' "1: $first" "2: $second"`
`perl -le 'print for @ARGV' '1: A' '2: B'`

julia> run(B);
1: A
2: B

```

The results are identical, and Julia's interpolation behavior mimics the shell's with some improvements due to the fact that Julia supports first-class iterable objects while most shells use strings split on spaces for this, which introduces ambiguities. When trying to port shell commands to Julia, try cut and pasting first. Since Julia shows commands to you before running them, you can easily and safely just examine its interpretation without doing any damage.

26.3 Pipelines

Shell metacharacters, such as `|`, `&`, and `>`, need to be quoted (or escaped) inside of Julia's backticks:

```

julia> run(`echo hello '|' sort`);
hello | sort

julia> run(`echo hello \| sort`);
hello | sort

```

This expression invokes the `echo` command with three words as arguments: `hello`, `|`, and `sort`. The result is that a single line is printed: `hello | sort`. How, then, does one construct a pipeline? Instead of using `'|'` inside of backticks, one uses `pipeline`:

```

julia> run(pipeline(`echo hello`, `sort`));
hello

```

This pipes the output of the `echo` command to the `sort` command. Of course, this isn't terribly interesting since there's only one line to sort, but we can certainly do much more interesting things:

```

julia> run(pipeline(`cut -d: -f3 /etc/passwd`, `sort -n`, `tail -n5`))
210
211
212
213
214

```

This prints the highest five user IDs on a UNIX system. The `cut`, `sort` and `tail` commands are all spawned as immediate children of the current `julia` process, with no intervening shell process. Julia itself does the

work to setup pipes and connect file descriptors that is normally done by the shell. Since Julia does this itself, it retains better control and can do some things that shells cannot.

Julia can run multiple commands in parallel:

```
julia> run(`echo hello` & `echo world`);
world
hello
```

The order of the output here is non-deterministic because the two echo processes are started nearly simultaneously, and race to make the first write to the `stdout` descriptor they share with each other and the julia parent process. Julia lets you pipe the output from both of these processes to another program:

```
julia> run(pipeline(`echo world` & `echo hello`, `sort`));
hello
world
```

In terms of UNIX plumbing, what's happening here is that a single UNIX pipe object is created and written to by both echo processes, and the other end of the pipe is read from by the sort command.

IO redirection can be accomplished by passing keyword arguments `stdin`, `stdout`, and `stderr` to the `pipeline` function:

```
pipeline(`do_work`, stdout=pipeline(`sort`, "out.txt"), stderr="errs.txt")
```

Avoiding Deadlock in Pipelines

When reading and writing to both ends of a pipeline from a single process, it is important to avoid forcing the kernel to buffer all of the data.

For example, when reading all of the output from a command, call `read(out, String)`, not `wait(process)`, since the former will actively consume all of the data written by the process, whereas the latter will attempt to store the data in the kernel's buffers while waiting for a reader to be connected.

Another common solution is to separate the reader and writer of the pipeline into separate [Tasks](#):

```
writer = @async write(process, "data")
reader = @async do_compute(read(process, String))
wait(writer)
fetch(reader)
```

(commonly also, reader is not a separate task, since we immediately fetch it anyways).

Complex Example

The combination of a high-level programming language, a first-class command abstraction, and automatic setup of pipes between processes is a powerful one. To give some sense of the complex pipelines that can be created easily, here are some more sophisticated examples, with apologies for the excessive use of Perl one-liners:

```
julia> prefixer(prefix, sleep) = `perl -nle '$|=1; print "'$prefix' ", $_; sleep '$sleep';`;

julia> run(pipeline(`perl -le '$|=1; for(0..5){ print; sleep 1 }`, prefixer("A",2) &
↳ prefixer("B",2)));
B 0
A 1
B 2
A 3
B 4
A 5
```

This is a classic example of a single producer feeding two concurrent consumers: one perl process generates lines with the numbers 0 through 5 on them, while two parallel processes consume that output, one prefixing lines with the letter "A", the other with the letter "B". Which consumer gets the first line is non-deterministic, but once that race has been won, the lines are consumed alternately by one process and then the other. (Setting `$|=1` in Perl causes each print statement to flush the `stdout` handle, which is necessary for this example to work. Otherwise all the output is buffered and printed to the pipe at once, to be read by just one consumer process.)

Here is an even more complex multi-stage producer-consumer example:

```
julia> run(pipeline(`perl -le '$|=1; for(0..5){ print; sleep 1 }`,
    prefixer("X",3) & prefixer("Y",3) & prefixer("Z",3),
    prefixer("A",2) & prefixer("B",2)));
A X 0
B Y 1
A Z 2
B X 3
A Y 4
B Z 5
```

This example is similar to the previous one, except there are two stages of consumers, and the stages have different latency so they use a different number of parallel workers, to maintain saturated throughput.

We strongly encourage you to try all these examples to see how they work.

26.4 Cmd Objects

The backtick syntax create an object of type `Cmd`. Such object may also be constructed directly from an existing `Cmd` or list of arguments:

```
run(Cmd(`pwd`, dir=".."))
run(Cmd(["pwd"], detach=true, ignorestatus=true))
```

This allows you to specify several aspects of the `Cmd`'s execution environment via keyword arguments. For example, the `dir` keyword provides control over the `Cmd`'s working directory:

```
julia> run(Cmd(`pwd`, dir="/"));
/
```

And the `env` keyword allows you to set execution environment variables:

```
julia> run(Cmd(`sh -c "echo foo \${HOWLONG}"`, env=("HOWLONG" => "ever!")));  
foo ever!
```

See `Cmd` for additional keyword arguments. The `setenv` and `addenv` commands provide another means for replacing or adding to the `Cmd` execution environment variables, respectively:

```
julia> run(setenv(`sh -c "echo foo \${HOWLONG}"`, ("HOWLONG" => "ever!")));  
foo ever!  
  
julia> run(addenv(`sh -c "echo foo \${HOWLONG}"`, "HOWLONG" => "ever!"));  
foo ever!
```

Chapter 27

Calling C and Fortran Code

Though most code can be written in Julia, there are many high-quality, mature libraries for numerical computing already written in C and Fortran. To allow easy use of this existing code, Julia makes it simple and efficient to call C and Fortran functions. Julia has a "no boilerplate" philosophy: functions can be called directly from Julia without any "glue" code, code generation, or compilation – even from the interactive prompt. This is accomplished just by making an appropriate call with the `@ccall` macro (or the less convenient `ccall` syntax, see the [ccall syntax section](#)).

The code to be called must be available as a shared library. Most C and Fortran libraries ship compiled as shared libraries already, but if you are compiling the code yourself using GCC (or Clang), you will need to use the `-shared` and `-fPIC` options. The machine instructions generated by Julia's JIT are the same as a native C call would be, so the resulting overhead is the same as calling a library function from C code. ¹

By default, Fortran compilers [generate mangled names](#) (for example, converting function names to lower-case or uppercase, often appending an underscore), and so to call a Fortran function you must pass the mangled identifier corresponding to the rule followed by your Fortran compiler. Also, when calling a Fortran function, all inputs must be passed as pointers to allocated values on the heap or stack. This applies not only to arrays and other mutable objects which are normally heap-allocated, but also to scalar values such as integers and floats which are normally stack-allocated and commonly passed in registers when using C or Julia calling conventions.

The syntax for `@ccall` to generate a call to the library function is:

```
@ccall library.function_name(argvalue1::argtype1, ...)::returntype
@ccall function_name(argvalue1::argtype1, ...)::returntype
@ccall $function_pointer(argvalue1::argtype1, ...)::returntype
```

where `library` is a string constant or literal (but see [Non-constant Function Specifications](#) below). The `library` may be omitted, in which case the function name is resolved in the current process. This form can be used to call C library functions, functions in the Julia runtime, or functions in an application linked to Julia. The full path to the library may also be specified. Alternatively, `@ccall` may also be used to call a function pointer `$function_pointer`, such as one returned by `Libdl.dlsym`. The `argtypes` corresponds to the C-function signature and the `argvalues` are the actual argument values to be passed to the function.

Note

See below for how to [map C types to Julia types](#).

As a complete but simple example, the following calls the `clock` function from the standard C library on most Unix-derived systems:

```
julia> t = @ccall clock()::Int32
2292761

julia> typeof(t)
Int32
```

`clock` takes no arguments and returns an `Int32`. To call the `getenv` function to get a pointer to the value of an environment variable, one makes a call like this:

```
julia> path = @ccall getenv("SHELL)::Cstring)::Cstring
Cstring(@0x00007fff5fbffc45)

julia> unsafe_string(path)
"/bin/bash"
```

In practice, especially when providing reusable functionality, one generally wraps `@ccall` uses in Julia functions that set up arguments and then check for errors in whatever manner the C or Fortran function specifies. And if an error occurs it is thrown as a normal Julia exception. This is especially important since C and Fortran APIs are notoriously inconsistent about how they indicate error conditions. For example, the `getenv` C library function is wrapped in the following Julia function, which is a simplified version of the actual definition from `env.jl`:

```
function getenv(var::AbstractString)
    val = @ccall getenv(var::Cstring)::Cstring
    if val == C_NULL
        error("getenv: undefined variable: ", var)
    end
    return unsafe_string(val)
end
```

The C `getenv` function indicates an error by returning `C_NULL`, but other standard C functions indicate errors in different ways, including by returning -1, 0, 1, and other special values. This wrapper throws an exception indicating the problem if the caller tries to get a non-existent environment variable:

```
julia> getenv("SHELL")
"/bin/bash"

julia> getenv("FOOBAR")
ERROR: getenv: undefined variable: FOOBAR
```

Here is a slightly more complex example that discovers the local machine's hostname.

```
function gethostname()
    hostname = Vector{UInt8}(undef, 256) # MAXHOSTNAMELEN
    err = @ccall gethostname(hostname::Ptr{UInt8}, sizeof(hostname)::Csize_t)::Int32
```

```

Base.systemerror("gethostname", err != 0)
hostname[end] = 0 # ensure null-termination
return GC.@preserve hostname unsafe_string(pointer(hostname))
end

```

This example first allocates an array of bytes. It then calls the C library function `gethostname` to populate the array with the hostname. Finally, it takes a pointer to the hostname buffer, and converts the pointer to a Julia string, assuming that it is a null-terminated C string.

It is common for C libraries to use this pattern of requiring the caller to allocate memory to be passed to the callee and populated. Allocation of memory from Julia like this is generally accomplished by creating an uninitialized array and passing a pointer to its data to the C function. This is why we don't use the `Cstring` type here: as the array is uninitialized, it could contain null bytes. Converting to a `Cstring` as part of the `@ccall` checks for contained null bytes and could therefore throw a conversion error.

Dereferencing `pointer(hostname)` with `unsafe_string` is an unsafe operation as it requires access to the memory allocated for `hostname` that may have been in the meanwhile garbage collected. The macro `GC.@preserve` prevents this from happening and therefore accessing an invalid memory location.

Finally, here is an example of specifying a library via a path. We create a shared library with the following content

```

#include <stdio.h>

void say_y(int y)
{
    printf("Hello from C: got y = %d.\n", y);
}

```

and compile it with `gcc -fPIC -shared -o mylib.so mylib.c`. It can then be called by specifying the (absolute) path as the library name:

```

julia> @ccall "./mylib.so".say_y(5::Cint)::Cvoid
Hello from C: got y = 5.

```

27.1 Creating C-Compatible Julia Function Pointers

It is possible to pass Julia functions to native C functions that accept function pointer arguments. For example, to match C prototypes of the form:

```
typedef returntype (*functiontype)(argumenttype, ...)
```

The macro `@cfunction` generates the C-compatible function pointer for a call to a Julia function. The arguments to `@cfunction` are:

1. A Julia function
2. The function's return type
3. A tuple of input types, corresponding to the function signature

Note

As with `@ccall`, the return type and the input types must be literal constants.

Note

Currently, only the platform-default C calling convention is supported. This means that `@cfunction`-generated pointers cannot be used in calls where WINAPI expects a `stdcall` function on 32-bit Windows, but can be used on WIN64 (where `stdcall` is unified with the C calling convention).

Note

Callback functions exposed via `@cfunction` should not throw errors, as that will return control to the Julia runtime unexpectedly and may leave the program in an undefined state.

A classic example is the standard C library `qsort` function, declared as:

```
void qsort(void *base, size_t nitems, size_t size,
          int (*compare)(const void*, const void*));
```

The `base` argument is a pointer to an array of length `nitems`, with elements of `size` bytes each. `compare` is a callback function which takes pointers to two elements `a` and `b` and returns an integer less/greater than zero if `a` should appear before/after `b` (or zero if any order is permitted).

Now, suppose that we have a 1-d array `A` of values in Julia that we want to sort using the `qsort` function (rather than Julia's built-in sort function). Before we consider calling `qsort` and passing arguments, we need to write a comparison function:

```
julia> function mycompare(a, b)::Cint
    return (a < b) ? -1 : ((a > b) ? +1 : 0)
end;
```

`qsort` expects a comparison function that return a C `int`, so we annotate the return type to be `Cint`.

In order to pass this function to C, we obtain its address using the macro `@cfunction`:

```
julia> mycompare_c = @cfunction(mycompare, Cint, (Ref{Cdouble}, Ref{Cdouble}));
```

`@cfunction` requires three arguments: the Julia function (`mycompare`), the return type (`Cint`), and a literal tuple of the input argument types, in this case to sort an array of `Cdouble` (`Float64`) elements.

The final call to `qsort` looks like this:

```
julia> A = [1.3, -2.7, 4.4, 3.1];

julia> @ccall qsort(A::Ptr{Cdouble}, length(A)::Csize_t, sizeof(elttype(A))::Csize_t,
    ↪ mycompare_c::Ptr{Cvoid})::Cvoid

julia> A
4-element Vector{Float64}:
-2.7
 1.3
 3.1
 4.4
```

As the example shows, the original Julia array *A* has now been sorted: `[-2.7, 1.3, 3.1, 4.4]`. Note that Julia [takes care of converting the array to a `Ptr{Cdouble}`](#), computing the size of the element type in bytes, and so on.

For fun, try inserting a `println("mycompare($a, $b)")` line into `mycompare`, which will allow you to see the comparisons that `qsort` is performing (and to verify that it is really calling the Julia function that you passed to it).

27.2 Mapping C Types to Julia

It is critical to exactly match the declared C type with its declaration in Julia. Inconsistencies can cause code that works correctly on one system to fail or produce indeterminate results on a different system.

Note that no C header files are used anywhere in the process of calling C functions: you are responsible for making sure that your Julia types and call signatures accurately reflect those in the C header file.²

Automatic Type Conversion

Julia automatically inserts calls to the [Base.convert](#) function to convert each argument to the specified type. For example, the following call:

```
| @ccall "libfoo".foo(x::Int32, y::Float64)::Cvoid
```

will behave as if it were written like this:

```
| @ccall "libfoo".foo(  
|     Base.unsafe_convert{Int32, Base.convert{Int32, x}}::Int32,  
|     Base.unsafe_convert{Float64, Base.convert{Float64, y}}::Float64  
| )::Cvoid
```

[Base.convert](#) normally just calls [convert](#), but can be defined to return an arbitrary new object more appropriate for passing to C. This should be used to perform all allocations of memory that will be accessed by the C code. For example, this is used to convert an Array of objects (e.g. strings) to an array of pointers.

[Base.unsafe_convert](#) handles conversion to [Ptr](#) types. It is considered unsafe because converting an object to a native pointer can hide the object from the garbage collector, causing it to be freed prematurely.

Type Correspondences

First, let's review some relevant Julia type terminology:

Bits Types

There are several special types to be aware of, as no other type can be defined to behave the same:

- `Float32`
Exactly corresponds to the `float` type in C (or `REAL*4` in Fortran).
- `Float64`
Exactly corresponds to the `double` type in C (or `REAL*8` in Fortran).

| Syntax / Keyword | Example | Description |
|---------------------|--------------------------------------|---|
| mutable struct | BitSet | "Leaf Type" :: A group of related data that includes a type-tag, is managed by the Julia GC, and is defined by object-identity. The type parameters of a leaf type must be fully defined (no TypeVars are allowed) in order for the instance to be constructed. |
| abstract type | Any, AbstractArray{T, N}, Complex{T} | "Super Type" :: A super-type (not a leaf-type) that cannot be instantiated, but can be used to describe a group of types. |
| T{A} | Vector{Int} | "Type Parameter" :: A specialization of a type (typically used for dispatch or storage optimization). |
| | | "TypeVar" :: The T in the type parameter declaration is referred to as a TypeVar (short for type variable). |
| primitive type | Int, Float64 | "Primitive Type" :: A type with no fields, but a size. It is stored and defined by-value. |
| struct | Pair{Int, Int} | "Struct" :: A type with all fields defined to be constant. It is defined by-value, and may be stored with a type-tag. |
| | ComplexF64 (isbits) | "Is-Bits" :: A primitive type, or a struct type where all fields are other isbits types. It is defined by-value, and is stored without a type-tag. |
| struct ...; end | nothing | "Singleton" :: a Leaf Type or Struct with no fields. |
| (...) or tuple(...) | (1, 2, 3) | "Tuple" :: an immutable data-structure similar to an anonymous struct type, or a constant array. Represented as either an array or a struct. |

- `ComplexF32`

Exactly corresponds to the `complex float` type in C (or `COMPLEX*8` in Fortran).

- `ComplexF64`

Exactly corresponds to the `complex double` type in C (or `COMPLEX*16` in Fortran).

- `Signed`

Exactly corresponds to the signed type annotation in C (or any `INTEGER` type in Fortran). Any Julia type that is not a subtype of `Signed` is assumed to be unsigned.

- `Ref{T}`

Behaves like a `Ptr{T}` that can manage its memory via the Julia GC.

- `Array{T,N}`

When an array is passed to C as a `Ptr{T}` argument, it is not reinterpret-cast: Julia requires that the element type of the array matches T, and the address of the first element is passed.

Therefore, if an Array contains data in the wrong format, it will have to be explicitly converted using a call such as `trunc.(Int32, A)`.

To pass an array A as a pointer of a different type without converting the data beforehand (for example, to pass a `Float64` array to a function that operates on uninterpreted bytes), you can declare the argument as `Ptr{Cvoid}`.

If an array of eltype `Ptr{T}` is passed as a `Ptr{Ptr{T}}` argument, `Base.cconvert` will attempt to first make a null-terminated copy of the array with each element replaced by its `Base.cconvert` version. This allows, for example, passing an `argv` pointer array of type `Vector{String}` to an argument of type `Ptr{Ptr{Cchar}}`.

On all systems we currently support, basic C/C++ value types may be translated to Julia types as follows. Every C type also has a corresponding Julia type with the same name, prefixed by `C`. This can help when writing portable code (and remembering that an `int` in C is not the same as an `Int` in Julia).

System Independent Types

The `Cstring` type is essentially a synonym for `Ptr{UInt8}`, except the conversion to `Cstring` throws an error if the Julia string contains any embedded null characters (which would cause the string to be silently truncated if the C routine treats null as the terminator). If you are passing a `char*` to a C routine that does not assume null termination (e.g. because you pass an explicit string length), or if you know for certain that your Julia string does not contain null and want to skip the check, you can use `Ptr{UInt8}` as the argument type. `Cstring` can also be used as the `ccall` return type, but in that case it obviously does not introduce any extra checks and is only meant to improve the readability of the call.

System Dependent Types

Note

When calling Fortran, all inputs must be passed by pointers to heap- or stack-allocated values, so all type correspondences above should contain an additional `Ptr{. .}` or `Ref{. .}` wrapper around their type specification.

Warning

For string arguments (`char*`) the Julia type should be `Cstring` (if null-terminated data is expected), or either `Ptr{Cchar}` or `Ptr{UInt8}` otherwise (these two pointer types have the same effect), as described above, not `String`. Similarly, for array arguments (`T[]` or `T*`), the Julia type should again be `Ptr{T}`, not `Vector{T}`.

Warning

Julia's `Char` type is 32 bits, which is not the same as the wide-character type (`wchar_t` or `wint_t`) on all platforms.

Warning

A return type of `Union{}` means the function will not return, i.e., C++11 `[[noreturn]]` or C11 `_Noreturn` (e.g. `jl_throw` or `longjmp`). Do not use this for functions that return no value (`void`) but do return, for those, use `Cvoid` instead.

Note

For `wchar_t*` arguments, the Julia type should be `Cwstring` (if the C routine expects a null-terminated string), or `Ptr{Cwchar_t}` otherwise. Note also that UTF-8 string data in Julia is internally null-terminated, so it can be passed to C functions expecting null-terminated data without making a copy (but using the `Cwstring` type will cause an error to be thrown if the string itself contains null characters).

Note

C functions that take an argument of type `char**` can be called by using a `Ptr{Ptr{UInt8}}` type within Julia. For example, C functions of the form:

```
int main(int argc, char **argv);
```

can be called via the following Julia code:

```
argv = [ "a.out", "arg1", "arg2" ]
@ccall main(length(argv)::Int32, argv::Ptr{Ptr{UInt8}})::Int32
```

Note

For Fortran functions taking variable length strings of type `character (len=*)` the string lengths are provided as hidden arguments. Type and position of these arguments in the list are compiler specific, where compiler vendors usually default to using `Csize_t` as type and append the hidden arguments at the end of the argument list. While this behaviour is fixed for some compilers (GNU), others optionally permit placing hidden arguments directly after the character argument (Intel, PGI). For example, Fortran subroutines of the form

```
subroutine test(str1, str2)
character(len=*) :: str1, str2
```

can be called via the following Julia code, where the lengths are appended

```
str1 = "foo"
str2 = "bar"
ccall(:test, Cvoid, (Ptr{UInt8}, Ptr{UInt8}, Csize_t, Csize_t),
      str1, str2, sizeof(str1), sizeof(str2))
```

Warning

Fortran compilers may also add other hidden arguments for pointers, assumed-shape `(:)` and assumed-size `(*)` arrays. Such behaviour can be avoided by using `ISO_C_BINDING` and including `bind(c)` in the definition of the subroutine, which is strongly recommended for interoperable code. In this case, there will be no hidden arguments, at the cost of some language features (e.g. only `character(len=1)` will be permitted to pass strings).

Note

A C function declared to return `Cvoid` will return the value `nothing` in Julia.

Struct Type Correspondences

Composite types such as `struct` in C or `TYPE` in Fortran90 (or `STRUCTURE` / `RECORD` in some variants of F77), can be mirrored in Julia by creating a `struct` definition with the same field layout.

When used recursively, `isbits` types are stored inline. All other types are stored as a pointer to the data. When mirroring a `struct` used by-value inside another `struct` in C, it is imperative that you do not attempt to manually copy the fields over, as this will not preserve the correct field alignment. Instead, declare an `isbits` `struct` type and use that instead. Unnamed `structs` are not possible in the translation to Julia.

Packed `structs` and union declarations are not supported by Julia.

You can get an approximation of a union if you know, a priori, the field that will have the greatest size (potentially including padding). When translating your fields to Julia, declare the Julia field to be only of that type.

Arrays of parameters can be expressed with `NTuple`. For example, the struct in C notation is written as

```
struct B {
    int A[3];
};

b_a_2 = B.A[2];
```

can be written in Julia as

```
struct B
    A::NTuple{3, Cint}
end

b_a_2 = B.A[3] # note the difference in indexing (1-based in Julia, 0-based in C)
```

Arrays of unknown size (C99-compliant variable length structs specified by `[]` or `[0]`) are not directly supported. Often the best way to deal with these is to deal with the byte offsets directly. For example, if a C library declared a proper string type and returned a pointer to it:

```
struct String {
    int strlen;
    char data[];
};
```

In Julia, we can access the parts independently to make a copy of that string:

```
str = from_c::Ptr{Cvoid}
len = unsafe_load(Ptr{Cint}(str))
unsafe_string(str + Core.sizeof(Cint), len)
```

Type Parameters

The type arguments to `@ccall` and `@cfunction` are evaluated statically, when the method containing the usage is defined. They therefore must take the form of a literal tuple, not a variable, and cannot reference local variables.

This may sound like a strange restriction, but remember that since C is not a dynamic language like Julia, its functions can only accept argument types with a statically-known, fixed signature.

However, while the type layout must be known statically to compute the intended C ABI, the static parameters of the function are considered to be part of this static environment. The static parameters of the function may be used as type parameters in the call signature, as long as they don't affect the layout of the type. For example, `f(x::T)` where `{T} = @ccall valid(x::Ptr{T})::Ptr{T}` is valid, since `Ptr` is always a word-size primitive type. But, `g(x::T)` where `{T} = @ccall notvalid(x::T)::T` is not valid, since the type layout of `T` is not known statically.

SIMD Values

Note: This feature is currently implemented on 64-bit x86 and AArch64 platforms only.

If a C/C++ routine has an argument or return value that is a native SIMD type, the corresponding Julia type is a homogeneous tuple of `VecElement` that naturally maps to the SIMD type. Specifically:

- The tuple must be the same size as the SIMD type. For example, a tuple representing an `__m128` on x86 must have a size of 16 bytes.
- The element type of the tuple must be an instance of `VecElement{T}` where `T` is a primitive type that is 1, 2, 4 or 8 bytes.

For instance, consider this C routine that uses AVX intrinsics:

```
#include <immintrin.h>

__m256 dist( __m256 a, __m256 b ) {
    return _mm256_sqrt_ps(_mm256_add_ps(_mm256_mul_ps(a, a),
                                         _mm256_mul_ps(b, b)));
}
```

The following Julia code calls `dist` using `ccall`:

```
const m256 = NTuple{8, VecElement{Float32}}

a = m256(ntuple(i -> VecElement(sin(Float32(i))), 8))
b = m256(ntuple(i -> VecElement(cos(Float32(i))), 8))

function call_dist(a::m256, b::m256)
    @ccall "libdist".dist(a::m256, b::m256)::m256
end

println(call_dist(a,b))
```

The host machine must have the requisite SIMD registers. For example, the code above will not work on hosts without AVX support.

Memory Ownership

malloc/free

Memory allocation and deallocation of such objects must be handled by calls to the appropriate cleanup routines in the libraries being used, just like in any C program. Do not try to free an object received from a C library with `Libc.free` in Julia, as this may result in the `free` function being called via the wrong library and cause the process to abort. The reverse (passing an object allocated in Julia to be freed by an external library) is equally invalid.

When to use `T`, `Ptr{T}` and `Ref{T}`

In Julia code wrapping calls to external C routines, ordinary (non-pointer) data should be declared to be of type `T` inside the `@ccall`, as they are passed by value. For C code accepting pointers, `Ref{T}` should

generally be used for the types of input arguments, allowing the use of pointers to memory managed by either Julia or C through the implicit call to `Base.cconvert`. In contrast, pointers returned by the C function called should be declared to be of the output type `Ptr{T}`, reflecting that the memory pointed to is managed by C only. Pointers contained in C structs should be represented as fields of type `Ptr{T}` within the corresponding Julia struct types designed to mimic the internal structure of corresponding C structs.

In Julia code wrapping calls to external Fortran routines, all input arguments should be declared as of type `Ref{T}`, as Fortran passes all variables by pointers to memory locations. The return type should either be `Cvoid` for Fortran subroutines, or a `T` for Fortran functions returning the type `T`.

27.3 Mapping C Functions to Julia

@ccall / @cfunction argument translation guide

For translating a C argument list to Julia:

- `T`, where `T` is one of the primitive types: `char`, `int`, `long`, `short`, `float`, `double`, `complex`, `enum` or any of their typedef equivalents
 - `T`, where `T` is an equivalent Julia Bits Type (per the table above)
 - if `T` is an enum, the argument type should be equivalent to `Cint` or `Cuint`
 - argument value will be copied (passed by value)
- `struct T` (including typedef to a struct)
 - `T`, where `T` is a Julia leaf type
 - argument value will be copied (passed by value)
- `void*`
 - depends on how this parameter is used, first translate this to the intended pointer type, then determine the Julia equivalent using the remaining rules in this list
 - this argument may be declared as `Ptr{Cvoid}` if it really is just an unknown pointer
- `jl_value_t*`
 - Any
 - argument value must be a valid Julia object
- `jl_value_t* const*`
 - `Ref{Any}`
 - argument list must be a valid Julia object (or `C_NULL`)
 - cannot be used for an output parameter, unless the user is able to separately arrange for the object to be GC-preserved
- `T*`
 - `Ref{T}`, where `T` is the Julia type corresponding to `T`

- argument value will be copied if it is an `inlinealloc` type (which includes `isbits` otherwise, the value must be a valid Julia object)
- `T (*) (...)` (e.g. a pointer to a function)
 - `Ptr{Cvoid}` (you may need to use `@cfunction` explicitly to create this pointer)
- `...` (e.g. a vararg)

for `ccall : T...`, where `T` is the single Julia type of all remaining arguments

for `@ccall : ; va_arg1::T, va_arg2::S, etc`, where `T` and `S` are the Julia type (i.e. separate the regular arguments from varargs with a `;`)

- currently unsupported by `@cfunction`
- `va_arg`
 - not supported by `ccall` or `@cfunction`

@ccall / @cfunction return type translation guide

For translating a C return type to Julia:

- `void`
 - `Cvoid` (this will return the singleton instance `nothing::Cvoid`)
- `T`, where `T` is one of the primitive types: `char`, `int`, `long`, `short`, `float`, `double`, `complex`, `enum` or any of their typedef equivalents
 - `T`, where `T` is an equivalent Julia Bits Type (per the table above)
 - if `T` is an enum, the argument type should be equivalent to `Cint` or `Cuint`
 - argument value will be copied (returned by-value)
- `struct T` (including typedef to a struct)
 - `T`, where `T` is a Julia Leaf Type
 - argument value will be copied (returned by-value)
- `void*`
 - depends on how this parameter is used, first translate this to the intended pointer type, then determine the Julia equivalent using the remaining rules in this list
 - this argument may be declared as `Ptr{Cvoid}` if it really is just an unknown pointer
- `jl_value_t*`
 - `Any`
 - argument value must be a valid Julia object
- `jl_value_t**`

- `Ptr{Any}` (`Ref{Any}` is invalid as a return type)
- `T*`
 - If the memory is already owned by Julia, or is an `isbits` type, and is known to be non-null:
 - * `Ref{T}`, where `T` is the Julia type corresponding to `T`
 - * a return type of `Ref{Any}` is invalid, it should either be `Any` (corresponding to `jl_value_t*`) or `Ptr{Any}` (corresponding to `jl_value_t**`)
 - * **C MUST NOT** modify the memory returned via `Ref{T}` if `T` is an `isbits` type
 - If the memory is owned by C:
 - * `Ptr{T}`, where `T` is the Julia type corresponding to `T`
- `T (*)(...)` (e.g. a pointer to a function)
 - `Ptr{Cvoid}` to call this directly from Julia you will need to pass this as the first argument to `@ccall`. See [Indirect Calls](#).

Passing Pointers for Modifying Inputs

Because C doesn't support multiple return values, often C functions will take pointers to data that the function will modify. To accomplish this within a `@ccall`, you need to first encapsulate the value inside a `Ref{T}` of the appropriate type. When you pass this `Ref` object as an argument, Julia will automatically pass a C pointer to the encapsulated data:

```
width = Ref{Cint}()
range = Ref{Cfloat}()
@ccall foo(width::Ref{Cint}, range::Ref{Cfloat})::Cvoid
```

Upon return, the contents of `width` and `range` can be retrieved (if they were changed by `foo`) by `width[]` and `range[]`; that is, they act like zero-dimensional arrays.

27.4 C Wrapper Examples

Let's start with a simple example of a C wrapper that returns a `Ptr` type:

```
mutable struct gsl_permutation
end

# The corresponding C signature is
#   gsl_permutation * gsl_permutation_alloc (size_t n);
function permutation_alloc(n::Integer)
    output_ptr = @ccall "libgsl".gsl_permutation_alloc(n::Csize_t)::Ptr{gsl_permutation}
    if output_ptr == C_NULL # Could not allocate memory
        throw(OutOfMemoryError())
    end
    return output_ptr
end
```

The [GNU Scientific Library](#) (here assumed to be accessible through `:libgsl`) defines an opaque pointer, `gsl_permutation *`, as the return type of the C function `gsl_permutation_alloc`. As user code never has to look inside the `gsl_permutation` struct, the corresponding Julia wrapper simply needs a new type declaration, `gsl_permutation`, that has no internal fields and whose sole purpose is to be placed in the type parameter of a `Ptr` type. The return type of the `ccall` is declared as `Ptr{gsl_permutation}`, since the memory allocated and pointed to by `output_ptr` is controlled by C.

The input `n` is passed by value, and so the function's input signature is simply declared as `::Csize_t` without any `Ref` or `Ptr` necessary. (If the wrapper was calling a Fortran function instead, the corresponding function input signature would instead be `::Ref{Csize_t}`, since Fortran variables are passed by pointers.) Furthermore, `n` can be any type that is convertible to a `Csize_t` integer; the `ccall` implicitly calls `Base.cconvert(Csize_t, n)`.

Here is a second example wrapping the corresponding destructor:

```
# The corresponding C signature is
# void gsl_permutation_free (gsl_permutation * p);
function permutation_free(p::Ptr{gsl_permutation})
    @ccall "libgsl".gsl_permutation_free(p::Ptr{gsl_permutation})::Cvoid
end
```

Here is a third example passing Julia arrays:

```
# The corresponding C signature is
# int gsl_sf_bessel_Jn_array (int nmin, int nmax, double x,
#                             double result_array[])
function sf_bessel_Jn_array(nmin::Integer, nmax::Integer, x::Real)
    if nmax < nmin
        throw(DomainError())
    end
    result_array = Vector{Cdouble}(undef, nmax - nmin + 1)
    errorcode = @ccall "libgsl".gsl_sf_bessel_Jn_array(
        nmin::Cint, nmax::Cint, x::Cdouble, result_array::Ref{Cdouble})::Cint
    if errorcode != 0
        error("GSL error code $errorcode")
    end
    return result_array
end
```

The C function wrapped returns an integer error code; the results of the actual evaluation of the Bessel J function populate the Julia array `result_array`. This variable is declared as a `Ref{Cdouble}`, since its memory is allocated and managed by Julia. The implicit call to `Base.cconvert(Ref{Cdouble}, result_array)` unpacks the Julia pointer to a Julia array data structure into a form understandable by C.

27.5 Fortran Wrapper Example

The following example utilizes `ccall` to call a function in a common Fortran library (`libBLAS`) to compute a dot product. Notice that the argument mapping is a bit different here than above, as we need to map from Julia to Fortran. On every argument type, we specify `Ref` or `Ptr`. This mangling convention may be specific to your Fortran compiler and operating system and is likely undocumented. However, wrapping each in a `Ref` (or `Ptr`, where equivalent) is a frequent requirement of Fortran compiler implementations:

```
function compute_dot(DX::Vector{Float64}, DY::Vector{Float64})
    @assert length(DX) == length(DY)
    n = length(DX)
    incx = incy = 1
    product = @ccall "libLAPACK".ddot(
        n::Ref{Int32}, DX::Ptr{Float64}, incx::Ref{Int32}, DY::Ptr{Float64},
        ↪ incy::Ref{Int32})::Float64
    return product
end
```

27.6 Garbage Collection Safety

When passing data to a `@ccall`, it is best to avoid using the `pointer` function. Instead define a `Base.cconvert` method and pass the variables directly to the `@ccall`. `@ccall` automatically arranges that all of its arguments will be preserved from garbage collection until the call returns. If a C API will store a reference to memory allocated by Julia, after the `@ccall` returns, you must ensure that the object remains visible to the garbage collector. The suggested way to do this is to make a global variable of type `Array{Ref, 1}` to hold these values until the C library notifies you that it is finished with them.

Whenever you have created a pointer to Julia data, you must ensure the original data exists until you have finished using the pointer. Many methods in Julia such as `unsafe_load` and `String` make copies of data instead of taking ownership of the buffer, so that it is safe to free (or alter) the original data without affecting Julia. A notable exception is `unsafe_wrap` which, for performance reasons, shares (or can be told to take ownership of) the underlying buffer.

The garbage collector does not guarantee any order of finalization. That is, if `a` contained a reference to `b` and both `a` and `b` are due for garbage collection, there is no guarantee that `b` would be finalized after `a`. If proper finalization of `a` depends on `b` being valid, it must be handled in other ways.

27.7 Non-constant Function Specifications

In some cases, the exact name or path of the needed library is not known in advance and must be computed at run time. To handle such cases, the library component specification can be a function call, e.g. `find_blas().dgemm`. The call expression will be executed when the `ccall` itself is executed. However, it is assumed that the library location does not change once it is determined, so the result of the call can be cached and reused. Therefore, the number of times the expression executes is unspecified, and returning different values for multiple calls results in unspecified behavior.

If even more flexibility is needed, it is possible to use computed values as function names by staging through `eval` as follows:

```
|@eval @ccall "lib".$(string("a", "b"))()::Cint
```

This expression constructs a name using `string`, then substitutes this name into a new `@ccall` expression, which is then evaluated. Keep in mind that `eval` only operates at the top level, so within this expression local variables will not be available (unless their values are substituted with `$`). For this reason, `eval` is typically only used to form top-level definitions, for example when wrapping libraries that contain many similar functions. A similar example can be constructed for `@cfunction`.

However, doing this will also be very slow and leak memory, so you should usually avoid this and instead keep reading. The next section discusses how to use indirect calls to efficiently achieve a similar effect.

27.8 Indirect Calls

The first argument to `@ccall` can also be an expression evaluated at run time. In this case, the expression must evaluate to a `Ptr`, which will be used as the address of the native function to call. This behavior occurs when the first `@ccall` argument contains references to non-constants, such as local variables, function arguments, or non-constant globals.

For example, you might look up the function via `dlsym`, then cache it in a shared reference for that session. For example:

```
macro dlsym(lib, func)
  z = Ref{Ptr{Cvoid}}(C_NULL)
  quote
    let zlocal = $z[]
    if zlocal == C_NULL
      zlocal = dlsym($(esc(lib))::Ptr{Cvoid}, $(esc(func))::Ptr{Cvoid})
      $z[] = zlocal
    end
    zlocal
  end
end
end

mylibvar = Libdl.dlopen("mylib")
@ccall $(@dlsym(mylibvar, "myfunc"))()::Cvoid
```

27.9 Closure cfunctions

The first argument to `@cfunction` can be marked with a `$`, in which case the return value will instead be a struct `CFunction` which closes over the argument. You must ensure that this return object is kept alive until all uses of it are done. The contents and code at the `cfunction` pointer will be erased via a `finalizer` when this reference is dropped and `atexit`. This is not usually needed, since this functionality is not present in C, but can be useful for dealing with ill-designed APIs which don't provide a separate closure environment parameter.

```
function qsort(a::Vector{T}, cmp) where T
  isbits(T) || throw(ArgumentError("this method can only qsort isbits arrays"))
  callback = @cfunction $cmp Cint (Ref{T}, Ref{T})
  # Here, `callback` isa Base.CFunction, which will be converted to Ptr{Cvoid}
  # (and protected against finalization) by the ccall
  @ccall qsort(a::Ptr{T}, length(a)::Csize_t, Base.elsize(a)::Csize_t, callback::Ptr{Cvoid})
  # We could instead use:
  # GC.@preserve callback begin
  #   use(Base.unsafe_convert{Ptr{Cvoid}, callback})
  # end
  # if we needed to use it outside of a `ccall`
  return a
end
```

Note

Closure `@cfunction` relies on LLVM trampolines, which are not available on all platforms (for example ARM and PowerPC).

27.10 Closing a Library

It is sometimes useful to close (unload) a library so that it can be reloaded. For instance, when developing C code for use with Julia, one may need to compile, call the C code from Julia, then close the library, make an edit, recompile, and load in the new changes. One can either restart Julia or use the `Libdl` functions to manage the library explicitly, such as:

```
lib = Libdl.dlopen("./my_lib.so") # Open the library explicitly.
sym = Libdl.dlsym(lib, :my_fcn)   # Get a symbol for the function to call.
@ccall $sym(...) # Use the pointer `sym` instead of the library.symbol tuple.
Libdl.dlclose(lib) # Close the library explicitly.
```

Note that when using `@ccall` with the input (e.g., `@ccall "./my_lib.so".my_fcn(...)::Cvoid`), the library is opened implicitly and it may not be explicitly closed.

27.11 Variadic function calls

To call variadic C functions a semicolon can be used in the argument list to separate required arguments from variadic arguments. An example with the `printf` function is given below:

```
julia> @ccall printf("%s = %d\n"::Cstring; "foo"::Cstring, foo::Cint)::Cint
foo = 3
8
```

27.12 ccall interface

There is another alternative interface to `@ccall`. This interface is slightly less convenient but it does allow one to specify a [calling convention](#).

The arguments to `ccall` are:

1. A `(:function, "library")` pair (most common),
OR
a `:function` name symbol or `"function"` name string (for symbols in the current process or `libc`),
OR
a function pointer (for example, from `dlsym`).
2. The function's return type
3. A tuple of input types, corresponding to the function signature. One common mistake is forgetting that a 1-tuple of argument types must be written with a trailing comma.
4. The actual argument values to be passed to the function, if any; each is a separate parameter.

Note

The `(:function, "library")` pair, return type, and input types must be literal constants (i.e., they can't be variables, but see [Non-constant Function Specifications](#)).

The remaining parameters are evaluated at compile-time, when the containing method is defined.

A table of translations between the macro and function interfaces is given below.

27.13 Calling Convention

The second argument to `ccall` (immediately preceding return type) can optionally be a calling convention specifier (the `@ccall` macro currently does not support giving a calling convention). Without any specifier, the platform-default C calling convention is used. Other supported conventions are: `stdcall`, `cdecl`, `fastcall`, and `thiscall` (no-op on 64-bit Windows). For example (from `base/libc.jl`) we see the same `gethostnameccall` as above, but with the correct signature for Windows:

```
hn = Vector{UInt8}(undef, 256)
err = ccall(:gethostname, stdcall, Int32, (Ptr{UInt8}, UInt32), hn, length(hn))
```

For more information, please see the [LLVM Language Reference](#).

There is one additional special calling convention `llvmcall`, which allows inserting calls to LLVM intrinsics directly. This can be especially useful when targeting unusual platforms such as GPGPUs. For example, for [CUDA](#), we need to be able to read the thread index:

```
ccall("llvm.nvvm.read.ptx.sreg.tid.x", llvmcall, Int32, ())
```

As with any `ccall`, it is essential to get the argument signature exactly correct. Also, note that there is no compatibility layer that ensures the intrinsic makes sense and works on the current target, unlike the equivalent Julia functions exposed by `Core.Intrinsics`.

27.14 Accessing Global Variables

Global variables exported by native libraries can be accessed by name using the `cglobal` function. The arguments to `cglobal` are a symbol specification identical to that used by `ccall`, and a type describing the value stored in the variable:

```
julia> cglobal(:errno, :libc, Int32)
Ptr{Int32} @0x00007f418d0816b8
```

The result is a pointer giving the address of the value. The value can be manipulated through this pointer using `unsafe_load` and `unsafe_store!`.

Note

This `errno` symbol may not be found in a library named "libc", as this is an implementation detail of your system compiler. Typically standard library symbols should be accessed just by name, allowing the compiler to fill in the correct one. Also, however, the `errno` symbol shown in this example is special in most compilers, and so the value seen here is probably not what you expect or want. Compiling the equivalent code in C on any multi-threaded-capable system would typically actually call a different function (via macro preprocessor overloading), and may give a different result than the legacy value printed here.

27.15 Accessing Data through a Pointer

The following methods are described as "unsafe" because a bad pointer or type declaration can cause Julia to terminate abruptly.

Given a `Ptr{T}`, the contents of type `T` can generally be copied from the referenced memory into a Julia object using `unsafe_load(ptr, [index])`. The `index` argument is optional (default is 1), and follows the Julia-convention of 1-based indexing. This function is intentionally similar to the behavior of `getindex` and `setindex!` (e.g. `[]` access syntax).

The return value will be a new object initialized to contain a copy of the contents of the referenced memory. The referenced memory can safely be freed or released.

If `T` is `Any`, then the memory is assumed to contain a reference to a Julia object (a `julia_value_t*`), the result will be a reference to this object, and the object will not be copied. You must be careful in this case to ensure that the object was always visible to the garbage collector (pointers do not count, but the new reference does) to ensure the memory is not prematurely freed. Note that if the object was not originally allocated by Julia, the new object will never be finalized by Julia's garbage collector. If the `Ptr` itself is actually a `julia_value_t*`, it can be converted back to a Julia object reference by `unsafe_pointer_to_objref(ptr)`. (Julia values `v` can be converted to `julia_value_t*` pointers, as `Ptr{Cvoid}`, by calling `pointer_from_objref(v)`.)

The reverse operation (writing data to a `Ptr{T}`), can be performed using `unsafe_store!(ptr, value, [index])`. Currently, this is only supported for primitive types or other pointer-free (isbits) immutable struct types.

Any operation that throws an error is probably currently unimplemented and should be posted as a bug so that it can be resolved.

If the pointer of interest is a plain-data array (primitive type or immutable struct), the function `unsafe_wrap(Array, ptr, dims, own = false)` may be more useful. The final parameter should be true if Julia should "take ownership" of the underlying buffer and call `free(ptr)` when the returned `Array` object is finalized. If the `own` parameter is omitted or false, the caller must ensure the buffer remains in existence until all access is complete.

Arithmetic on the `Ptr` type in Julia (e.g. using `+`) does not behave the same as C's pointer arithmetic. Adding an integer to a `Ptr` in Julia always moves the pointer by some number of bytes, not elements. This way, the address values obtained from pointer arithmetic do not depend on the element types of pointers.

27.16 Thread-safety

Some C libraries execute their callbacks from a different thread, and since Julia isn't thread-safe you'll need to take some extra precautions. In particular, you'll need to set up a two-layered system: the C callback should only schedule (via Julia's event loop) the execution of your "real" callback. To do this, create an `AsyncCondition` object and `wait` on it:

```
| cond = Base.AsyncCondition()
| wait(cond)
```

The callback you pass to C should only execute a `ccall` to `:uv_async_send`, passing `cond.handle` as the argument, taking care to avoid any allocations or other interactions with the Julia runtime.

Note that events may be coalesced, so multiple calls to `uv_async_send` may result in a single wakeup notification to the condition.

27.17 More About Callbacks

For more details on how to pass callbacks to C libraries, see this [blog post](#).

27.18 C++

For tools to create C++ bindings, see the [CxxWrap](#) package.

¹Non-library function calls in both C and Julia can be inlined and thus may have even less overhead than calls to shared library functions. The point above is that the cost of actually doing foreign function call is about the same as doing a call in either native language.

²The [Clang package](#) can be used to auto-generate Julia code from a C header file.

| C name | Fortran name | Standard Julia Alias | Julia Base Type |
|--|----------------------|----------------------|--|
| unsigned char | CHARACTER | Cuchar | UInt8 |
| bool (<code>_Bool</code> in C99+) | | Cuchar | UInt8 |
| short | INTEGER*2, LOGICAL*2 | Cshort | Int16 |
| unsigned short | | Cushort | UInt16 |
| int, BOOL (C, typical) | INTEGER*4, LOGICAL*4 | Cint | Int32 |
| unsigned int | | Cuint | UInt32 |
| long long | INTEGER*8, LOGICAL*8 | Clonglong | Int64 |
| unsigned long long | | Culonglong | UInt64 |
| intmax_t | | Cintmax_t | Int64 |
| uintmax_t | | Cuintmax_t | UInt64 |
| float | REAL*4i | Cfloat | Float32 |
| double | REAL*8 | Cdouble | Float64 |
| complex float | COMPLEX*8 | ComplexF32 | Complex{Float32} |
| complex double | COMPLEX*16 | ComplexF64 | Complex{Float64} |
| ptrdiff_t | | Cptrdiff_t | Int |
| ssize_t | | Cssize_t | Int |
| size_t | | Csize_t | UInt |
| void | | | Cvoid |
| void and <code>[[noreturn]]</code> or <code>_Noreturn</code> | | | Union{} |
| void* | | | Ptr{Cvoid} (or similarly <code>Ref{Cvoid}</code>) |
| T* (where T represents an appropriately defined type) | | | Ref{T} (T may be safely mutated only if T is an <code>isbits</code> type) |
| char* (or <code>char[]</code> , e.g. a string) | CHARACTER*N | | Cstring if null-terminated, or <code>Ptr{UInt8}</code> if not |
| char** (or <code>*char[]</code>) | | | <code>Ptr{Ptr{UInt8}}</code> |
| <code>jl_value_t*</code> (any Julia Type) | | | Any |
| <code>jl_value_t* const*</code> (a reference to a Julia value) | | | <code>Ref{Any}</code> (const, since mutation would require a write barrier, which is not possible to insert correctly) |
| va_arg | | | Not supported |
| ... (variadic function specification) | | | T... (where T is one of the above types, when using the <code>ccall</code> function) |
| ... (variadic function specification) | | | ; <code>va_arg1::T</code> , <code>va_arg2::S</code> , etc. (only supported with <code>@ccall</code> macro) |

| C name | Standard Julia Alias | Julia Base Type |
|---------------|----------------------|--|
| char | Cchar | Int8 (x86, x86_64), UInt8 (powerpc, arm) |
| long | Clong | Int (UNIX), Int32 (Windows) |
| unsigned long | Culong | UInt (UNIX), UInt32 (Windows) |
| wchar_t | Cwchar_t | Int32 (UNIX), UInt16 (Windows) |

| @ccall | ccall |
|--|---|
| @ccall clock()::Int32 | ccall(:clock, Int32, ()) |
| @ccall f(a::Cint)::Cint | ccall(:a, Cint, (Cint,), a) |
| @ccall "mylib".f(a::Cint, b::Cdouble)::Cvoid | ccall((:f, "mylib"), Cvoid, (Cint, Cdouble), (a, b)) |
| @ccall \$fptr.f()::Cvoid | ccall(fp_ptr, f, Cvoid, ()) |
| @ccall printf("%s = %d\n"::Cstring ; "foo"::Cstring, foo::Cint)::Cint | <unavailable> |
| @ccall printf("%s = %d\n"::Cstring ; "2 + 2"::Cstring, "5"::Cstring)::Cint | ccall(:printf, Cint, (Cstring, Cstring...), "%s = %s\n", "2 + 2", "5") |
| <unavailable> | ccall(:gethostname, stdcall, Int32, (Ptr{UInt8}, UInt32), hn, length(hn)) |

Chapter 28

Handling Operating System Variation

When writing cross-platform applications or libraries, it is often necessary to allow for differences between operating systems. The variable `Sys.KERNEL` can be used to handle such cases. There are several functions in the `Sys` module intended to make this easier, such as `isunix`, `islinux`, `isapple`, `isbsd`, `isfreebsd`, and `iswindows`. These may be used as follows:

```
if Sys.iswindows()
    windows_specific_thing(a)
end
```

Note that `islinux`, `isapple`, and `isfreebsd` are mutually exclusive subsets of `isunix`. Additionally, there is a macro `@static` which makes it possible to use these functions to conditionally hide invalid code, as demonstrated in the following examples.

Simple blocks:

```
ccall((@static Sys.iswindows() ? :_fopen : :fopen), ...)
```

Complex blocks:

```
@static if Sys.islinux()
    linux_specific_thing(a)
elseif Sys.isapple()
    apple_specific_thing(a)
else
    generic_thing(a)
end
```

When nesting conditionals, the `@static` must be repeated for each level (parentheses optional, but recommended for readability):

```
@static Sys.iswindows() ? :a : (@static Sys.isapple() ? :b : :c)
```

Chapter 29

Environment Variables

Julia can be configured with a number of environment variables, set either in the usual way for each operating system, or in a portable way from within Julia. Supposing that you want to set the environment variable `JULIA_EDITOR` to `vim`, you can type `ENV["JULIA_EDITOR"] = "vim"` (for instance, in the REPL) to make this change on a case by case basis, or add the same to the user configuration file `~/.julia/config/startup.jl` in the user's home directory to have a permanent effect. The current value of the same environment variable can be determined by evaluating `ENV["JULIA_EDITOR"]`.

The environment variables that Julia uses generally start with `JULIA`. If `InteractiveUtils.versioninfo` is called with the keyword `verbose=true`, then the output will list any defined environment variables relevant for Julia, including those which include `JULIA` in their names.

Note

Some variables, such as `JULIA_NUM_THREADS` and `JULIA_PROJECT`, need to be set before Julia starts, therefore adding these to `~/.julia/config/startup.jl` is too late in the startup process. In Bash, environment variables can either be set manually by running, e.g., `export JULIA_NUM_THREADS=4` before starting Julia, or by adding the same command to `~/.bashrc` or `~/.bash_profile` to set the variable each time Bash is started.

29.1 File locations

`JULIA_BINDIR`

The absolute path of the directory containing the Julia executable, which sets the global variable `Sys.BINDIR`. If `$JULIA_BINDIR` is not set, then Julia determines the value `Sys.BINDIR` at run-time.

The executable itself is one of

```
| $JULIA_BINDIR/julia
| $JULIA_BINDIR/julia-debug
```

by default.

The global variable `Base.DATAROOTDIR` determines a relative path from `Sys.BINDIR` to the data directory associated with Julia. Then the path

```
| $JULIA_BINDIR/$DATAROOTDIR/julia/base
```

determines the directory in which Julia initially searches for source files (via `Base.find_source_file()`).

Likewise, the global variable `Base.SYSCONFDIR` determines a relative path to the configuration file directory. Then Julia searches for a `startup.jl` file at

```
| $JULIA_BINDIR/$SYSCONFDIR/julia/startup.jl
| $JULIA_BINDIR/../etc/julia/startup.jl
```

by default (via `Base.load_julia_startup()`).

For example, a Linux installation with a Julia executable located at `/bin/julia`, a `DATAROOTDIR` of `../share`, and a `SYSCONFDIR` of `../etc` will have `JULIA_BINDIR` set to `/bin`, a source-file search path of

```
| /share/julia/base
```

and a global configuration search path of

```
| /etc/julia/startup.jl
```

JULIA_PROJECT

A directory path that indicates which project should be the initial active project. Setting this environment variable has the same effect as specifying the `--project` start-up option, but `--project` has higher precedence. If the variable is set to `@.` (note the trailing dot) then Julia tries to find a project directory that contains `Project.toml` or `JuliaProject.toml` file from the current directory and its parents. See also the chapter on [Code Loading](#).

Note

`JULIA_PROJECT` must be defined before starting Julia; defining it in `startup.jl` is too late in the startup process.

JULIA_LOAD_PATH

The `JULIA_LOAD_PATH` environment variable is used to populate the global Julia [LOAD_PATH](#) variable, which determines which packages can be loaded via `import` and `using` (see [Code Loading](#)).

Unlike the shell `PATH` variable, empty entries in `JULIA_LOAD_PATH` are expanded to the default value of `LOAD_PATH`, `["@.", "@v#.#", "@stdlib"]` when populating `LOAD_PATH`. This allows easy appending, prepending, etc. of the load path value in shell scripts regardless of whether `JULIA_LOAD_PATH` is already set or not. For example, to prepend the directory `/foo/bar` to `LOAD_PATH` just do

```
| export JULIA_LOAD_PATH="/foo/bar:$JULIA_LOAD_PATH"
```

If the `JULIA_LOAD_PATH` environment variable is already set, its old value will be prepended with `/foo/bar`. On the other hand, if `JULIA_LOAD_PATH` is not set, then it will be set to `/foo/bar`: which will expand to a `LOAD_PATH` value of `["/foo/bar", "@.", "@v#.#", "@stdlib"]`. If `JULIA_LOAD_PATH` is set to the empty string, it expands to an empty `LOAD_PATH` array. In other words, the empty string is interpreted as a zero-element array, not a one-element array of the empty string. This behavior was chosen so that it would be possible to set an empty load path via the environment variable. If you want the default load path, either unset the environment variable or if it must have a value, set it to the string `:`.

Note

On Windows, path elements are separated by the `;` character, as is the case with most path lists on Windows. Replace `:` with `;` in the above paragraph.

JULIA_DEPOT_PATH

The `JULIA_DEPOT_PATH` environment variable is used to populate the global Julia `DEPOT_PATH` variable, which controls where the package manager, as well as Julia's code loading mechanisms, look for package registries, installed packages, named environments, repo clones, cached compiled package images, configuration files, and the default location of the REPL's history file.

Unlike the shell `PATH` variable but similar to `JULIA_LOAD_PATH`, empty entries in `JULIA_DEPOT_PATH` are expanded to the default value of `DEPOT_PATH`. This allows easy appending, prepending, etc. of the depot path value in shell scripts regardless of whether `JULIA_DEPOT_PATH` is already set or not. For example, to prepend the directory `/foo/bar` to `DEPOT_PATH` just do

```
| export JULIA_DEPOT_PATH="/foo/bar:$JULIA_DEPOT_PATH"
```

If the `JULIA_DEPOT_PATH` environment variable is already set, its old value will be prepended with `/foo/bar`. On the other hand, if `JULIA_DEPOT_PATH` is not set, then it will be set to `/foo/bar`: which will have the effect of prepending `/foo/bar` to the default depot path. If `JULIA_DEPOT_PATH` is set to the empty string, it expands to an empty `DEPOT_PATH` array. In other words, the empty string is interpreted as a zero-element array, not a one-element array of the empty string. This behavior was chosen so that it would be possible to set an empty depot path via the environment variable. If you want the default depot path, either unset the environment variable or if it must have a value, set it to the string `:`.

Note

On Windows, path elements are separated by the `;` character, as is the case with most path lists on Windows. Replace `:` with `;` in the above paragraph.

Note

`JULIA_DEPOT_PATH` must be defined before starting Julia; defining it in `startup.jl` is too late in the startup process; at that point you can instead directly modify the `DEPOT_PATH` array, which is populated from the environment variable.

JULIA_HISTORY

The absolute path `REPL.find_hist_file()` of the REPL's history file. If `$JULIA_HISTORY` is not set, then `REPL.find_hist_file()` defaults to

```
| $(DEPOT_PATH[1])/logs/repl_history.jl
```

JULIA_MAX_NUM_PRECOMPILE_FILES

Sets the maximum number of different instances of a single package that are to be stored in the precompile cache (default = 10).

JULIA_VERBOSE_LINKING

If set to true, linker commands will be displayed during precompilation.

29.2 Pkg.jl

JULIA_CI

If set to `true`, this indicates to the package server that any package operations are part of a continuous integration (CI) system for the purposes of gathering package usage statistics.

JULIA_NUM_PRECOMPILE_TASKS

The number of parallel tasks to use when precompiling packages. See [Pkg.precompile](#).

JULIA_PKG_DEVDIR

The default directory used by [Pkg.develop](#) for downloading packages.

JULIA_PKG_IGNORE_HASHES

If set to `1`, this will ignore incorrect hashes in artifacts. This should be used carefully, as it disables verification of downloads, but can resolve issues when moving files across different types of file systems. See [Pkg.jl issue #2317](#) for more details.

Julia 1.6

This is only supported in Julia 1.6 and above.

JULIA_PKG_OFFLINE

If set to `true`, this will enable offline mode: see [Pkg.offline](#).

Julia 1.5

Pkg's offline mode requires Julia 1.5 or later.

JULIA_PKG_PRECOMPILE_AUTO

If set to `0`, this will disable automatic precompilation by package actions which change the manifest. See [Pkg.precompile](#).

JULIA_PKG_SERVER

Specifies the URL of the package registry to use. By default, Pkg uses `https://pkg.julialang.org` to fetch Julia packages. In addition, you can disable the use of the PkgServer protocol, and instead access the packages directly from their hosts (GitHub, GitLab, etc.) by setting: `export JULIA_PKG_SERVER=""`

JULIA_PKG_SERVER_REGISTRY_PREFERENCE

Specifies the preferred registry flavor. Currently supported values are `conservative` (the default), which will only publish resources that have been processed by the storage server (and thereby have a higher probability of being available from the PkgServers), whereas `eager` will publish registries whose resources have not necessarily been processed by the storage servers. Users behind restrictive firewalls that do not allow downloading from arbitrary servers should not use the `eager` flavor.

Julia 1.7

This only affects Julia 1.7 and above.

JULIA_PKG_UNPACK_REGISTRY

If set to `true`, this will unpack the registry instead of storing it as a compressed tarball.

Julia 1.7

This only affects Julia 1.7 and above. Earlier versions will always unpack the registry.

JULIA_PKG_USE_CLI_GIT

If set to `true`, Pkg operations which use the git protocol will use an external git executable instead of the default libgit2 library.

Julia 1.7

Use of the git executable is only supported on Julia 1.7 and above.

JULIA_PKGRESOLVE_ACCURACY

The accuracy of the package resolver. This should be a positive integer, the default is 1.

JULIA_PKG_PRESERVE_TIERED_INSTALLED

Change the default package installation strategy to `Pkg.PRESERVE_TIERED_INSTALLED` to let the package manager try to install versions of packages while keeping as many versions of packages already installed as possible.

Julia 1.9

This only affects Julia 1.9 and above.

29.3 Network transport**JULIA_NO_VERIFY_HOSTS / JULIA_SSL_NO_VERIFY_HOSTS / JULIA_SSH_NO_VERIFY_HOSTS / JULIA_ALWAYS_VERIFY_HOSTS**

Specify hosts whose identity should or should not be verified for specific transport layers. See [NetworkOptions.verify_host](#)

JULIA_SSL_CA_ROOTS_PATH

Specify the file or directory containing the certificate authority roots. See [NetworkOptions.ca_roots](#)

29.4 External applications**JULIA_SHELL**

The absolute path of the shell with which Julia should execute external commands (via `Base.repl_cmd()`). Defaults to the environment variable `$SHELL`, and falls back to `/bin/sh` if `$SHELL` is unset.

Note

On Windows, this environment variable is ignored, and external commands are executed directly.

JULIA_EDITOR

The editor returned by `InteractiveUtils.editor()` and used in, e.g., `InteractiveUtils.edit`, referring to the command of the preferred editor, for instance `vim`.

`$JULIA_EDITOR` takes precedence over `$VISUAL`, which in turn takes precedence over `$EDITOR`. If none of these environment variables is set, then the editor is taken to be open on Windows and OS X, or `/etc/alternatives/editor` if it exists, or `emacs` otherwise.

To use Visual Studio Code on Windows, set `$JULIA_EDITOR` to `code.cmd`.

29.5 Parallelization**JULIA_CPU_THREADS**

Overrides the global variable `Base.Sys.CPU_THREADS`, the number of logical CPU cores available.

JULIA_WORKER_TIMEOUT

A `Float64` that sets the value of `Distributed.worker_timeout()` (default: `60.0`). This function gives the number of seconds a worker process will wait for a master process to establish a connection before dying.

JULIA_NUM_THREADS

An unsigned 64-bit integer (`uint64_t`) that sets the maximum number of threads available to Julia. If `$JULIA_NUM_THREADS` is not positive or is not set, or if the number of CPU threads cannot be determined through system calls, then the number of threads is set to 1.

If `$JULIA_NUM_THREADS` is set to `auto`, then the number of threads will be set to the number of CPU threads.

Note

`JULIA_NUM_THREADS` must be defined before starting Julia; defining it in `startup.jl` is too late in the startup process.

Julia 1.5

In Julia 1.5 and above the number of threads can also be specified on startup using the `-t/--threads` command line argument.

Julia 1.7

The `auto` value for `$JULIA_NUM_THREADS` requires Julia 1.7 or above.

JULIA_THREAD_SLEEP_THRESHOLD

If set to a string that starts with the case-insensitive substring `"infinite"`, then spinning threads never sleep. Otherwise, `$JULIA_THREAD_SLEEP_THRESHOLD` is interpreted as an unsigned 64-bit integer (`uint64_t`) and gives, in nanoseconds, the amount of time after which spinning threads should sleep.

JULIA_NUM_GC_THREADS

Sets the number of threads used by Garbage Collection. If unspecified is set to half of the number of worker threads.

Julia 1.10

The environment variable was added in 1.10

JULIA_IMAGE_THREADS

An unsigned 32-bit integer that sets the number of threads used by image compilation in this Julia process. The value of this variable may be ignored if the module is a small module. If left unspecified, the smaller of the value of [JULIA_CPU_THREADS](#) or half the number of logical CPU cores is used in its place.

JULIA_IMAGE_TIMINGS

A boolean value that determines if detailed timing information is printed during image compilation. Defaults to 0.

JULIA_EXCLUSIVE

If set to anything besides 0, then Julia's thread policy is consistent with running on a dedicated machine: the master thread is on proc 0, and threads are affinitized. Otherwise, Julia lets the operating system handle thread policy.

29.6 REPL formatting

Environment variables that determine how REPL output should be formatted at the terminal. Generally, these variables should be set to [ANSI terminal escape sequences](#). Julia provides a high-level interface with much of the same functionality; see the section on [The Julia REPL](#).

JULIA_ERROR_COLOR

The formatting `Base.error_color()` (default: light red, "\033[91m") that errors should have at the terminal.

JULIA_WARN_COLOR

The formatting `Base.warn_color()` (default: yellow, "\033[93m") that warnings should have at the terminal.

JULIA_INFO_COLOR

The formatting `Base.info_color()` (default: cyan, "\033[36m") that info should have at the terminal.

JULIA_INPUT_COLOR

The formatting `Base.input_color()` (default: normal, "\033[0m") that input should have at the terminal.

JULIA_ANSWER_COLOR

The formatting `Base.answer_color()` (default: `normal`, `"\033[0m"`) that output should have at the terminal.

29.7 System and Package Image Building**JULIA_CPU_TARGET**

Modify the target machine architecture for (pre)compiling [system](#) and [package images](#). `JULIA_CPU_TARGET` only affects machine code image generation being output to a disk cache. Unlike the `--cpu-target`, or `-C`, [command line option](#), it does not influence just-in-time (JIT) code generation within a Julia session where machine code is only stored in memory.

Valid values for `JULIA_CPU_TARGET` can be obtained by executing `julia -C help`.

Setting `JULIA_CPU_TARGET` is important for heterogeneous compute systems where processors of distinct types or features may be present. This is commonly encountered in high performance computing (HPC) clusters since the component nodes may be using distinct processors.

The CPU target string is a list of strings separated by `;` each string starts with a CPU or architecture name and followed by an optional list of features separated by `,`. A generic or empty CPU name means the basic required feature set of the target ISA which is at least the architecture the C/C++ runtime is compiled with. Each string is interpreted by LLVM.

A few special features are supported:

1. `clone_all`

This forces the target to have all functions in sysimg cloned. When used in negative form (i.e. `-clone_all`), this disables full clone that's enabled by default for certain targets.

2. `base([0-9]*)`

This specifies the (0-based) base target index. The base target is the target that the current target is based on, i.e. the functions that are not being cloned will use the version in the base target. This option causes the base target to be fully cloned (as if `clone_all` is specified for it) if it is not the default target (0). The index can only be smaller than the current index.

3. `opt_size`

Optimize for size with minimum performance impact. Clang/GCC's `-Os`.

4. `min_size`

Optimize only for size. Clang's `-Oz`.

29.8 Debugging and profiling**JULIA_DEBUG**

Enable debug logging for a file or module, see [Logging](#) for more information.

JULIA_GC_ALLOC_POOL, JULIA_GC_ALLOC_OTHER, JULIA_GC_ALLOC_PRINT

If set, these environment variables take strings that optionally start with the character 'r', followed by a string interpolation of a colon-separated list of three signed 64-bit integers (`int64_t`). This triple of integers `a:b:c` represents the arithmetic sequence `a`, `a + b`, `a + 2*b`, ... `c`.

- If it's the `n`th time that `jl_gc_pool_alloc()` has been called, and `n` belongs to the arithmetic sequence represented by `$JULIA_GC_ALLOC_POOL`, then garbage collection is forced.
- If it's the `n`th time that `maybe_collect()` has been called, and `n` belongs to the arithmetic sequence represented by `$JULIA_GC_ALLOC_OTHER`, then garbage collection is forced.
- If it's the `n`th time that `jl_gc_collect()` has been called, and `n` belongs to the arithmetic sequence represented by `$JULIA_GC_ALLOC_PRINT`, then counts for the number of calls to `jl_gc_pool_alloc()` and `maybe_collect()` are printed.

If the value of the environment variable begins with the character 'r', then the interval between garbage collection events is randomized.

Note

These environment variables only have an effect if Julia was compiled with garbage-collection debugging (that is, if `WITH_GC_DEBUG_ENV` is set to 1 in the build configuration).

JULIA_GC_NO_GENERATIONAL

If set to anything besides 0, then the Julia garbage collector never performs "quick sweeps" of memory.

Note

This environment variable only has an effect if Julia was compiled with garbage-collection debugging (that is, if `WITH_GC_DEBUG_ENV` is set to 1 in the build configuration).

JULIA_GC_WAIT_FOR_DEBUGGER

If set to anything besides 0, then the Julia garbage collector will wait for a debugger to attach instead of aborting whenever there's a critical error.

Note

This environment variable only has an effect if Julia was compiled with garbage-collection debugging (that is, if `WITH_GC_DEBUG_ENV` is set to 1 in the build configuration).

ENABLE_JITPROFILING

If set to anything besides 0, then the compiler will create and register an event listener for just-in-time (JIT) profiling.

Note

This environment variable only has an effect if Julia was compiled with JIT profiling support, using either

- Intel's [VTune™ Amplifier](#) (USE_INTEL_JITEVENTS set to 1 in the build configuration), or
- [OProfile](#) (USE_OPROFILE_JITEVENTS set to 1 in the build configuration).
- [Perf](#) (USE_PERF_JITEVENTS set to 1 in the build configuration). This integration is enabled by default.

ENABLE_GDBLISTENER

If set to anything besides 0 enables GDB registration of Julia code on release builds. On debug builds of Julia this is always enabled. Recommended to use with -g 2.

JULIA_LLVM_ARGS

Arguments to be passed to the LLVM backend.

Chapter 30

Embedding Julia

As we have seen in [Calling C and Fortran Code](#), Julia has a simple and efficient way to call functions written in C. But there are situations where the opposite is needed: calling Julia functions from C code. This can be used to integrate Julia code into a larger C/C++ project, without the need to rewrite everything in C/C++. Julia has a C API to make this possible. As almost all programming languages have some way to call C functions, the Julia C API can also be used to build further language bridges (e.g. calling Julia from Python, Rust or C#). Even though Rust and C++ can use the C embedding API directly, both have packages helping with it, for C++ [Jluna](#) is useful.

30.1 High-Level Embedding

Note: This section covers embedding Julia code in C on Unix-like operating systems. For doing this on Windows, please see the section following this, [High-Level Embedding on Windows with Visual Studio](#).

We start with a simple C program that initializes Julia and calls some Julia code:

```
#include <julia.h>
JULIA_DEFINE_FAST_TLS // only define this once, in an executable (not in a shared library) if you
                        want fast code.

int main(int argc, char *argv[])
{
    /* required: setup the Julia context */
    jl_init();

    /* run Julia commands */
    jl_eval_string("print(sqrt(2.0))");

    /* strongly recommended: notify Julia that the
       program is about to terminate. this allows
       Julia time to cleanup pending write requests
       and run all finalizers
    */
    jl_atexit_hook(0);
    return 0;
}
```

In order to build this program you must add the path to the Julia header to the include path and link against `libjulia`. For instance, when Julia is installed to `$JULIA_DIR`, one can compile the above test program `test.c` with `gcc` using:

```
gcc -o test -fPIC -I$JULIA_DIR/include/julia -L$JULIA_DIR/lib -Wl,-rpath,$JULIA_DIR/lib test.c -ljulia
```

Alternatively, look at the `embedding.c` program in the Julia source tree in the `test/embedding/` folder. The file `cli/loader_exe.c` program is another simple example of how to set `julia_options` options while linking against `libjulia`.

The first thing that must be done before calling any other Julia C function is to initialize Julia. This is done by calling `julia_init`, which tries to automatically determine Julia's install location. If you need to specify a custom location, or specify which system image to load, use `julia_init_with_image` instead.

The second statement in the test program evaluates a Julia statement using a call to `julia_eval_string`.

Before the program terminates, it is strongly recommended that `julia_atexit_hook` is called. The above example program calls this just before returning from `main`.

Note

Currently, dynamically linking with the `libjulia` shared library requires passing the `RTLD_GLOBAL` option. In Python, this looks like:

```
>>> julia=CDLL('./libjulia.dylib',RTLD_GLOBAL)
>>> julia.julia_init.argtypes = []
>>> julia.julia_init()
250593296
```

Note

If the Julia program needs to access symbols from the main executable, it may be necessary to add the `-Wl,--export-dynamic` linker flag at compile time on Linux in addition to the ones generated by `julia-config.jl` described below. This is not necessary when compiling a shared library.

Using `julia-config` to automatically determine build parameters

The script `julia-config.jl` was created to aid in determining what build parameters are required by a program that uses embedded Julia. This script uses the build parameters and system configuration of the particular Julia distribution it is invoked by to export the necessary compiler flags for an embedding program to interact with that distribution. This script is located in the Julia shared data directory.

Example

```
#include <julia.h>

int main(int argc, char *argv[])
{
    julia_init();
    (void)julia_eval_string("println(sqrt(2.0))");
    julia_atexit_hook(0);
    return 0;
}
```

On the command line

A simple use of this script is from the command line. Assuming that `julia-config.jl` is located in `/usr/local/julia/share/julia`, it can be invoked on the command line directly and takes any combination of three flags:

```
| /usr/local/julia/share/julia/julia-config.jl
| Usage: julia-config [--cflags|--ldflags|--ldlibs]
```

If the above example source is saved in the file `embed_example.c`, then the following command will compile it into an executable program on Linux and Windows (MSYS2 environment). On macOS, substitute `clang` for `gcc`:

```
| /usr/local/julia/share/julia/julia-config.jl --cflags --ldflags --ldlibs | xargs gcc
|     embed_example.c
```

Use in Makefiles

In general, embedding projects will be more complicated than the above example, and so the following allows general makefile support as well – assuming GNU make because of the use of the **shell** macro expansions. Furthermore, although `julia-config.jl` is usually in the `/usr/local` directory, if it isn't, then Julia itself can be used to find `julia-config.jl`, and the makefile can take advantage of this. The above example is extended to use a makefile:

```
| JL_SHARE = $(shell julia -e 'print(joinpath(Sys.BINDIR, Base.DATAROOTDIR, "julia"))')
| CFLAGS   += $(shell $(JL_SHARE)/julia-config.jl --cflags)
| CXXFLAGS += $(shell $(JL_SHARE)/julia-config.jl --cflags)
| LDFLAGS  += $(shell $(JL_SHARE)/julia-config.jl --ldflags)
| LDLIBS   += $(shell $(JL_SHARE)/julia-config.jl --ldlibs)
|
| all: embed_example
```

Now the build command is simply `make`.

30.2 High-Level Embedding on Windows with Visual Studio

If the `JULIA_DIR` environment variable hasn't been setup, add it using the System panel before starting Visual Studio. The `bin` folder under `JULIA_DIR` should be on the system `PATH`.

We start by opening Visual Studio and creating a new Console Application project. Open the `'stdafx.h'` header file, and add the following lines at the end:

```
| #include <julia.h>
```

Then, replace the `main()` function in the project with this code:

```
| int main(int argc, char *argv[])
| {
|     /* required: setup the Julia context */
|     jl_init();
|
|     /* run Julia commands */
|     jl_eval_string("print(sqrt(2.0))");
| }
```

```

    /* strongly recommended: notify Julia that the
       program is about to terminate. this allows
       Julia time to cleanup pending write requests
       and run all finalizers
    */
    jl_atexit_hook(0);
    return 0;
}

```

The next step is to set up the project to find the Julia include files and the libraries. It's important to know whether the Julia installation is 32- or 64-bit. Remove any platform configuration that doesn't correspond to the Julia installation before proceeding.

Using the project Properties dialog, go to C/C++ | General and add `$(JULIA_DIR)\include\julia\` to the Additional Include Directories property. Then, go to the Linker | General section and add `$(JULIA_DIR)\lib` to the Additional Library Directories property. Finally, under Linker | Input, add `libjulia.dll.a;libopenlibm.dll.a;` to the list of libraries.

At this point, the project should build and run.

30.3 Converting Types

Real applications will not only need to execute expressions, but also return their values to the host program. `jl_eval_string` returns a `jl_value_t*`, which is a pointer to a heap-allocated Julia object. Storing simple data types like `Float64` in this way is called boxing, and extracting the stored primitive data is called unboxing. Our improved sample program that calculates the square root of 2 in Julia and reads back the result in C has a body that now contains this code:

```

jl_value_t *ret = jl_eval_string("sqrt(2.0)");

if (jl_typeis(ret, jl_float64_type)) {
    double ret_unboxed = jl_unbox_float64(ret);
    printf("sqrt(2.0) in C: %e \n", ret_unboxed);
}
else {
    printf("ERROR: unexpected return type from sqrt(::Float64)\n");
}

```

In order to check whether `ret` is of a specific Julia type, we can use the `jl_isa`, `jl_typeis`, or `jl_is_...` functions. By typing `typeof(sqrt(2.0))` into the Julia shell we can see that the return type is `Float64` (double in C). To convert the boxed Julia value into a C double the `jl_unbox_float64` function is used in the above code snippet.

Corresponding `jl_box_...` functions are used to convert the other way:

```

jl_value_t *a = jl_box_float64(3.0);
jl_value_t *b = jl_box_float32(3.0f);
jl_value_t *c = jl_box_int32(3);

```

As we will see next, boxing is required to call Julia functions with specific arguments.

30.4 Calling Julia Functions

While `j_l_eval_string` allows C to obtain the result of a Julia expression, it does not allow passing arguments computed in C to Julia. For this you will need to invoke Julia functions directly, using `j_l_call`:

```
j_l_function_t *func = j_l_get_function(j_l_base_module, "sqrt");
j_l_value_t *argument = j_l_box_float64(2.0);
j_l_value_t *ret = j_l_call1(func, argument);
```

In the first step, a handle to the Julia function `sqrt` is retrieved by calling `j_l_get_function`. The first argument passed to `j_l_get_function` is a pointer to the Base module in which `sqrt` is defined. Then, the double value is boxed using `j_l_box_float64`. Finally, in the last step, the function is called using `j_l_call1`. `j_l_call0`, `j_l_call2`, and `j_l_call3` functions also exist, to conveniently handle different numbers of arguments. To pass more arguments, use `j_l_call`:

```
j_l_value_t *j_l_call(j_l_function_t *f, j_l_value_t **args, int32_t nargs)
```

Its second argument `args` is an array of `j_l_value_t*` arguments and `nargs` is the number of arguments.

There is also an alternative, possibly simpler, way of calling Julia functions and that is via [@cfunction](#). Using `@cfunction` allows you to do the type conversions on the Julia side which typically is easier than doing it on the C side. The `sqrt` example above would with `@cfunction` be written as:

```
double (*sqrt_jl)(double) = j_l_unbox_voidpointer(j_l_eval_string("@cfunction(sqrt, Float64, (
    Float64,))"));
double ret = sqrt_jl(2.0);
```

where we first define a C callable function in Julia, extract the function pointer from it and finally call it.

30.5 Memory Management

As we have seen, Julia objects are represented in C as pointers of type `j_l_value_t*`. This raises the question of who is responsible for freeing these objects.

Typically, Julia objects are freed by the garbage collector (GC), but the GC does not automatically know that we are holding a reference to a Julia value from C. This means the GC can free objects out from under you, rendering pointers invalid.

The GC will only run when new Julia objects are being allocated. Calls like `j_l_box_float64` perform allocation, but allocation might also happen at any point in running Julia code.

When writing code that embeds Julia, it is generally safe to use `j_l_value_t*` values in between `j_l...` calls (as GC will only get triggered by those calls). But in order to make sure that values can survive `j_l...` calls, we have to tell Julia that we still hold a reference to Julia [root](#) values, a process called "GC rooting". Rooting a value will ensure that the garbage collector does not accidentally identify this value as unused and free the memory backing that value. This can be done using the `JL_GC_PUSH` macros:

```
j_l_value_t *ret = j_l_eval_string("sqrt(2.0)");
JL_GC_PUSH1(&ret);
// Do something with ret
JL_GC_POP();
```

The `JL_GC_POP` call releases the references established by the previous `JL_GC_PUSH`. Note that `JL_GC_PUSH` stores references on the C stack, so it must be exactly paired with a `JL_GC_POP` before the scope is exited.

That is, before the function returns, or control flow otherwise leaves the block in which the `JL_GC_PUSH` was invoked.

Several Julia values can be pushed at once using the `JL_GC_PUSH2` to `JL_GC_PUSH6` macros:

```
JL_GC_PUSH2(&ret1, &ret2);
// ...
JL_GC_PUSH6(&ret1, &ret2, &ret3, &ret4, &ret5, &ret6);
```

To push an array of Julia values one can use the `JL_GC_PUSHARGS` macro, which can be used as follows:

```
j_l_value_t **args;
JL_GC_PUSHARGS(args, 2); // args can now hold 2 `j_l_value_t*` objects
args[0] = some_value;
args[1] = some_other_value;
// Do something with args (e.g. call j_l... functions)
JL_GC_POP();
```

Each scope must have only one call to `JL_GC_PUSH*`, and should be paired with only a single `JL_GC_POP` call. If all necessary variables you want to root cannot be pushed by a one single call to `JL_GC_PUSH*`, or if there are more than 6 variables to be pushed and using an array of arguments is not an option, then one can use inner blocks:

```
j_l_value_t *ret1 = j_l_eval_string("sqrt(2.0)");
JL_GC_PUSH1(&ret1);
j_l_value_t *ret2 = 0;
{
    j_l_function_t *func = j_l_get_function(j_l_base_module, "exp");
    ret2 = j_l_call1(func, ret1);
    JL_GC_PUSH1(&ret2);
    // Do something with ret2.
    JL_GC_POP();    // This pops ret2.
}
JL_GC_POP();    // This pops ret1.
```

Note that it is not necessary to have valid `j_l_value_t*` values before calling `JL_GC_PUSH*`. It is fine to have a number of them initialized to `NULL`, pass those to `JL_GC_PUSH*` and then create the actual Julia values. For example:

```
j_l_value_t *ret1 = NULL, *ret2 = NULL;
JL_GC_PUSH2(&ret1, &ret2);
ret1 = j_l_eval_string("sqrt(2.0)");
ret2 = j_l_eval_string("sqrt(3.0)");
// Use ret1 and ret2
JL_GC_POP();
```

If it is required to hold the pointer to a variable between functions (or block scopes), then it is not possible to use `JL_GC_PUSH*`. In this case, it is necessary to create and keep a reference to the variable in the Julia global scope. One simple way to accomplish this is to use a global `IdDict` that will hold the references, avoiding deallocation by the GC. However, this method will only work properly with mutable types.

```
// This functions shall be executed only once, during the initialization.
j_l_value_t* refs = j_l_eval_string("refs = IdDict()");
j_l_function_t* setindex = j_l_get_function(j_l_base_module, "setindex!");
```

```

...

// `var` is the variable we want to protect between function calls.
jl_value_t* var = 0;

...

// `var` is a `Vector{Float64}`, which is mutable.
var = jl_eval_string("[sqrt(2.0); sqrt(4.0); sqrt(6.0)]");

// To protect `var`, add its reference to `refs`.
jl_call3(setindex, refs, var, var);

```

If the variable is immutable, then it needs to be wrapped in an equivalent mutable container or, preferably, in a `RefValue{Any}` before it is pushed to `IdDict`. In this approach, the container has to be created or filled in via C code using, for example, the function `jl_new_struct`. If the container is created by `jl_call*`, then you will need to reload the pointer to be used in C code.

```

// This functions shall be executed only once, during the initialization.
jl_value_t* refs = jl_eval_string("refs = IdDict()");
jl_function_t* setindex = jl_get_function(jl_base_module, "setindex!");
jl_datatype_t* reft = (jl_datatype_t*)jl_eval_string("Base.RefValue{Any}");

...

// `var` is the variable we want to protect between function calls.
jl_value_t* var = 0;

...

// `var` is a `Float64`, which is immutable.
var = jl_eval_string("sqrt(2.0)");

// Protect `var` until we add its reference to `refs`.
JL_GC_PUSH1(&var);

// Wrap `var` in `RefValue{Any}` and push to `refs` to protect it.
jl_value_t* rvar = jl_new_struct(reft, var);
JL_GC_POP();

jl_call3(setindex, refs, rvar, rvar);

```

The GC can be allowed to deallocate a variable by removing the reference to it from `refs` using the function `delete!`, provided that no other reference to the variable is kept anywhere:

```

jl_function_t* delete = jl_get_function(jl_base_module, "delete!");
jl_call2(delete, refs, rvar);

```

As an alternative for very simple cases, it is possible to just create a global container of type `Vector{Any}` and fetch the elements from that when necessary, or even to create one global variable per pointer using

```

jl_module_t *mod = jl_main_module;
jl_sym_t *var = jl_symbol("var");
jl_binding_t *bp = jl_get_binding_wr(mod, var);
jl_checked_assignment(bp, mod, var, val);

```

Updating fields of GC-managed objects

The garbage collector also operates under the assumption that it is aware of every older-generation object pointing to a younger-generation one. Any time a pointer is updated breaking that assumption, it must be signaled to the collector with the `j1_gc_wb` (write barrier) function like so:

```
j1_value_t *parent = some_old_value, *child = some_young_value;
((some_specific_type*)parent)->field = child;
j1_gc_wb(parent, child);
```

It is in general impossible to predict which values will be old at runtime, so the write barrier must be inserted after all explicit stores. One notable exception is if the parent object has just been allocated and no garbage collection has run since then. Note that most `j1_...` functions can sometimes invoke garbage collection.

The write barrier is also necessary for arrays of pointers when updating their data directly. For example:

```
j1_array_t *some_array = ...; // e.g. a Vector{Any}
void **data = (void**)j1_array_data(some_array);
j1_value_t *some_value = ...;
data[0] = some_value;
j1_gc_wb(some_array, some_value);
```

Controlling the Garbage Collector

There are some functions to control the GC. In normal use cases, these should not be necessary.

| Function | Description |
|---------------------------------|--|
| <code>j1_gc_collect()</code> | Force a GC run |
| <code>j1_gc_enable(0)</code> | Disable the GC, return previous state as int |
| <code>j1_gc_enable(1)</code> | Enable the GC, return previous state as int |
| <code>j1_gc_is_enabled()</code> | Return current state as int |

30.6 Working with Arrays

Julia and C can share array data without copying. The next example will show how this works.

Julia arrays are represented in C by the datatype `j1_array_t*`. Basically, `j1_array_t` is a struct that contains:

- Information about the datatype
- A pointer to the data block
- Information about the sizes of the array

To keep things simple, we start with a 1D array. Creating an array containing Float64 elements of length 10 can be done like this:

```
j1_value_t* array_type = j1_apply_array_type((j1_value_t*)j1_float64_type, 1);
j1_array_t* x          = j1_alloc_array_1d(array_type, 10);
```

Alternatively, if you have already allocated the array you can generate a thin wrapper around its data:

```
double *existingArray = (double*)malloc(sizeof(double)*10);
jl_array_t *x = jl_ptr_to_array_1d(array_type, existingArray, 10, 0);
```

The last argument is a boolean indicating whether Julia should take ownership of the data. If this argument is non-zero, the GC will call `free` on the data pointer when the array is no longer referenced.

In order to access the data of `x`, we can use `jl_array_data`:

```
double *xData = (double*)jl_array_data(x);
```

Now we can fill the array:

```
for(size_t i=0; i<jl_array_len(x); i++)
    xData[i] = i;
```

Now let us call a Julia function that performs an in-place operation on `x`:

```
jl_function_t *func = jl_get_function(jl_base_module, "reverse!");
jl_call1(func, (jl_value_t*)x);
```

By printing the array, one can verify that the elements of `x` are now reversed.

Accessing Returned Arrays

If a Julia function returns an array, the return value of `jl_eval_string` and `jl_call` can be cast to a `jl_array_t*`:

```
jl_function_t *func = jl_get_function(jl_base_module, "reverse");
jl_array_t *y = (jl_array_t*)jl_call1(func, (jl_value_t*)x);
```

Now the content of `y` can be accessed as before using `jl_array_data`. As always, be sure to keep a reference to the array while it is in use.

Multidimensional Arrays

Julia's multidimensional arrays are stored in memory in column-major order. Here is some code that creates a 2D array and accesses its properties:

```
// Create 2D array of float64 type
jl_value_t *array_type = jl_apply_array_type((jl_value_t*)jl_float64_type, 2);
jl_array_t *x = jl_alloc_array_2d(array_type, 10, 5);

// Get array pointer
double *p = (double*)jl_array_data(x);
// Get number of dimensions
int ndims = jl_array_ndims(x);
// Get the size of the i-th dim
size_t size0 = jl_array_dim(x,0);
size_t size1 = jl_array_dim(x,1);

// Fill array with data
for(size_t i=0; i<size1; i++)
    for(size_t j=0; j<size0; j++)
        p[j + size0*i] = i + j;
```

Notice that while Julia arrays use 1-based indexing, the C API uses 0-based indexing (for example in calling `jl_array_dim`) in order to read as idiomatic C code.

30.7 Exceptions

Julia code can throw exceptions. For example, consider:

```
| jl_eval_string("this_function_does_not_exist());
```

This call will appear to do nothing. However, it is possible to check whether an exception was thrown:

```
| if (jl_exception_occurred())
|     printf("%s \n", jl_typeof_str(jl_exception_occurred()));
```

If you are using the Julia C API from a language that supports exceptions (e.g. Python, C#, C++), it makes sense to wrap each call into `libjulia` with a function that checks whether an exception was thrown, and then rethrows the exception in the host language.

Throwing Julia Exceptions

When writing Julia callable functions, it might be necessary to validate arguments and throw exceptions to indicate errors. A typical type check looks like:

```
| if (!jl_typeis(val, jl_float64_type)) {
|     jl_type_error(function_name, (jl_value_t*)jl_float64_type, val);
| }
```

General exceptions can be raised using the functions:

```
| void jl_error(const char *str);
| void jl_errorf(const char *fmt, ...);
```

`jl_error` takes a C string, and `jl_errorf` is called like `printf`:

```
| jl_errorf("argument x = %d is too large", x);
```

where in this example `x` is assumed to be an integer.

Thread-safety

In general, the Julia C API is not fully thread-safe. When embedding Julia in a multi-threaded application care needs to be taken not to violate the following restrictions:

- `jl_init()` may only be called once in the application life-time. The same applies to `jl_atexit_hook()`, and it may only be called after `jl_init()`.
- `jl_...()` API functions may only be called from the thread in which `jl_init()` was called, or from threads started by the Julia runtime. Calling Julia API functions from user-started threads is not supported, and may lead to undefined behaviour and crashes.

The second condition above implies that you can not safely call `jl_...()` functions from threads that were not started by Julia (the thread calling `jl_init()` being the exception). For example, the following is not supported and will most likely segfault:

```

void *func(void*)
{
    // Wrong, jl_eval_string() called from thread that was not started by Julia
    jl_eval_string("println(Threads.threadid())");
    return NULL;
}

int main()
{
    pthread_t t;

    jl_init();

    // Start a new thread
    pthread_create(&t, NULL, func, NULL);
    pthread_join(t, NULL);

    jl_atexit_hook(0);
}

```

Instead, performing all Julia calls from the same user-created thread will work:

```

void *func(void*)
{
    // Okay, all jl_...() calls from the same thread,
    // even though it is not the main application thread
    jl_init();
    jl_eval_string("println(Threads.threadid())");
    jl_atexit_hook(0);
    return NULL;
}

int main()
{
    pthread_t t;
    // Create a new thread, which runs func()
    pthread_create(&t, NULL, func, NULL);
    pthread_join(t, NULL);
}

```

An example of calling the Julia C API from a thread started by Julia itself:

```

#include <julia/julia.h>
JULIA_DEFINE_FAST_TLS

double c_func(int i)
{
    printf("[C %08x] i = %d\n", pthread_self(), i);

    // Call the Julia sqrt() function to compute the square root of i, and return it
    jl_function_t *sqrt = jl_get_function(jl_base_module, "sqrt");
    jl_value_t* arg = jl_box_int32(i);
    double ret = jl_unbox_float64(jl_call1(sqrt, arg));
}

```

```

    return ret;
}

int main()
{
    jl_init();

    // Define a Julia function func() that calls our c_func() defined in C above
    jl_eval_string("func(i) = ccall(:c_func, Float64, (Int32,), i)");

    // Call func() multiple times, using multiple threads to do so
    jl_eval_string("println(Threads.threadpoolsize())");
    jl_eval_string("use(i) = println(\"[J \$(Threads.threadid())] i = \$(i) -> \$(func(i))\")");
    jl_eval_string("Threads.@threads for i in 1:5 use(i) end");

    jl_atexit_hook(0);
}

```

If we run this code with 2 Julia threads we get the following output (note: the output will vary per run and system):

```

$ JULIA_NUM_THREADS=2 ./thread_example
2
[C 3bfd9c00] i = 1
[C 23938640] i = 4
[J 1] i = 1 -> 1.0
[C 3bfd9c00] i = 2
[J 1] i = 2 -> 1.4142135623730951
[C 3bfd9c00] i = 3
[J 2] i = 4 -> 2.0
[C 23938640] i = 5
[J 1] i = 3 -> 1.7320508075688772
[J 2] i = 5 -> 2.23606797749979

```

As can be seen, Julia thread 1 corresponds to pthread ID 3bfd9c00, and Julia thread 2 corresponds to ID 23938640, showing that indeed multiple threads are used at the C level, and that we can safely call Julia C API routines from those threads.

Chapter 31

Code Loading

Note

This chapter covers the technical details of package loading. To install packages, use [Pkg](#), Julia's built-in package manager, to add packages to your active environment. To use packages already in your active environment, write `import X` or `using X`, as described in the [Modules documentation](#).

31.1 Definitions

Julia has two mechanisms for loading code:

1. **Code inclusion:** e.g. `include("source.jl")`. Inclusion allows you to split a single program across multiple source files. The expression `include("source.jl")` causes the contents of the file `source.jl` to be evaluated in the global scope of the module where the `include` call occurs. If `include("source.jl")` is called multiple times, `source.jl` is evaluated multiple times. The included path, `source.jl`, is interpreted relative to the file where the `include` call occurs. This makes it simple to relocate a subtree of source files. In the REPL, included paths are interpreted relative to the current working directory, `pwd()`.
2. **Package loading:** e.g. `import X` or `using X`. The import mechanism allows you to load a package—i.e. an independent, reusable collection of Julia code, wrapped in a module—and makes the resulting module available by the name `X` inside of the importing module. If the same `X` package is imported multiple times in the same Julia session, it is only loaded the first time—on subsequent imports, the importing module gets a reference to the same module. Note though, that `import X` can load different packages in different contexts: `X` can refer to one package named `X` in the main project but potentially to different packages also named `X` in each dependency. More on this below.

Code inclusion is quite straightforward and simple: it evaluates the given source file in the context of the caller. Package loading is built on top of code inclusion and serves a [different purpose](#). The rest of this chapter focuses on the behavior and mechanics of package loading.

A package is a source tree with a standard layout providing functionality that can be reused by other Julia projects. A package is loaded by `import X` or `using X` statements. These statements also make the module named `X`—which results from loading the package code—available within the module where the import statement occurs. The meaning of `X` in `import X` is context-dependent: which `X` package is loaded

depends on what code the statement occurs in. Thus, handling of `import X` happens in two stages: first, it determines **what** package is defined to be `X` in this context; second, it determines **where** that particular `X` package is found.

These questions are answered by searching through the project environments listed in `LOAD_PATH` for project files (`Project.toml` or `JuliaProject.toml`), manifest files (`Manifest.toml` or `JuliaManifest.toml`), or folders of source files.

31.2 Federation of packages

Most of the time, a package is uniquely identifiable simply from its name. However, sometimes a project might encounter a situation where it needs to use two different packages that share the same name. While you might be able to fix this by renaming one of the packages, being forced to do so can be highly disruptive in a large, shared code base. Instead, Julia's code loading mechanism allows the same package name to refer to different packages in different components of an application.

Julia supports federated package management, which means that multiple independent parties can maintain both public and private packages and registries of packages, and that projects can depend on a mix of public and private packages from different registries. Packages from various registries are installed and managed using a common set of tools and workflows. The Pkg package manager that ships with Julia lets you install and manage your projects' dependencies. It assists in creating and manipulating project files (which describe what other projects that your project depends on), and manifest files (which snapshot exact versions of your project's complete dependency graph).

One consequence of federation is that there cannot be a central authority for package naming. Different entities may use the same name to refer to unrelated packages. This possibility is unavoidable since these entities do not coordinate and may not even know about each other. Because of the lack of a central naming authority, a single project may end up depending on different packages that have the same name. Julia's package loading mechanism does not require package names to be globally unique, even within the dependency graph of a single project. Instead, packages are identified by **universally unique identifiers** (UUIDs), which get assigned when each package is created. Usually you won't have to work directly with these somewhat cumbersome 128-bit identifiers since Pkg will take care of generating and tracking them for you. However, these UUIDs provide the definitive answer to the question of "what package does `X` refer to?"

Since the decentralized naming problem is somewhat abstract, it may help to walk through a concrete scenario to understand the issue. Suppose you're developing an application called `App`, which uses two packages: `Pub` and `Priv`. `Priv` is a private package that you created, whereas `Pub` is a public package that you use but don't control. When you created `Priv`, there was no public package by the name `Priv`. Subsequently, however, an unrelated package also named `Priv` has been published and become popular. In fact, the `Pub` package has started to use it. Therefore, when you next upgrade `Pub` to get the latest bug fixes and features, `App` will end up depending on two different packages named `Priv`—through no action of yours other than upgrading. `App` has a direct dependency on your private `Priv` package, and an indirect dependency, through `Pub`, on the new public `Priv` package. Since these two `Priv` packages are different but are both required for `App` to continue working correctly, the expression `import Priv` must refer to different `Priv` packages depending on whether it occurs in `App`'s code or in `Pub`'s code. To handle this, Julia's package loading mechanism distinguishes the two `Priv` packages by their UUID and picks the correct one based on its context (the module that called `import`). How this distinction works is determined by environments, as explained in the following sections.

31.3 Environments

An environment determines what `import X` and `using X` mean in various code contexts and what files these statements cause to be loaded. Julia understands two kinds of environments:

1. **A project environment** is a directory with a project file and an optional manifest file, and forms an explicit environment. The project file determines what the names and identities of the direct dependencies of a project are. The manifest file, if present, gives a complete dependency graph, including all direct and indirect dependencies, exact versions of each dependency, and sufficient information to locate and load the correct version.
2. **A package directory** is a directory containing the source trees of a set of packages as subdirectories, and forms an implicit environment. If `X` is a subdirectory of a package directory and `X/src/X.jl` exists, then the package `X` is available in the package directory environment and `X/src/X.jl` is the source file by which it is loaded.

These can be intermixed to create **a stacked environment**: an ordered set of project environments and package directories, overlaid to make a single composite environment. The precedence and visibility rules then combine to determine which packages are available and where they get loaded from. Julia's load path forms a stacked environment, for example.

These environment each serve a different purpose:

- Project environments provide **reproducibility**. By checking a project environment into version control—e.g. a git repository—along with the rest of the project's source code, you can reproduce the exact state of the project and all of its dependencies. The manifest file, in particular, captures the exact version of every dependency, identified by a cryptographic hash of its source tree, which makes it possible for Pkg to retrieve the correct versions and be sure that you are running the exact code that was recorded for all dependencies.
- Package directories provide **convenience** when a full carefully-tracked project environment is unnecessary. They are useful when you want to put a set of packages somewhere and be able to directly use them, without needing to create a project environment for them.
- Stacked environments allow for **adding** tools to the primary environment. You can push an environment of development tools onto the end of the stack to make them available from the REPL and scripts, but not from inside packages.

At a high-level, each environment conceptually defines three maps: `roots`, `graph` and `paths`. When resolving the meaning of `import X`, the `roots` and `graph` maps are used to determine the identity of `X`, while the `paths` map is used to locate the source code of `X`. The specific roles of the three maps are:

- **roots**: `name::Symbol → uuid::UUID`

An environment's `roots` map assigns package names to UUIDs for all the top-level dependencies that the environment makes available to the main project (i.e. the ones that can be loaded in `Main`). When Julia encounters `import X` in the main project, it looks up the identity of `X` as `roots[:X]`.

- **graph:** `context::UUID → name::Symbol → uuid::UUID`

An environment's graph is a multilevel map which assigns, for each context UUID, a map from names to UUIDs, similar to the roots map but specific to that context. When Julia sees `import X` in the code of the package whose UUID is context, it looks up the identity of X as `graph[context][:X]`. In particular, this means that `import X` can refer to different packages depending on context.

- **paths:** `uuid::UUID × name::Symbol → path::String`

The paths map assigns to each package UUID-name pair, the location of that package's entry-point source file. After the identity of X in `import X` has been resolved to a UUID via roots or graph (depending on whether it is loaded from the main project or a dependency), Julia determines what file to load to acquire X by looking up `paths[uuid, :X]` in the environment. Including this file should define a module named X. Once this package is loaded, any subsequent import resolving to the same uuid will create a new binding to the already-loaded package module.

Each kind of environment defines these three maps differently, as detailed in the following sections.

Note

For ease of understanding, the examples throughout this chapter show full data structures for roots, graph and paths. However, Julia's package loading code does not explicitly create these. Instead, it lazily computes only as much of each structure as it needs to load a given package.

Project environments

A project environment is determined by a directory containing a project file called `Project.toml`, and optionally a manifest file called `Manifest.toml`. These files may also be called `JuliaProject.toml` and `JuliaManifest.toml`, in which case `Project.toml` and `Manifest.toml` are ignored. This allows for coexistence with other tools that might consider files called `Project.toml` and `Manifest.toml` significant. For pure Julia projects, however, the names `Project.toml` and `Manifest.toml` are preferred.

The roots, graph and paths maps of a project environment are defined as follows:

The roots map of the environment is determined by the contents of the project file, specifically, its top-level name and uuid entries and its `[deps]` section (all optional). Consider the following example project file for the hypothetical application, App, as described earlier:

```
name = "App"
uuid = "8f986787-14fe-4607-ba5d-fbffa2944afa9"

[deps]
Priv = "ba13f791-ae1d-465a-978b-69c3ad90f72b"
Pub  = "c07ecb7d-0dc9-4db7-8803-fadaaeaf08e1"
```

This project file implies the following roots map, if it was represented by a Julia dictionary:

```
roots = Dict{
  :App => UUID("8f986787-14fe-4607-ba5d-fbffa2944afa9"),
  :Priv => UUID("ba13f791-ae1d-465a-978b-69c3ad90f72b"),
  :Pub  => UUID("c07ecb7d-0dc9-4db7-8803-fadaaeaf08e1"),
}
```

Given this roots map, in App's code the statement `import Priv` will cause Julia to look up `roots[:Priv]`, which yields `ba13f791-ae1d-465a-978b-69c3ad90f72b`, the UUID of the `Priv` package that is to be loaded in that context. This UUID identifies which `Priv` package to load and use when the main application evaluates `import Priv`.

The dependency graph of a project environment is determined by the contents of the manifest file, if present. If there is no manifest file, graph is empty. A manifest file contains a stanza for each of a project's direct or indirect dependencies. For each dependency, the file lists the package's UUID and a source tree hash or an explicit path to the source code. Consider the following example manifest file for App:

```
[[Priv]] # the private one
deps = ["Pub", "Zebra"]
uuid = "ba13f791-ae1d-465a-978b-69c3ad90f72b"
path = "deps/Priv"

[[Priv]] # the public one
uuid = "2d15fe94-a1f7-436c-a4d8-07a9a496e01c"
git-tree-sha1 = "1bf63d3be994fe83456a03b874b409cfd59a6373"
version = "0.1.5"

[[Pub]]
uuid = "c07ecb7d-0dc9-4db7-8803-fadaaeaf08e1"
git-tree-sha1 = "9ebd50e2b0dd1e110e842df3b433cb5869b0dd38"
version = "2.1.4"

[Pub.deps]
Priv = "2d15fe94-a1f7-436c-a4d8-07a9a496e01c"
Zebra = "f7a24cb4-21fc-4002-ac70-f0e3a0dd3f62"

[[Zebra]]
uuid = "f7a24cb4-21fc-4002-ac70-f0e3a0dd3f62"

version = "3.4.2"
```

This manifest file describes a possible complete dependency graph for the App project:

- There are two different packages named `Priv` that the application uses. It uses a private package, which is a root dependency, and a public one, which is an indirect dependency through `Pub`. These are differentiated by their distinct UUIDs, and they have different deps:
 - The private `Priv` depends on the `Pub` and `Zebra` packages.
 - The public `Priv` has no dependencies.
- The application also depends on the `Pub` package, which in turn depends on the public `Priv` and the same `Zebra` package that the private `Priv` package depends on.

This dependency graph represented as a dictionary, looks like this:

```
graph = Dict{
  # Priv – the private one:
  UUID("ba13f791-ae1d-465a-978b-69c3ad90f72b") => Dict{
```

```

        :Pub    => UUID("c07ecb7d-0dc9-4db7-8803-fadaaeaf08e1"),
        :Zebra => UUID("f7a24cb4-21fc-4002-ac70-f0e3a0dd3f62"),
    ),
    # Priv – the public one:
    UUID("2d15fe94-a1f7-436c-a4d8-07a9a496e01c") => Dict(),
    # Pub:
    UUID("c07ecb7d-0dc9-4db7-8803-fadaaeaf08e1") => Dict(
        :Priv => UUID("2d15fe94-a1f7-436c-a4d8-07a9a496e01c"),
        :Zebra => UUID("f7a24cb4-21fc-4002-ac70-f0e3a0dd3f62"),
    ),
    # Zebra:
    UUID("f7a24cb4-21fc-4002-ac70-f0e3a0dd3f62") => Dict(),
)

```

Given this dependency graph, when Julia sees `import Priv` in the Pub package—which has UUID `c07ecb7d-0dc9-4db7-8803-fadaaeaf08e1`—it looks up:

```
graph[UUID("c07ecb7d-0dc9-4db7-8803-fadaaeaf08e1")][:Priv]
```

and gets `2d15fe94-a1f7-436c-a4d8-07a9a496e01c`, which indicates that in the context of the Pub package, `import Priv` refers to the public Priv package, rather than the private one which the app depends on directly. This is how the name `Priv` can refer to different packages in the main project than it does in one of its package's dependencies, which allows for duplicate names in the package ecosystem.

What happens if `import Zebra` is evaluated in the main App code base? Since Zebra does not appear in the project file, the import will fail even though Zebra does appear in the manifest file. Moreover, if `import Zebra` occurs in the public Priv package—the one with UUID `2d15fe94-a1f7-436c-a4d8-07a9a496e01c`—then that would also fail since that Priv package has no declared dependencies in the manifest file and therefore cannot load any packages. The Zebra package can only be loaded by packages for which it appears as an explicit dependency in the manifest file: the Pub package and one of the Priv packages.

The paths map of a project environment is extracted from the manifest file. The path of a package uuid named `X` is determined by these rules (in order):

1. If the project file in the directory matches uuid and name `X`, then either:
 - It has a toplevel path entry, then uuid will be mapped to that path, interpreted relative to the directory containing the project file.
 - Otherwise, uuid is mapped to `src/X.jl` relative to the directory containing the project file.
2. If the above is not the case and the project file has a corresponding manifest file and the manifest contains a stanza matching uuid then:
 - If it has a path entry, use that path (relative to the directory containing the manifest file).
 - If it has a `git-tree-sha1` entry, compute a deterministic hash function of uuid and `git-tree-sha1`—call it `slug`—and look for a directory named `packages/X/$slug` in each directory in the Julia `DEPOT_PATH` global array. Use the first such directory that exists.

If any of these result in success, the path to the source code entry point will be either that result, the relative path from that result plus `src/X.jl`; otherwise, there is no path mapping for `uuid`. When loading `X`, if no source code path is found, the lookup will fail, and the user may be prompted to install the appropriate package version or to take other corrective action (e.g. declaring `X` as a dependency).

In the example manifest file above, to find the path of the first `Priv` package—the one with UUID `ba13f791-ae1d-465a-978b-69c3ad90f72b`—Julia looks for its stanza in the manifest file, sees that it has a `path` entry, looks at `deps/Priv` relative to the `App` project directory—let's suppose the `App` code lives in `/home/me/projects/App`—sees that `/home/me/projects/App/deps/Priv` exists and therefore loads `Priv` from there.

If, on the other hand, Julia was loading the other `Priv` package—the one with UUID `2d15fe94-a1f7-436c-a4d8-07a9a496e01c`—it finds its stanza in the manifest, see that it does not have a `path` entry, but that it does have a `git-tree-sha1` entry. It then computes the `slug` for this UUID/SHA-1 pair, which is `HDkrT` (the exact details of this computation aren't important, but it is consistent and deterministic). This means that the path to this `Priv` package will be `packages/Priv/HDkrT/src/Priv.jl` in one of the package depots. Suppose the contents of `DEPOT_PATH` is `[/home/me/.julia, "/usr/local/julia"]`, then Julia will look at the following paths to see if they exist:

1. `/home/me/.julia/packages/Priv/HDkrT`
2. `/usr/local/julia/packages/Priv/HDkrT`

Julia uses the first of these that exists to try to load the public `Priv` package from the file `packages/Priv/HDkrT/src/Priv.jl` in the depot where it was found.

Here is a representation of a possible paths map for our example `App` project environment, as provided in the Manifest given above for the dependency graph, after searching the local file system:

```
paths = Dict{
  # Priv – the private one:
  (UUID("ba13f791-ae1d-465a-978b-69c3ad90f72b"), :Priv) =>
    # relative entry-point inside `App` repo:
    "/home/me/projects/App/deps/Priv/src/Priv.jl",
  # Priv – the public one:
  (UUID("2d15fe94-a1f7-436c-a4d8-07a9a496e01c"), :Priv) =>
    # package installed in the system depot:
    "/usr/local/julia/packages/Priv/HDkr/src/Priv.jl",
  # Pub:
  (UUID("c07ecb7d-0dc9-4db7-8803-fadaaeaf08e1"), :Pub) =>
    # package installed in the user depot:
    "/home/me/.julia/packages/Pub/oKpw/src/Pub.jl",
  # Zebra:
  (UUID("f7a24cb4-21fc-4002-ac70-f0e3a0dd3f62"), :Zebra) =>
    # package installed in the system depot:
    "/usr/local/julia/packages/Zebra/me9k/src/Zebra.jl",
}
```

This example map includes three different kinds of package locations (the first and third are part of the default load path):

1. The private `Priv` package is "`vendored`" inside the `App` repository.

2. The public `Priv` and `Zebra` packages are in the system depot, where packages installed and managed by the system administrator live. These are available to all users on the system.
3. The `Pub` package is in the user depot, where packages installed by the user live. These are only available to the user who installed them.

Package directories

Package directories provide a simpler kind of environment without the ability to handle name collisions. In a package directory, the set of top-level packages is the set of subdirectories that "look like" packages. A package `X` exists in a package directory if the directory contains one of the following "entry point" files:

- `X.jl`
- `X/src/X.jl`
- `X.jl/src/X.jl`

Which dependencies a package in a package directory can import depends on whether the package contains a project file:

- If it has a project file, it can only import those packages which are identified in the `[deps]` section of the project file.
- If it does not have a project file, it can import any top-level package—i.e. the same packages that can be loaded in `Main` or the `REPL`.

The roots map is determined by examining the contents of the package directory to generate a list of all packages that exist. Additionally, a UUID will be assigned to each entry as follows: For a given package found inside the folder `X...`

1. If `X/Project.toml` exists and has a `uuid` entry, then `uuid` is that value.
2. If `X/Project.toml` exists and but does not have a top-level UUID entry, `uuid` is a dummy UUID generated by hashing the canonical (real) path to `X/Project.toml`.
3. Otherwise (if `Project.toml` does not exist), then `uuid` is the all-zero `nil` UUID.

The dependency graph of a project directory is determined by the presence and contents of project files in the subdirectory of each package. The rules are:

- If a package subdirectory has no project file, then it is omitted from graph and import statements in its code are treated as top-level, the same as the main project and `REPL`.
- If a package subdirectory has a project file, then the graph entry for its UUID is the `[deps]` map of the project file, which is considered to be empty if the section is absent.

As an example, suppose a package directory has the following structure and content:

```

Aardvark/
  src/Aardvark.jl:
    import Bobcat
    import Cobra

Bobcat/
  Project.toml:
    [deps]
    Cobra = "4725e24d-f727-424b-bca0-c4307a3456fa"
    Dingo = "7a7925be-828c-4418-bbeb-bac8dfc843bc"

  src/Bobcat.jl:
    import Cobra
    import Dingo

Cobra/
  Project.toml:
    uuid = "4725e24d-f727-424b-bca0-c4307a3456fa"
    [deps]
    Dingo = "7a7925be-828c-4418-bbeb-bac8dfc843bc"

  src/Cobra.jl:
    import Dingo

Dingo/
  Project.toml:
    uuid = "7a7925be-828c-4418-bbeb-bac8dfc843bc"

  src/Dingo.jl:
    # no imports

```

Here is a corresponding roots structure, represented as a dictionary:

```

roots = Dict(
  :Aardvark => UUID("00000000-0000-0000-0000-000000000000"), # no project file, nil UUID
  :Bobcat   => UUID("85ad11c7-31f6-5d08-84db-0a4914d4cadf"), # dummy UUID based on path
  :Cobra    => UUID("4725e24d-f727-424b-bca0-c4307a3456fa"), # UUID from project file
  :Dingo    => UUID("7a7925be-828c-4418-bbeb-bac8dfc843bc"), # UUID from project file
)

```

Here is the corresponding graph structure, represented as a dictionary:

```

graph = Dict(
  # Bobcat:
  UUID("85ad11c7-31f6-5d08-84db-0a4914d4cadf") => Dict(
    :Cobra => UUID("4725e24d-f727-424b-bca0-c4307a3456fa"),
    :Dingo => UUID("7a7925be-828c-4418-bbeb-bac8dfc843bc"),
  ),
  # Cobra:
  UUID("4725e24d-f727-424b-bca0-c4307a3456fa") => Dict(
    :Dingo => UUID("7a7925be-828c-4418-bbeb-bac8dfc843bc"),
  ),
)

```

```
| # Dingo:
|   UUID("7a7925be-828c-4418-bbeb-bac8dfc843bc") => Dict(),
| )
```

A few general rules to note:

1. A package without a project file can depend on any top-level dependency, and since every package in a package directory is available at the top-level, it can import all packages in the environment.
2. A package with a project file cannot depend on one without a project file since packages with project files can only load packages in graph and packages without project files do not appear in graph.
3. A package with a project file but no explicit UUID can only be depended on by packages without project files since dummy UUIDs assigned to these packages are strictly internal.

Observe the following specific instances of these rules in our example:

- Aardvark can import on any of Bobcat, Cobra or Dingo; it does import Bobcat and Cobra.
- Bobcat can and does import both Cobra and Dingo, which both have project files with UUIDs and are declared as dependencies in Bobcat's [deps] section.
- Bobcat cannot depend on Aardvark since Aardvark does not have a project file.
- Cobra can and does import Dingo, which has a project file and UUID, and is declared as a dependency in Cobra's [deps] section.
- Cobra cannot depend on Aardvark or Bobcat since neither have real UUIDs.
- Dingo cannot import anything because it has a project file without a [deps] section.

The paths map in a package directory is simple: it maps subdirectory names to their corresponding entry-point paths. In other words, if the path to our example project directory is `/home/me/animals` then the paths map could be represented by this dictionary:

```
| paths = Dict(
|   (UUID("00000000-0000-0000-0000-000000000000"), :Aardvark) =>
|     "/home/me/AnimalPackages/Aardvark/src/Aardvark.jl",
|   (UUID("85ad11c7-31f6-5d08-84db-0a4914d4cadf"), :Bobcat) =>
|     "/home/me/AnimalPackages/Bobcat/src/Bobcat.jl",
|   (UUID("4725e24d-f727-424b-bca0-c4307a3456fa"), :Cobra) =>
|     "/home/me/AnimalPackages/Cobra/src/Cobra.jl",
|   (UUID("7a7925be-828c-4418-bbeb-bac8dfc843bc"), :Dingo) =>
|     "/home/me/AnimalPackages/Dingo/src/Dingo.jl",
| )
```

Since all packages in a package directory environment are, by definition, subdirectories with the expected entry-point files, their paths map entries always have this form.

Environment stacks

The third and final kind of environment is one that combines other environments by overlaying several of them, making the packages in each available in a single composite environment. These composite environments are called environment stacks. The Julia `LOAD_PATH` global defines an environment stack—the environment in which the Julia process operates. If you want your Julia process to have access only to the packages in one project or package directory, make it the only entry in `LOAD_PATH`. It is often quite useful, however, to have access to some of your favorite tools—standard libraries, profilers, debuggers, personal utilities, etc.—even if they are not dependencies of the project you're working on. By adding an environment containing these tools to the load path, you immediately have access to them in top-level code without needing to add them to your project.

The mechanism for combining the roots, graph and paths data structures of the components of an environment stack is simple: they are merged as dictionaries, favoring earlier entries over later ones in the case of key collisions. In other words, if we have `stack = [env1, env2, ...]` then we have:

```
roots = reduce(merge, reverse([roots1, roots2, ...]))
graph = reduce(merge, reverse([graph1, graph2, ...]))
paths = reduce(merge, reverse([paths1, paths2, ...]))
```

The subscripted `rootsi`, `graphi` and `pathsi` variables correspond to the subscripted environments, `envi`, contained in `stack`. The `reverse` is present because `merge` favors the last argument rather than first when there are collisions between keys in its argument dictionaries. There are a couple of noteworthy features of this design:

1. The primary environment—i.e. the first environment in a stack—is faithfully embedded in a stacked environment. The full dependency graph of the first environment in a stack is guaranteed to be included intact in the stacked environment including the same versions of all dependencies.
2. Packages in non-primary environments can end up using incompatible versions of their dependencies even if their own environments are entirely compatible. This can happen when one of their dependencies is shadowed by a version in an earlier environment in the stack (either by graph or path, or both).

Since the primary environment is typically the environment of a project you're working on, while environments later in the stack contain additional tools, this is the right trade-off: it's better to break your development tools but keep the project working. When such incompatibilities occur, you'll typically want to upgrade your dev tools to versions that are compatible with the main project.

Package Extensions

A package "extension" is a module that is automatically loaded when a specified set of other packages (its "extension dependencies") are loaded in the current Julia session. Extensions are defined under the `[extensions]` section in the project file. The extension dependencies of an extension are a subset of those packages listed under the `[weakdeps]` section of the project file. Those packages can have `compat` entries like other packages.

```
name = "MyPackage"

[compat]
```

```

ExtDep = "1.0"
OtherExtDep = "1.0"

[weakdeps]
ExtDep = "c9a23..." # uuid
OtherExtDep = "862e..." # uuid

[extensions]
BarExt = ["ExtDep", "OtherExtDep"]
FooExt = "ExtDep"
...

```

The keys under `extensions` are the names of the extensions. They are loaded when all the packages on the right hand side (the extension dependencies) of that extension are loaded. If an extension only has one extension dependency the list of extension dependencies can be written as just a string for brevity. The location for the entry point of the extension is either in `ext/FooExt.jl` or `ext/FooExt/FooExt.jl` for extension `FooExt`. The content of an extension is often structured as:

```

module FooExt

# Load main package and extension dependencies
using MyPackage, ExtDep

# Extend functionality in main package with types from the extension dependencies
MyPackage.func(x::ExtDep.SomeStruct) = ...

end

```

When a package with extensions is added to an environment, the `weakdeps` and `extensions` sections are stored in the manifest file in the section for that package. The dependency lookup rules for a package are the same as for its "parent" except that the listed extension dependencies are also considered as dependencies.

Package/Environment Preferences

Preferences are dictionaries of metadata that influence package behavior within an environment. The preferences system supports reading preferences at compile-time, which means that at code-loading time, we must ensure that the precompilation files selected by Julia were built with the same preferences as the current environment before loading them. The public API for modifying Preferences is contained within the [Preferences.jl](#) package. Preferences are stored as TOML dictionaries within a `(Julia)LocalPreferences.toml` file next to the currently-active project. If a preference is "exported", it is instead stored within the `(Julia)Project.toml` instead. The intention is to allow shared projects to contain shared preferences, while allowing for users themselves to override those preferences with their own settings in the `LocalPreferences.toml` file, which should be `.gitignored` as the name implies.

Preferences that are accessed during compilation are automatically marked as compile-time preferences, and any change recorded to these preferences will cause the Julia compiler to recompile any cached precompilation file(s) (`.ji` and corresponding `.so`, `.dll`, or `.dylib` files) for that module. This is done by serializing the hash of all compile-time preferences during compilation, then checking that hash against the current environment when searching for the proper file(s) to load.

Preferences can be set with depot-wide defaults; if package `Foo` is installed within your global environment and it has preferences set, these preferences will apply as long as your global environment is part of

your `LOAD_PATH`. Preferences in environments higher up in the environment stack get overridden by the more proximal entries in the load path, ending with the currently active project. This allows depot-wide preference defaults to exist, with active projects able to merge or even completely overwrite these inherited preferences. See the docstring for `Preferences.set_preferences!()` for the full details of how to set preferences to allow or disallow merging.

31.4 Conclusion

Federated package management and precise software reproducibility are difficult but worthy goals in a package system. In combination, these goals lead to a more complex package loading mechanism than most dynamic languages have, but it also yields scalability and reproducibility that is more commonly associated with static languages. Typically, Julia users should be able to use the built-in package manager to manage their projects without needing a precise understanding of these interactions. A call to `Pkg.add("X")` will add to the appropriate project and manifest files, selected via `Pkg.activate("Y")`, so that a future call to `import X` will load X without further thought.

Chapter 32

Profiling

The Profile module provides tools to help developers improve the performance of their code. When used, it takes measurements on running code, and produces output that helps you understand how much time is spent on individual line(s). The most common usage is to identify "bottlenecks" as targets for optimization.

Profile implements what is known as a "sampling" or [statistical profiler](#). It works by periodically taking a backtrace during the execution of any task. Each backtrace captures the currently-running function and line number, plus the complete chain of function calls that led to this line, and hence is a "snapshot" of the current state of execution.

If much of your run time is spent executing a particular line of code, this line will show up frequently in the set of all backtraces. In other words, the "cost" of a given line—or really, the cost of the sequence of function calls up to and including this line—is proportional to how often it appears in the set of all backtraces.

A sampling profiler does not provide complete line-by-line coverage, because the backtraces occur at intervals (by default, 1 ms on Unix systems and 10 ms on Windows, although the actual scheduling is subject to operating system load). Moreover, as discussed further below, because samples are collected at a sparse subset of all execution points, the data collected by a sampling profiler is subject to statistical noise.

Despite these limitations, sampling profilers have substantial strengths:

- You do not have to make any modifications to your code to take timing measurements.
- It can profile into Julia's core code and even (optionally) into C and Fortran libraries.
- By running "infrequently" there is very little performance overhead; while profiling, your code can run at nearly native speed.

For these reasons, it's recommended that you try using the built-in sampling profiler before considering any alternatives.

32.1 Basic usage

Let's work with a simple test case:

```
julia> function myfunc()
    A = rand(200, 200, 400)
```

```

        maximum(A)
    end

```

It's a good idea to first run the code you intend to profile at least once (unless you want to profile Julia's JIT-compiler):

```
julia> myfunc() # run once to force compilation
```

Now we're ready to profile this function:

```
julia> using Profile

julia> @profile myfunc()
```

To see the profiling results, there are several graphical browsers. One "family" of visualizers is based on [FlameGraphs.jl](#), with each family member providing a different user interface:

- [VS Code](#) is a full IDE with built-in support for profile visualization
- [ProfileView.jl](#) is a stand-alone visualizer based on GTK
- [ProfileVega.jl](#) uses VegaLight and integrates well with Jupyter notebooks
- [StatProfilerHTML.jl](#) produces HTML and presents some additional summaries, and also integrates well with Jupyter notebooks
- [ProfileSVG.jl](#) renders SVG
- [PProf.jl](#) serves a local website for inspecting graphs, flamegraphs and more
- [ProfileCanvas.jl](#) is a HTML canvas based profile viewer UI, used by the [Julia VS Code extension](#), but can also generate interactive HTML files.

An entirely independent approach to profile visualization is [PProf.jl](#), which uses the external pprof tool.

Here, though, we'll use the text-based display that comes with the standard library:

```
julia> Profile.print()
80 ./event.jl:73; (::Base.REPL.##1#2{Base.REPL.REPLBackend})()
80 ./REPL.jl:97; macro expansion
80 ./REPL.jl:66; eval_user_input(::Any, ::Base.REPL.REPLBackend)
80 ./boot.jl:235; eval(::Module, ::Any)
80 ./<missing>:?: anonymous
80 ./profile.jl:23; macro expansion
52 ./REPL[1]:2; myfunc()
38 ./random.jl:431; rand! (::MersenneTwister, ::Array{Float64,3}, ::Int64, ::Type{B...
38 ./dSFMT.jl:84; dsfmt_fill_array_close_open! (::Base.dSFMT.DSFMT_state, ::Ptr{F...
14 ./random.jl:278; rand
14 ./random.jl:277; rand
14 ./random.jl:366; rand
14 ./random.jl:369; rand
```

```

28 ./REPL[1]:3; myfunc()
28 ./reduce.jl:270; _mapreduce(::Base.#identity, ::Base.#scalarmax, ::IndexLinear,...
3  ./reduce.jl:426; mapreduce_impl(::Base.#identity, ::Base.#scalarmax, ::Array{F...
25 ./reduce.jl:428; mapreduce_impl(::Base.#identity, ::Base.#scalarmax, ::Array{F...

```

Each line of this display represents a particular spot (line number) in the code. Indentation is used to indicate the nested sequence of function calls, with more-indented lines being deeper in the sequence of calls. In each line, the first "field" is the number of backtraces (samples) taken at this line or in any functions executed by this line. The second field is the file name and line number and the third field is the function name. Note that the specific line numbers may change as Julia's code changes; if you want to follow along, it's best to run this example yourself.

In this example, we can see that the top level function called is in the file `event.jl`. This is the function that runs the REPL when you launch Julia. If you examine line 97 of `REPL.jl`, you'll see this is where the function `eval_user_input()` is called. This is the function that evaluates what you type at the REPL, and since we're working interactively these functions were invoked when we entered `@profile myfunc()`. The next line reflects actions taken in the `@profile` macro.

The first line shows that 80 backtraces were taken at line 73 of `event.jl`, but it's not that this line was "expensive" on its own: the third line reveals that all 80 of these backtraces were actually triggered inside its call to `eval_user_input`, and so on. To find out which operations are actually taking the time, we need to look deeper in the call chain.

The first "important" line in this output is this one:

```

52 ./REPL[1]:2; myfunc()

```

REPL refers to the fact that we defined `myfunc` in the REPL, rather than putting it in a file; if we had used a file, this would show the file name. The `[1]` shows that the function `myfunc` was the first expression evaluated in this REPL session. Line 2 of `myfunc()` contains the call to `rand`, and there were 52 (out of 80) backtraces that occurred at this line. Below that, you can see a call to `dsfmt_fill_array_close_open!` inside `dsfmt.jl`.

A little further down, you see:

```

28 ./REPL[1]:3; myfunc()

```

Line 3 of `myfunc` contains the call to `maximum`, and there were 28 (out of 80) backtraces taken here. Below that, you can see the specific places in `base/reduce.jl` that carry out the time-consuming operations in the `maximum` function for this type of input data.

Overall, we can tentatively conclude that generating the random numbers is approximately twice as expensive as finding the maximum element. We could increase our confidence in this result by collecting more samples:

```

julia> @profile (for i = 1:100; myfunc(); end)

julia> Profile.print()
[....]
3821 ./REPL[1]:2; myfunc()
3511 ./random.jl:431; rand!(::MersenneTwister, ::Array{Float64,3}, ::Int64, ::Type...
3511 ./dsfmt.jl:84; dsfmt_fill_array_close_open! (::Base.dsfmt.DSfmt_state, ::Ptr...
310  ./random.jl:278; rand

```

```
[...]
2893 ./REPL[1]:3; myfunc()
2893 ./reduce.jl:270; _mapreduce(::Base.#identity, ::Base.#scalarmax, ::IndexLinea...
[...]
```

In general, if you have N samples collected at a line, you can expect an uncertainty on the order of \sqrt{N} (barring other sources of noise, like how busy the computer is with other tasks). The major exception to this rule is garbage collection, which runs infrequently but tends to be quite expensive. (Since Julia's garbage collector is written in C, such events can be detected using the `C=true` output mode described below, or by using [ProfileView.jl](#).)

This illustrates the default "tree" dump; an alternative is the "flat" dump, which accumulates counts independent of their nesting:

```
julia> Profile.print(format=:flat)
Count File          Line Function
6714 ./<missing>      -1 anonymous
6714 ./REPL.jl        66 eval_user_input(::Any, ::Base.REPL.REPLBackend)
6714 ./REPL.jl        97 macro expansion
3821 ./REPL[1]        2 myfunc()
2893 ./REPL[1]        3 myfunc()
6714 ./REPL[7]        1 macro expansion
6714 ./boot.jl        235 eval(::Module, ::Any)
3511 ./dSFMT.jl        84 dsfmt_fill_array_close_open! (::Base.dSFMT.DSFMT_s...
6714 ./event.jl        73 (::Base.REPL.##1#2{Base.REPL.REPLBackend})()
6714 ./profile.jl      23 macro expansion
3511 ./random.jl       431 rand! (::MersenneTwister, ::Array{Float64,3}, ::In...
310 ./random.jl       277 rand
310 ./random.jl       278 rand
310 ./random.jl       366 rand
310 ./random.jl       369 rand
2893 ./reduce.jl       270 _mapreduce (::Base.#identity, ::Base.#scalarmax, ...
5 ./reduce.jl         420 mapreduce_impl (::Base.#identity, ::Base.#scalarma...
253 ./reduce.jl        426 mapreduce_impl (::Base.#identity, ::Base.#scalarma...
2592 ./reduce.jl        428 mapreduce_impl (::Base.#identity, ::Base.#scalarma...
43 ./reduce.jl         429 mapreduce_impl (::Base.#identity, ::Base.#scalarma...
```

If your code has recursion, one potentially-confusing point is that a line in a "child" function can accumulate more counts than there are total backtraces. Consider the following function definitions:

```
dumbsum(n::Integer) = n == 1 ? 1 : 1 + dumbsum(n-1)
dumbsum3() = dumbsum(3)
```

If you were to profile `dumbsum3`, and a backtrace was taken while it was executing `dumbsum(1)`, the backtrace would look like this:

```
dumbsum3
  dumbsum(3)
    dumbsum(2)
      dumbsum(1)
```

Consequently, this child function gets 3 counts, even though the parent only gets one. The "tree" representation makes this much clearer, and for this reason (among others) is probably the most useful way to view the results.

32.2 Accumulation and clearing

Results from `@profile` accumulate in a buffer; if you run multiple pieces of code under `@profile`, then `Profile.print()` will show you the combined results. This can be very useful, but sometimes you want to start fresh; you can do so with `Profile.clear()`.

32.3 Options for controlling the display of profile results

`Profile.print` has more options than we've described so far. Let's see the full declaration:

```
| function print(io::IO = stdout, data = fetch(); kwargs...)
```

Let's first discuss the two positional arguments, and later the keyword arguments:

- `io` – Allows you to save the results to a buffer, e.g. a file, but the default is to print to `stdout` (the console).
- `data` – Contains the data you want to analyze; by default that is obtained from `Profile.fetch()`, which pulls out the backtraces from a pre-allocated buffer. For example, if you want to profile the profiler, you could say:

```
| data = copy(Profile.fetch())
| Profile.clear()
| @profile Profile.print(stdout, data) # Prints the previous results
| Profile.print()                    # Prints results from Profile.print()
```

The keyword arguments can be any combination of:

- `format` – Introduced above, determines whether backtraces are printed with (default, `:tree`) or without (`:flat`) indentation indicating tree structure.
- `C` – If `true`, backtraces from C and Fortran code are shown (normally they are excluded). Try running the introductory example with `Profile.print(C = true)`. This can be extremely helpful in deciding whether it's Julia code or C code that is causing a bottleneck; setting `C = true` also improves the interpretability of the nesting, at the cost of longer profile dumps.
- `combine` – Some lines of code contain multiple operations; for example, `s += A[i]` contains both an array reference (`A[i]`) and a sum operation. These correspond to different lines in the generated machine code, and hence there may be two or more different addresses captured during backtraces on this line. `combine = true` lumps them together, and is probably what you typically want, but you can generate an output separately for each unique instruction pointer with `combine = false`.
- `maxdepth` – Limits frames at a depth higher than `maxdepth` in the `:tree` format.
- `sortedby` – Controls the order in `:flat` format. `:filefuncline` (default) sorts by the source line, whereas `:count` sorts in order of number of collected samples.

- `noisefloor` – Limits frames that are below the heuristic noise floor of the sample (only applies to format `:tree`). A suggested value to try for this is 2.0 (the default is 0). This parameter hides samples for which $n \leq \text{noisefloor} * \sqrt{N}$, where n is the number of samples on this line, and N is the number of samples for the callee.
- `mincount` – Limits frames with less than `mincount` occurrences.

File/function names are sometimes truncated (with `...`), and indentation is truncated with a `+n` at the beginning, where n is the number of extra spaces that would have been inserted, had there been room. If you want a complete profile of deeply-nested code, often a good idea is to save to a file using a wide `displaysize` in an `IOContext`:

```
open("/tmp/prof.txt", "w") do s
    Profile.print(IOContext(s, :displaysize => (24, 500)))
end
```

32.4 Configuration

`@profile` just accumulates backtraces, and the analysis happens when you call `Profile.print()`. For a long-running computation, it's entirely possible that the pre-allocated buffer for storing backtraces will be filled. If that happens, the backtraces stop but your computation continues. As a consequence, you may miss some important profiling data (you will get a warning when that happens).

You can obtain and configure the relevant parameters this way:

```
Profile.init() # returns the current settings
Profile.init(n = 10^7, delay = 0.01)
```

n is the total number of instruction pointers you can store, with a default value of 10^6 . If your typical backtrace is 20 instruction pointers, then you can collect 50000 backtraces, which suggests a statistical uncertainty of less than 1%. This may be good enough for most applications.

Consequently, you are more likely to need to modify `delay`, expressed in seconds, which sets the amount of time that Julia gets between snapshots to perform the requested computations. A very long-running job might not need frequent backtraces. The default setting is `delay = 0.001`. Of course, you can decrease the delay as well as increase it; however, the overhead of profiling grows once the delay becomes similar to the amount of time needed to take a backtrace (~30 microseconds on the author's laptop).

32.5 Memory allocation analysis

One of the most common techniques to improve performance is to reduce memory allocation. Julia provides several tools measure this:

`@time`

The total amount of allocation can be measured with `@time`, `@allocated` and `@allocations`, and specific lines triggering allocation can often be inferred from profiling via the cost of garbage collection that these lines incur. However, sometimes it is more efficient to directly measure the amount of memory allocated by each line of code.

GC Logging

While `@time` logs high-level stats about memory usage and garbage collection over the course of evaluating an expression, it can be useful to log each garbage collection event, to get an intuitive sense of how often the garbage collector is running, how long it's running each time, and how much garbage it collects each time. This can be enabled with `GC.enable_logging(true)`, which causes Julia to log to stderr every time a garbage collection happens.

Allocation Profiler

Julia 1.8

This functionality requires at least Julia 1.8.

The allocation profiler records the stack trace, type, and size of each allocation while it is running. It can be invoked with `Profile.Allocs.@profile`.

This information about the allocations is returned as an array of `Alloc` objects, wrapped in an `AllocResults` object. The best way to visualize these is currently with the `PProf.jl` and `ProfileCanvas.jl` packages, which can visualize the call stacks which are making the most allocations.

The allocation profiler does have significant overhead, so a `sample_rate` argument can be passed to speed it up by making it skip some allocations. Passing `sample_rate=1.0` will make it record everything (which is slow); `sample_rate=0.1` will record only 10% of the allocations (faster), etc.

Note

The current implementation of the Allocations Profiler does not capture types for all allocations. Allocations for which the profiler could not capture the type are represented as having type `Profile.Allocs.UnknownType`.

You can read more about the missing types and the plan to improve this, here: [issue #43688](#).

Line-by-Line Allocation Tracking

An alternative way to measure allocations is to start Julia with the `--track-allocation=<setting>` command-line option, for which you can choose `none` (the default, do not measure allocation), `user` (measure memory allocation everywhere except Julia's core code), or `all` (measure memory allocation at each line of Julia code). Allocation gets measured for each line of compiled code. When you quit Julia, the cumulative results are written to text files with `.mem` appended after the file name, residing in the same directory as the source file. Each line lists the total number of bytes allocated. The [Coverage package](#) contains some elementary analysis tools, for example to sort the lines in order of number of bytes allocated.

In interpreting the results, there are a few important details. Under the `user` setting, the first line of any function directly called from the REPL will exhibit allocation due to events that happen in the REPL code itself. More significantly, JIT-compilation also adds to allocation counts, because much of Julia's compiler is written in Julia (and compilation usually requires memory allocation). The recommended procedure is to force compilation by executing all the commands you want to analyze, then call `Profile.clear_malloc_data()` to reset all allocation counters. Finally, execute the desired commands and quit Julia to trigger the generation of the `.mem` files.

Note

--track-allocation changes code generation to log the allocations, and so the allocations may be different than what happens without the option. We recommend using the [allocation profiler](#) instead.

32.6 External Profiling

Currently Julia supports Intel VTune, OProfile and perf as external profiling tools.

Depending on the tool you choose, compile with `USE_INTEL_JITEVENTS`, `USE_OPROFILE_JITEVENTS` and `USE_PERF_JITEVENTS` set to 1 in `Make.user`. Multiple flags are supported.

Before running Julia set the environment variable `ENABLE_JITPROFILING` to 1.

Now you have a multitude of ways to employ those tools! For example with OProfile you can try a simple recording :

```
|>ENABLE_JITPROFILING=1 sudo operf -Vdebug ./julia test/fastmath.jl  
|>opreport -l `which ./julia`
```

Or similarly with perf :

```
|$ ENABLE_JITPROFILING=1 perf record -o /tmp/perf.data --call-graph dwarf -k 1 ./julia /test/  
|fastmath.jl  
|$ perf inject --jit --input /tmp/perf.data --output /tmp/perf-jit.data  
|$ perf report --call-graph -G -i /tmp/perf-jit.data
```

There are many more interesting things that you can measure about your program, to get a comprehensive list please read the [Linux perf examples page](#).

Remember that perf saves for each execution a `perf.data` file that, even for small programs, can get quite large. Also the perf LLVM module saves temporarily debug objects in `~/.debug/jit`, remember to clean that folder frequently.

Chapter 33

Stack Traces

The `StackTraces` module provides simple stack traces that are both human readable and easy to use programmatically.

33.1 Viewing a stack trace

The primary function used to obtain a stack trace is `stacktrace`:

```
6-element Array{Base.StackTraces.StackFrame,1}:
 top-level scope
 eval at boot.jl:317 [inlined]
 eval(::Module, ::Expr) at REPL.jl:5
 eval_user_input(::Any, ::REPL.REPLBackend) at REPL.jl:85
 macro_expansion at REPL.jl:116 [inlined]
 (::getfield(REPL, Symbol("##28#29")){REPL.REPLBackend})() at event.jl:92
```

Calling `stacktrace()` returns a vector of `StackTraces.StackFrame`s. For ease of use, the alias `StackTraces.StackTrace` can be used in place of `Vector{StackFrame}`. (Examples with `[...]` indicate that output may vary depending on how the code is run.)

```
julia> example() = stacktrace()
example (generic function with 1 method)

julia> example()
7-element Array{Base.StackTraces.StackFrame,1}:
 example() at REPL[1]:1
 top-level scope
 eval at boot.jl:317 [inlined]
 [...]

julia> @noinline child() = stacktrace()
child (generic function with 1 method)

julia> @noinline parent() = child()
parent (generic function with 1 method)
```

```
julia> grandparent() = parent()
grandparent (generic function with 1 method)

julia> grandparent()
9-element Array{Base.StackTraces.StackFrame,1}:
 child() at REPL[3]:1
 parent() at REPL[4]:1
 grandparent() at REPL[5]:1
 [...]
```

Note that when calling `stacktrace()` you'll typically see a frame with `eval` at `boot.jl`. When calling `stacktrace()` from the REPL you'll also have a few extra frames in the stack from `REPL.jl`, usually looking something like this:

```
julia> example() = stacktrace()
example (generic function with 1 method)

julia> example()
7-element Array{Base.StackTraces.StackFrame,1}:
 example() at REPL[1]:1
 top-level scope
 eval at boot.jl:317 [inlined]
 eval(::Module, ::Expr) at REPL.jl:5
 eval_user_input(::Any, ::REPL.REPLBackend) at REPL.jl:85
 macro expansion at REPL.jl:116 [inlined]
 (::getfield(REPL, Symbol("##28#29")){REPL.REPLBackend})() at event.jl:92
```

33.2 Extracting useful information

Each `StackTraces.StackFrame` contains the function name, file name, line number, lambda info, a flag indicating whether the frame has been inlined, a flag indicating whether it is a C function (by default C functions do not appear in the stack trace), and an integer representation of the pointer returned by `backtrace`:

```
julia> frame = stacktrace()[3]
eval(::Module, ::Expr) at REPL.jl:5

julia> frame.func
:eval

julia> frame.file
Symbol("~/julia/usr/share/julia/stdlib/v0.7/REPL/src/REPL.jl")

julia> frame.line
5

julia> frame.linfo
MethodInstance for eval(::Module, ::Expr)

julia> frame.inlined
false
```

```
julia> frame.from_c
false
```

```
julia> frame.pointer
0x00007f92d6293171
```

This makes stack trace information available programmatically for logging, error handling, and more.

33.3 Error handling

While having easy access to information about the current state of the callstack can be helpful in many places, the most obvious application is in error handling and debugging.

```
julia> @noinline bad_function() = undeclared_variable
bad_function (generic function with 1 method)
```

```
julia> @noinline example() = try
    bad_function()
catch
    stacktrace()
end
example (generic function with 1 method)
```

```
julia> example()
7-element Array{Base.StackTraces.StackFrame,1}:
 example() at REPL[2]:4
 top-level scope
 eval at boot.jl:317 [inlined]
 [...]
```

You may notice that in the example above the first stack frame points at line 4, where `stacktrace` is called, rather than line 2, where `bad_function` is called, and `bad_function`'s frame is missing entirely. This is understandable, given that `stacktrace` is called from the context of the `catch`. While in this example it's fairly easy to find the actual source of the error, in complex cases tracking down the source of the error becomes nontrivial.

This can be remedied by passing the result of `catch_backtrace` to `stacktrace`. Instead of returning callstack information for the current context, `catch_backtrace` returns stack information for the context of the most recent exception:

```
julia> @noinline bad_function() = undeclared_variable
bad_function (generic function with 1 method)
```

```
julia> @noinline example() = try
    bad_function()
catch
    stacktrace(catch_backtrace())
end
example (generic function with 1 method)
```

```
julia> example()
8-element Array{Base.StackTraces.StackFrame,1}:
 bad_function() at REPL[1]:1
 example() at REPL[2]:2
 [...]
```

Notice that the stack trace now indicates the appropriate line number and the missing frame.

```
julia> @noinline child() = error("Whoops!")
child (generic function with 1 method)

julia> @noinline parent() = child()
parent (generic function with 1 method)

julia> @noinline function grandparent()
    try
        parent()
    catch err
        println("ERROR: ", err.msg)
        stacktrace(catch_backtrace())
    end
end
grandparent (generic function with 1 method)

julia> grandparent()
ERROR: Whoops!
10-element Array{Base.StackTraces.StackFrame,1}:
 error at error.jl:33 [inlined]
 child() at REPL[1]:1
 parent() at REPL[2]:1
 grandparent() at REPL[3]:3
 [...]
```

33.4 Exception stacks and `current_exceptions`

Julia 1.1

Exception stacks requires at least Julia 1.1.

While handling an exception further exceptions may be thrown. It can be useful to inspect all these exceptions to identify the root cause of a problem. The Julia runtime supports this by pushing each exception onto an internal exception stack as it occurs. When the code exits a `catch` normally, any exceptions which were pushed onto the stack in the associated `try` are considered to be successfully handled and are removed from the stack.

The stack of current exceptions can be accessed using the `current_exceptions` function. For example,

```
julia> try
    error("(A) The root cause")
catch
    try
        error("(B) An exception while handling the exception")
    end
end
```

```

catch
  for (exc, bt) in current_exceptions()
    showerror(stdout, exc, bt)
    println(stdout)
  end
end
end

```

(A) The root cause

Stacktrace:

```

[1] error(::String) at error.jl:33
[2] top-level scope at REPL[7]:2
[3] eval(::Module, ::Any) at boot.jl:319
[4] eval_user_input(::Any, ::REPL.REPLBackend) at REPL.jl:85
[5] macro expansion at REPL.jl:117 [inlined]
[6] (::getfield(REPL, Symbol("##26#27")){REPL.REPLBackend})() at task.jl:259

```

(B) An exception while handling the exception

Stacktrace:

```

[1] error(::String) at error.jl:33
[2] top-level scope at REPL[7]:5
[3] eval(::Module, ::Any) at boot.jl:319
[4] eval_user_input(::Any, ::REPL.REPLBackend) at REPL.jl:85
[5] macro expansion at REPL.jl:117 [inlined]
[6] (::getfield(REPL, Symbol("##26#27")){REPL.REPLBackend})() at task.jl:259

```

In this example the root cause exception (A) is first on the stack, with a further exception (B) following it. After exiting both catch blocks normally (i.e., without throwing a further exception) all exceptions are removed from the stack and are no longer accessible.

The exception stack is stored on the Task where the exceptions occurred. When a task fails with uncaught exceptions, `current_exceptions(task)` may be used to inspect the exception stack for that task.

33.5 Comparison with backtrace

A call to `backtrace` returns a vector of `Union{Ptr{Nothing}, Base.InterpreterIP}`, which may then be passed into `stacktrace` for translation:

```
julia> trace = backtrace()
18-element Array{Union{Ptr{Nothing}, Base.InterpreterIP},1}:
Ptr{Nothing} @0x00007fd8734c6209
Ptr{Nothing} @0x00007fd87362b342
Ptr{Nothing} @0x00007fd87362c136
Ptr{Nothing} @0x00007fd87362c986
Ptr{Nothing} @0x00007fd87362d089
Base.InterpreterIP(CodeInfo(: (begin
    Core.SSAValue(0) = backtrace()
    trace = Core.SSAValue(0)
    return Core.SSAValue(0)
end)), 0x0000000000000000)
Ptr{Nothing} @0x00007fd87362e4cf
[...]
```

```
6-element Array{Base.StackTraces.StackFrame,1}:
 top-level scope
 eval at boot.jl:317 [inlined]
 eval(::Module, ::Expr) at REPL.jl:5
 eval_user_input(::Any, ::REPL.REPLBackend) at REPL.jl:85
 macro expansion at REPL.jl:116 [inlined]
 (::getfield(REPL, Symbol("##28#29")){REPL.REPLBackend})() at event.jl:92
```

Notice that the vector returned by `backtrace` had 18 elements, while the vector returned by `stacktrace` only has 6. This is because, by default, `stacktrace` removes any lower-level C functions from the stack. If you want to include stack frames from C calls, you can do it like this:

```
julia> stacktrace(trace, true)
21-element Array{Base.StackTraces.StackFrame,1}:
 jl_apply_generic at gf.c:2167
 do_call at interpreter.c:324
 eval_value at interpreter.c:416
 eval_body at interpreter.c:559
 jl_interpret_toplevel_thunk_callback at interpreter.c:798
 top-level scope
 jl_interpret_toplevel_thunk at interpreter.c:807
 jl_toplevel_eval_flex at toplevel.c:856
 jl_toplevel_eval_in at builtins.c:624
 eval at boot.jl:317 [inlined]
 eval(::Module, ::Expr) at REPL.jl:5
 jl_apply_generic at gf.c:2167
 eval_user_input(::Any, ::REPL.REPLBackend) at REPL.jl:85
 jl_apply_generic at gf.c:2167
 macro expansion at REPL.jl:116 [inlined]
 (::getfield(REPL, Symbol("##28#29")){REPL.REPLBackend})() at event.jl:92
 jl_fptr_trampoline at gf.c:1838
 jl_apply_generic at gf.c:2167
 jl_apply at julia.h:1540 [inlined]
 start_task at task.c:268
 ip:0xffffffffffffffff
```

Individual pointers returned by `backtrace` can be translated into `StackTraces.StackFrame`s by passing them into `StackTraces.lookup`:

```
julia> pointer = backtrace()[1];

julia> frame = StackTraces.lookup(pointer)
1-element Array{Base.StackTraces.StackFrame,1}:
 jl_apply_generic at gf.c:2167

julia> println("The top frame is from $(frame[1].func)!")
The top frame is from jl_apply_generic!
```

Chapter 34

Performance Tips

In the following sections, we briefly go through a few techniques that can help make your Julia code run as fast as possible.

34.1 Performance critical code should be inside a function

Any code that is performance critical should be inside a function. Code inside functions tends to run much faster than top level code, due to how Julia's compiler works.

The use of functions is not only important for performance: functions are more reusable and testable, and clarify what steps are being done and what their inputs and outputs are, [Write functions, not just scripts](#) is also a recommendation of Julia's Styleguide.

The functions should take arguments, instead of operating directly on global variables, see the next point.

34.2 Avoid untyped global variables

The value of an untyped global variable might change at any point, possibly leading to a change of its type. This makes it difficult for the compiler to optimize code using global variables. This also applies to type-valued variables, i.e. type aliases on the global level. Variables should be local, or passed as arguments to functions, whenever possible.

We find that global names are frequently constants, and declaring them as such greatly improves performance:

```
| const DEFAULT_VAL = 0
```

If a global is known to always be of the same type, [the type should be annotated](#).

Uses of untyped globals can be optimized by annotating their types at the point of use:

```
| global x = rand(1000)
|
| function loop_over_global()
|     s = 0.0
|     for i in x::Vector{Float64}
|         s += i
|     end
| end
```

```

    end
    return s
end

```

Passing arguments to functions is better style. It leads to more reusable code and clarifies what the inputs and outputs are.

Note

All code in the REPL is evaluated in global scope, so a variable defined and assigned at top level will be a **global** variable. Variables defined at top level scope inside modules are also global.

In the following REPL session:

```
julia> x = 1.0
```

is equivalent to:

```
julia> global x = 1.0
```

so all the performance issues discussed previously apply.

34.3 Measure performance with @time and pay attention to memory allocation

A useful tool for measuring performance is the `@time` macro. We here repeat the example with the global variable above, but this time with the type annotation removed:

```

julia> x = rand(1000);

julia> function sum_global()
    s = 0.0
    for i in x
        s += i
    end
    return s
end;

julia> @time sum_global()
0.011539 seconds (9.08 k allocations: 373.386 KiB, 98.69% compilation time)
523.0007221951678

julia> @time sum_global()
0.000091 seconds (3.49 k allocations: 70.156 KiB)
523.0007221951678

```

On the first call (`@time sum_global()`) the function gets compiled. (If you've not yet used `@time` in this session, it will also compile functions needed for timing.) You should not take the results of this run seriously. For the second run, note that in addition to reporting the time, it also indicated that a significant amount of memory was allocated. We are here just computing a sum over all elements in a vector of 64-bit floats so there should be no need to allocate (heap) memory.

We should clarify that what `@time` reports is specifically heap allocations, which are typically needed for either mutable objects or for creating/growing variable-sized containers (such as `Array` or `Dict`, strings, or "type-unstable" objects whose type is only known at runtime). Allocating (or deallocating) such blocks of memory may require an expensive system call (e.g. via `malloc` in C), and they must be tracked for garbage collection. In contrast, immutable values like numbers (except bignums), tuples, and immutable structs can be stored much more cheaply, e.g. in stack or CPU-register memory, so one doesn't typically worry about the performance cost of "allocating" them.

Unexpected memory allocation is almost always a sign of some problem with your code, usually a problem with type-stability or creating many small temporary arrays. Consequently, in addition to the allocation itself, it's very likely that the code generated for your function is far from optimal. Take such indications seriously and follow the advice below.

In this particular case, the memory allocation is due to the usage of a type-unstable global variable `x`, so if we instead pass `x` as an argument to the function it no longer allocates memory (the remaining allocation reported below is due to running the `@time` macro in global scope) and is significantly faster after the first call:

```
julia> x = rand(1000);

julia> function sum_arg(x)
    s = 0.0
    for i in x
        s += i
    end
    return s
end;

julia> @time sum_arg(x)
0.007551 seconds (3.98 k allocations: 200.548 KiB, 99.77% compilation time)
523.0007221951678

julia> @time sum_arg(x)
0.000006 seconds (1 allocation: 16 bytes)
523.0007221951678
```

The 1 allocation seen is from running the `@time` macro itself in global scope. If we instead run the timing in a function, we can see that indeed no allocations are performed:

```
julia> time_sum(x) = @time sum_arg(x);

julia> time_sum(x)
0.000002 seconds
523.0007221951678
```

In some situations, your function may need to allocate memory as part of its operation, and this can complicate the simple picture above. In such cases, consider using one of the [tools](#) below to diagnose problems, or write a version of your function that separates allocation from its algorithmic aspects (see [Pre-allocating outputs](#)).

Note

For more serious benchmarking, consider the [BenchmarkTools.jl](#) package which among other things evaluates the function multiple times in order to reduce noise.

34.4 Tools

Julia and its package ecosystem includes tools that may help you diagnose problems and improve the performance of your code:

- [Profiling](#) allows you to measure the performance of your running code and identify lines that serve as bottlenecks. For complex projects, the [ProfileView](#) package can help you visualize your profiling results.
- The [Traceur](#) package can help you find common performance problems in your code.
- Unexpectedly-large memory allocations—as reported by [@time](#), [@allocated](#), or the profiler (through calls to the garbage-collection routines)—hint that there might be issues with your code. If you don't see another reason for the allocations, suspect a type problem. You can also start Julia with the `--track-allocation=user` option and examine the resulting `*.mem` files to see information about where those allocations occur. See [Memory allocation analysis](#).
- `@code_warntype` generates a representation of your code that can be helpful in finding expressions that result in type uncertainty. See [@code_warntype](#) below.

34.5 Avoid containers with abstract type parameters

When working with parameterized types, including arrays, it is best to avoid parameterizing with abstract types where possible.

Consider the following:

```
julia> a = Real[]
Real[]

julia> push!(a, 1); push!(a, 2.0); push!(a, π)
3-element Vector{Real}:
 1
 2.0
 π = 3.1415926535897...
```

Because `a` is an array of abstract type `Real`, it must be able to hold any `Real` value. Since `Real` objects can be of arbitrary size and structure, `a` must be represented as an array of pointers to individually allocated `Real` objects. However, if we instead only allow numbers of the same type, e.g. `Float64`, to be stored in `a` these can be stored more efficiently:

```
julia> a = Float64[]
Float64[]

julia> push!(a, 1); push!(a, 2.0); push!(a, π)
3-element Vector{Float64}:
 1.0
 2.0
 3.141592653589793
```

Assigning numbers into `a` will now convert them to `Float64` and `a` will be stored as a contiguous block of 64-bit floating-point values that can be manipulated efficiently.

If you cannot avoid containers with abstract value types, it is sometimes better to parametrize with `Any` to avoid runtime type checking. E.g. `IdDict{Any, Any}` performs better than `IdDict{Type, Vector}`

See also the discussion under [Parametric Types](#).

34.6 Type declarations

In many languages with optional type declarations, adding declarations is the principal way to make code run faster. This is not the case in Julia. In Julia, the compiler generally knows the types of all function arguments, local variables, and expressions. However, there are a few specific instances where declarations are helpful.

Avoid fields with abstract type

Types can be declared without specifying the types of their fields:

```
julia> struct MyAmbiguousType
    a
end
```

This allows `a` to be of any type. This can often be useful, but it does have a downside: for objects of type `MyAmbiguousType`, the compiler will not be able to generate high-performance code. The reason is that the compiler uses the types of objects, not their values, to determine how to build code. Unfortunately, very little can be inferred about an object of type `MyAmbiguousType`:

```
julia> b = MyAmbiguousType("Hello")
MyAmbiguousType("Hello")

julia> c = MyAmbiguousType(17)
MyAmbiguousType(17)

julia> typeof(b)
MyAmbiguousType

julia> typeof(c)
MyAmbiguousType
```

The values of `b` and `c` have the same type, yet their underlying representation of data in memory is very different. Even if you stored just numeric values in field `a`, the fact that the memory representation of `a`

`UInt8` differs from a `Float64` also means that the CPU needs to handle them using two different kinds of instructions. Since the required information is not available in the type, such decisions have to be made at run-time. This slows performance.

You can do better by declaring the type of `a`. Here, we are focused on the case where `a` might be any one of several types, in which case the natural solution is to use parameters. For example:

```
julia> mutable struct MyType{T<:AbstractFloat}
    a::T
end
```

This is a better choice than

```
julia> mutable struct MyStillAmbiguousType
    a::AbstractFloat
end
```

because the first version specifies the type of `a` from the type of the wrapper object. For example:

```
julia> m = MyType(3.2)
MyType{Float64}(3.2)

julia> t = MyStillAmbiguousType(3.2)
MyStillAmbiguousType(3.2)

julia> typeof(m)
MyType{Float64}

julia> typeof(t)
MyStillAmbiguousType
```

The type of field `a` can be readily determined from the type of `m`, but not from the type of `t`. Indeed, in `t` it's possible to change the type of the field `a`:

```
julia> typeof(t.a)
Float64

julia> t.a = 4.5f0
4.5f0

julia> typeof(t.a)
Float32
```

In contrast, once `m` is constructed, the type of `m.a` cannot change:

```
julia> m.a = 4.5f0
4.5f0

julia> typeof(m.a)
Float64
```

The fact that the type of `m.a` is known from `m`'s type—coupled with the fact that its type cannot change mid-function—allows the compiler to generate highly-optimized code for objects like `m` but not for objects like `t`.

Of course, all of this is true only if we construct `m` with a concrete type. We can break this by explicitly constructing it with an abstract type:

```
julia> m = MyType{AbstractFloat}(3.2)
MyType{AbstractFloat}(3.2)

julia> typeof(m.a)
Float64

julia> m.a = 4.5f0
4.5f0

julia> typeof(m.a)
Float32
```

For all practical purposes, such objects behave identically to those of `MyStillAmbiguousType`.

It's quite instructive to compare the sheer amount of code generated for a simple function

```
func(m::MyType) = m.a+1
```

using

```
code_llvm(func, Tuple{MyType{Float64}})
code_llvm(func, Tuple{MyType{AbstractFloat}})
```

For reasons of length the results are not shown here, but you may wish to try this yourself. Because the type is fully-specified in the first case, the compiler doesn't need to generate any code to resolve the type at run-time. This results in shorter and faster code.

One should also keep in mind that not-fully-parameterized types behave like abstract types. For example, even though a fully specified `Array{T, n}` is concrete, `Array` itself with no parameters given is not concrete:

```
julia> !isconcretetype(Array), !isabstracttype(Array), isstructtype(Array),
↪ !isconcretetype(Array{Int}), isconcretetype(Array{Int,1})
(true, true, true, true, true)
```

In this case, it would be better to avoid declaring `MyType` with a field `a::Array` and instead declare the field as `a::Array{T,N}` or as `a::A`, where `{T,N}` or `A` are parameters of `MyType`.

Avoid fields with abstract containers

The same best practices also work for container types:

```
julia> struct MySimpleContainer{A<:AbstractVector}
    a::A
end

julia> struct MyAmbiguousContainer{T}
    a::AbstractVector{T}
end

julia> struct MyAlsoAmbiguousContainer
    a::Array
end
```

For example:

```
julia> c = MySimpleContainer(1:3);

julia> typeof(c)
MySimpleContainer{UnitRange{Int64}}

julia> c = MySimpleContainer([1:3;]);

julia> typeof(c)
MySimpleContainer{Vector{Int64}}

julia> b = MyAmbiguousContainer(1:3);

julia> typeof(b)
MyAmbiguousContainer{Int64}

julia> b = MyAmbiguousContainer([1:3;]);

julia> typeof(b)
MyAmbiguousContainer{Int64}

julia> d = MyAlsoAmbiguousContainer(1:3);

julia> typeof(d), typeof(d.a)
(MyAlsoAmbiguousContainer, Vector{Int64})

julia> d = MyAlsoAmbiguousContainer(1:1.0:3);

julia> typeof(d), typeof(d.a)
(MyAlsoAmbiguousContainer, Vector{Float64})
```

For `MySimpleContainer`, the object is fully-specified by its type and parameters, so the compiler can generate optimized functions. In most instances, this will probably suffice.

While the compiler can now do its job perfectly well, there are cases where you might wish that your code could do different things depending on the element type of `a`. Usually the best way to achieve this is to wrap your specific operation (here, `foo`) in a separate function:

```
julia> function sumfoo(c::MySimpleContainer)
    s = 0
```

```

        for x in c.a
            s += foo(x)
        end
    end
    s
end
sumfoo (generic function with 1 method)

julia> foo(x::Integer) = x
foo (generic function with 1 method)

julia> foo(x::AbstractFloat) = round(x)
foo (generic function with 2 methods)

```

This keeps things simple, while allowing the compiler to generate optimized code in all cases.

However, there are cases where you may need to declare different versions of the outer function for different element types or types of the `AbstractVector` of the field `a` in `MySimpleContainer`. You could do it like this:

```

julia> function myfunc(c::MySimpleContainer{<:AbstractArray{<:Integer}})
    return c.a[1]+1
end
myfunc (generic function with 1 method)

julia> function myfunc(c::MySimpleContainer{<:AbstractArray{<:AbstractFloat}})
    return c.a[1]+2
end
myfunc (generic function with 2 methods)

julia> function myfunc(c::MySimpleContainer{Vector{T}}) where T <: Integer
    return c.a[1]+3
end
myfunc (generic function with 3 methods)

julia> myfunc(MySimpleContainer{1:3})
2

julia> myfunc(MySimpleContainer{1.0:3})
3.0

julia> myfunc(MySimpleContainer{[1:3;]})
4

```

Annotate values taken from untyped locations

It is often convenient to work with data structures that may contain values of any type (arrays of type `Array{Any}`). But, if you're using one of these structures and happen to know the type of an element, it helps to share this knowledge with the compiler:

```

function foo(a::Array{Any}, l)
    x = a[l]::Int32
    b = x+1
end

```

```
...
end
```

Here, we happened to know that the first element of `a` would be an `Int32`. Making an annotation like this has the added benefit that it will raise a run-time error if the value is not of the expected type, potentially catching certain bugs earlier.

In the case that the type of `a[1]` is not known precisely, `x` can be declared via `x = convert{Int32, a[1]}::Int32`. The use of the `convert` function allows `a[1]` to be any object convertible to an `Int32` (such as `UInt8`), thus increasing the genericity of the code by loosening the type requirement. Notice that `convert` itself needs a type annotation in this context in order to achieve type stability. This is because the compiler cannot deduce the type of the return value of a function, even `convert`, unless the types of all the function's arguments are known.

Type annotation will not enhance (and can actually hinder) performance if the type is abstract, or constructed at run-time. This is because the compiler cannot use the annotation to specialize the subsequent code, and the type-check itself takes time. For example, in the code:

```
function nr(a, prec)
    ctype = prec == 32 ? Float32 : Float64
    b = Complex{ctype}(a)
    c = (b + 1.0f0)::Complex{ctype}
    abs(c)
end
```

the annotation of `c` harms performance. To write performant code involving types constructed at run-time, use the [function-barrier technique](#) discussed below, and ensure that the constructed type appears among the argument types of the kernel function so that the kernel operations are properly specialized by the compiler. For example, in the above snippet, as soon as `b` is constructed, it can be passed to another function `k`, the kernel. If, for example, function `k` declares `b` as an argument of type `Complex{T}`, where `T` is a type parameter, then a type annotation appearing in an assignment statement within `k` of the form:

```
| c = (b + 1.0f0)::Complex{T}
```

does not hinder performance (but does not help either) since the compiler can determine the type of `c` at the time `k` is compiled.

Be aware of when Julia avoids specializing

As a heuristic, Julia avoids automatically [specializing](#) on argument type parameters in three specific cases: Type, Function, and Vararg. Julia will always specialize when the argument is used within the method, but not if the argument is just passed through to another function. This usually has no performance impact at runtime and [improves compiler performance](#). If you find it does have a performance impact at runtime in your case, you can trigger specialization by adding a type parameter to the method declaration. Here are some examples:

This will not specialize:

```
function f_type(t) # or t::Type
    x = ones(t, 10)
    return sum(map(sin, x))
end
```

but this will:

```
function g_type(t::Type{T}) where T
    x = ones(T, 10)
    return sum(map(sin, x))
end
```

These will not specialize:

```
f_func(f, num) = ntuple(f, div(num, 2))
g_func(g::Function, num) = ntuple(g, div(num, 2))
```

but this will:

```
h_func(h::H, num) where {H} = ntuple(h, div(num, 2))
```

This will not specialize:

```
f_vararg(x::Int...) = tuple(x...)
```

but this will:

```
g_vararg(x::Vararg{Int, N}) where {N} = tuple(x...)
```

One only needs to introduce a single type parameter to force specialization, even if the other types are unconstrained. For example, this will also specialize, and is useful when the arguments are not all of the same type:

```
h_vararg(x::Vararg{Any, N}) where {N} = tuple(x...)
```

Note that `@code_typed` and friends will always show you specialized code, even if Julia would not normally specialize that method call. You need to check the [method internals](#) if you want to see whether specializations are generated when argument types are changed, i.e., if `Base.specializations(@which f(...))` contains specializations for the argument in question.

34.7 Break functions into multiple definitions

Writing a function as many small definitions allows the compiler to directly call the most applicable code, or even inline it.

Here is an example of a "compound function" that should really be written as multiple definitions:

```

using LinearAlgebra

function mynorm(A)
    if isa(A, Vector)
        return sqrt(real(dot(A,A)))
    elseif isa(A, Matrix)
        return maximum(svdvals(A))
    else
        error("mynorm: invalid argument")
    end
end
end

```

This can be written more concisely and efficiently as:

```

mynorm(x::Vector) = sqrt(real(dot(x, x)))
mynorm(A::Matrix) = maximum(svdvals(A))

```

It should however be noted that the compiler is quite efficient at optimizing away the dead branches in code written as the `mynorm` example.

34.8 Write "type-stable" functions

When possible, it helps to ensure that a function always returns a value of the same type. Consider the following definition:

```

pos(x) = x < 0 ? 0 : x

```

Although this seems innocent enough, the problem is that `0` is an integer (of type `Int`) and `x` might be of any type. Thus, depending on the value of `x`, this function might return a value of either of two types. This behavior is allowed, and may be desirable in some cases. But it can easily be fixed as follows:

```

pos(x) = x < 0 ? zero(x) : x

```

There is also a `oneunit` function, and a more general `oftype(x, y)` function, which returns `y` converted to the type of `x`.

34.9 Avoid changing the type of a variable

An analogous "type-stability" problem exists for variables used repeatedly within a function:

```

function foo()
    x = 1
    for i = 1:10
        x /= rand()
    end
    return x
end
end

```

Local variable `x` starts as an integer, and after one loop iteration becomes a floating-point number (the result of `/` operator). This makes it more difficult for the compiler to optimize the body of the loop. There are several possible fixes:

- Initialize `x` with `x = 1.0`
- Declare the type of `x` explicitly as `x::Float64 = 1`
- Use an explicit conversion by `x = oneunit(Float64)`
- Initialize with the first loop iteration, to `x = 1 / rand()`, then loop for `i = 2:10`

34.10 Separate kernel functions (aka, function barriers)

Many functions follow a pattern of performing some set-up work, and then running many iterations to perform a core computation. Where possible, it is a good idea to put these core computations in separate functions. For example, the following contrived function returns an array of a randomly-chosen type:

```
julia> function strange_twos(n)
    a = Vector{rand{Bool} ? Int64 : Float64}(undef, n)
    for i = 1:n
        a[i] = 2
    end
    return a
end;

julia> strange_twos(3)
3-element Vector{Int64}:
 2
 2
 2
```

This should be written as:

```
julia> function fill_twos!(a)
    for i = eachindex(a)
        a[i] = 2
    end
end;

julia> function strange_twos(n)
    a = Vector{rand{Bool} ? Int64 : Float64}(undef, n)
    fill_twos!(a)
    return a
end;

julia> strange_twos(3)
3-element Vector{Int64}:
 2
 2
 2
```

Julia's compiler specializes code for argument types at function boundaries, so in the original implementation it does not know the type of `a` during the loop (since it is chosen randomly). Therefore the second version is generally faster since the inner loop can be recompiled as part of `fill_twos!` for different types of `a`.

The second form is also often better style and can lead to more code reuse.

This pattern is used in several places in Julia Base. For example, see `vcats` and `hcats` in `abstractarray.jl`, or the `fill!` function, which we could have used instead of writing our own `fill_twos!`.

Functions like `strange_twos` occur when dealing with data of uncertain type, for example data loaded from an input file that might contain either integers, floats, strings, or something else.

34.11 Types with values-as-parameters

Let's say you want to create an N -dimensional array that has size 3 along each axis. Such arrays can be created like this:

```
julia> A = fill(5.0, (3, 3))
3×3 Matrix{Float64}:
 5.0  5.0  5.0
 5.0  5.0  5.0
 5.0  5.0  5.0
```

This approach works very well: the compiler can figure out that `A` is an `Array{Float64, 2}` because it knows the type of the fill value (`5.0::Float64`) and the dimensionality (`(3, 3)::NTuple{2, Int}`). This implies that the compiler can generate very efficient code for any future usage of `A` in the same function.

But now let's say you want to write a function that creates a $3 \times 3 \times \dots$ array in arbitrary dimensions; you might be tempted to write a function

```
julia> function array3(fillval, N)
    fill(fillval, ntuple(d->3, N))
end
array3 (generic function with 1 method)

julia> array3(5.0, 2)
3×3 Matrix{Float64}:
 5.0  5.0  5.0
 5.0  5.0  5.0
 5.0  5.0  5.0
```

This works, but (as you can verify for yourself using `@code_warntype array3(5.0, 2)`) the problem is that the output type cannot be inferred: the argument `N` is a value of type `Int`, and type-inference does not (and cannot) predict its value in advance. This means that code using the output of this function has to be conservative, checking the type on each access of `A`; such code will be very slow.

Now, one very good way to solve such problems is by using the [function-barrier technique](#). However, in some cases you might want to eliminate the type-instability altogether. In such cases, one approach is to pass the dimensionality as a parameter, for example through `Val{T}()` (see ["Value types"](#)):

```
julia> function array3(fillval, ::Val{N}) where N
    fill(fillval, ntuple(d->3, Val(N)))
end
array3 (generic function with 1 method)

julia> array3(5.0, Val(2))
3×3 Matrix{Float64}:
 5.0  5.0  5.0
 5.0  5.0  5.0
 5.0  5.0  5.0
```

Julia has a specialized version of `ntuple` that accepts a `Val{::Int}` instance as the second parameter; by passing `N` as a type-parameter, you make its "value" known to the compiler. Consequently, this version of `array3` allows the compiler to predict the return type.

However, making use of such techniques can be surprisingly subtle. For example, it would be of no help if you called `array3` from a function like this:

```
function call_array3(fillval, n)
    A = array3(fillval, Val(n))
end
```

Here, you've created the same problem all over again: the compiler can't guess what `n` is, so it doesn't know the type of `Val(n)`. Attempting to use `Val`, but doing so incorrectly, can easily make performance worse in many situations. (Only in situations where you're effectively combining `Val` with the function-barrier trick, to make the kernel function more efficient, should code like the above be used.)

An example of correct usage of `Val` would be:

```
function filter3(A::AbstractArray{T,N}) where {T,N}
    kernel = array3(1, Val(N))
    filter(A, kernel)
end
```

In this example, `N` is passed as a parameter, so its "value" is known to the compiler. Essentially, `Val(T)` works only when `T` is either hard-coded/literal (`Val(3)`) or already specified in the type-domain.

34.12 The dangers of abusing multiple dispatch (aka, more on types with values-as-parameters)

Once one learns to appreciate multiple dispatch, there's an understandable tendency to go overboard and try to use it for everything. For example, you might imagine using it to store information, e.g.

```
struct Car{Make, Model}
    year::Int
    ...more fields...
end
```

and then dispatch on objects like `Car{::Honda, ::Accord}(year, args...)`.

This might be worthwhile when either of the following are true:

- You require CPU-intensive processing on each `Car`, and it becomes vastly more efficient if you know the `Make` and `Model` at compile time and the total number of different `Make` or `Model` that will be used is not too large.
- You have homogeneous lists of the same type of `Car` to process, so that you can store them all in an `Array{Car{ :Honda, :Accord }, N}`.

When the latter holds, a function processing such a homogeneous array can be productively specialized: Julia knows the type of each element in advance (all objects in the container have the same concrete type), so Julia can "look up" the correct method calls when the function is being compiled (obviating the need to check at run-time) and thereby emit efficient code for processing the whole list.

When these do not hold, then it's likely that you'll get no benefit; worse, the resulting "combinatorial explosion of types" will be counterproductive. If `items[i+1]` has a different type than `item[i]`, Julia has to look up the type at run-time, search for the appropriate method in method tables, decide (via type intersection) which one matches, determine whether it has been JIT-compiled yet (and do so if not), and then make the call. In essence, you're asking the full type- system and JIT-compilation machinery to basically execute the equivalent of a switch statement or dictionary lookup in your own code.

Some run-time benchmarks comparing (1) type dispatch, (2) dictionary lookup, and (3) a "switch" statement can be found [on the mailing list](#).

Perhaps even worse than the run-time impact is the compile-time impact: Julia will compile specialized functions for each different `Car{Make, Model}`; if you have hundreds or thousands of such types, then every function that accepts such an object as a parameter (from a custom `get_year` function you might write yourself, to the generic `push!` function in Julia Base) will have hundreds or thousands of variants compiled for it. Each of these increases the size of the cache of compiled code, the length of internal lists of methods, etc. Excess enthusiasm for values-as-parameters can easily waste enormous resources.

34.13 Access arrays in memory order, along columns

Multidimensional arrays in Julia are stored in column-major order. This means that arrays are stacked one column at a time. This can be verified using the `vec` function or the syntax `[:]` as shown below (notice that the array is ordered `[1 3 2 4]`, not `[1 2 3 4]`):

```
julia> x = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> x[:]
4-element Vector{Int64}:
 1
 3
 2
 4
```

This convention for ordering arrays is common in many languages like Fortran, Matlab, and R (to name a few). The alternative to column-major ordering is row-major ordering, which is the convention adopted by C and Python (numpy) among other languages. Remembering the ordering of arrays can have significant performance effects when looping over arrays. A rule of thumb to keep in mind is that with column-major

arrays, the first index changes most rapidly. Essentially this means that looping will be faster if the inner-most loop index is the first to appear in a slice expression. Keep in mind that indexing an array with `:` is an implicit loop that iteratively accesses all elements within a particular dimension; it can be faster to extract columns than rows, for example.

Consider the following contrived example. Imagine we wanted to write a function that accepts a `Vector` and returns a square `Matrix` with either the rows or the columns filled with copies of the input vector. Assume that it is not important whether rows or columns are filled with these copies (perhaps the rest of the code can be easily adapted accordingly). We could conceivably do this in at least four ways (in addition to the recommended call to the built-in `repeat`):

```
function copy_cols(x::Vector{T}) where T
    inds = axes(x, 1)
    out = similar{Array{T}}(inds, inds)
    for i = inds
        out[:, i] = x
    end
    return out
end

function copy_rows(x::Vector{T}) where T
    inds = axes(x, 1)
    out = similar{Array{T}}(inds, inds)
    for i = inds
        out[i, :] = x
    end
    return out
end

function copy_col_row(x::Vector{T}) where T
    inds = axes(x, 1)
    out = similar{Array{T}}(inds, inds)
    for col = inds, row = inds
        out[row, col] = x[row]
    end
    return out
end

function copy_row_col(x::Vector{T}) where T
    inds = axes(x, 1)
    out = similar{Array{T}}(inds, inds)
    for row = inds, col = inds
        out[row, col] = x[col]
    end
    return out
end
```

Now we will time each of these functions using the same random 10000 by 1 input vector:

```
julia> x = randn(10000);

julia> fmt(f) = println(rpad(string(f)*": ", 14, ' '), @elapsed f(x))
```

```
julia> map(fmt, [copy_cols, copy_rows, copy_col_row, copy_row_col]);
copy_cols:    0.331706323
copy_rows:    1.799009911
copy_col_row: 0.415630047
copy_row_col: 1.721531501
```

Notice that `copy_cols` is much faster than `copy_rows`. This is expected because `copy_cols` respects the column-based memory layout of the `Matrix` and fills it one column at a time. Additionally, `copy_col_row` is much faster than `copy_row_col` because it follows our rule of thumb that the first element to appear in a slice expression should be coupled with the inner-most loop.

34.14 Pre-allocating outputs

If your function returns an `Array` or some other complex type, it may have to allocate memory. Unfortunately, oftentimes allocation and its converse, garbage collection, are substantial bottlenecks.

Sometimes you can circumvent the need to allocate memory on each function call by preallocating the output. As a trivial example, compare

```
julia> function xinc(x)
    return [x, x+1, x+2]
end;

julia> function loopinc()
    y = 0
    for i = 1:10^7
        ret = xinc(i)
        y += ret[2]
    end
    return y
end;
```

with

```
julia> function xinc!(ret::AbstractVector{T}, x::T) where T
    ret[1] = x
    ret[2] = x+1
    ret[3] = x+2
    nothing
end;

julia> function loopinc_prealloc()
    ret = Vector{Int}(undef, 3)
    y = 0
    for i = 1:10^7
        xinc!(ret, i)
        y += ret[2]
    end
    return y
end;
```

Timing results:

```
julia> @time loopinc()
0.529894 seconds (40.00 M allocations: 1.490 GiB, 12.14% gc time)
50000015000000

julia> @time loopinc_prealloc()
0.030850 seconds (6 allocations: 288 bytes)
50000015000000
```

Preallocation has other advantages, for example by allowing the caller to control the "output" type from an algorithm. In the example above, we could have passed a `SubArray` rather than an `Array`, had we so desired.

Taken to its extreme, pre-allocation can make your code uglier, so performance measurements and some judgment may be required. However, for "vectorized" (element-wise) functions, the convenient syntax `x .= f.(y)` can be used for in-place operations with fused loops and no temporary arrays (see the [dot syntax for vectorizing functions](#)).

34.15 More dots: Fuse vectorized operations

Julia has a special [dot syntax](#) that converts any scalar function into a "vectorized" function call, and any operator into a "vectorized" operator, with the special property that nested "dot calls" are fusing: they are combined at the syntax level into a single loop, without allocating temporary arrays. If you use `.=` and similar assignment operators, the result can also be stored in-place in a pre-allocated array (see above).

In a linear-algebra context, this means that even though operations like `vector + vector` and `vector * scalar` are defined, it can be advantageous to instead use `vector .+ vector` and `vector .* scalar` because the resulting loops can be fused with surrounding computations. For example, consider the two functions:

```
julia> f(x) = 3x.^2 + 4x + 7x.^3;

julia> fdot(x) = @. 3x^2 + 4x + 7x^3; # equivalent to 3 .* x.^2 .+ 4 .* x .+ 7 .* x.^3
```

Both `f` and `fdot` compute the same thing. However, `fdot` (defined with the help of the `@.` macro) is significantly faster when applied to an array:

```
julia> x = rand(10^6);

julia> @time f(x);
0.019049 seconds (16 allocations: 45.777 MiB, 18.59% gc time)

julia> @time fdot(x);
0.002790 seconds (6 allocations: 7.630 MiB)

julia> @time f.(x);
0.002626 seconds (8 allocations: 7.630 MiB)
```

That is, `fdot(x)` is ten times faster and allocates 1/6 the memory of `f(x)`, because each `*` and `+` operation in `f(x)` allocates a new temporary array and executes in a separate loop. In this example `f.(x)` is as fast as `fdot(x)` but in many contexts it is more convenient to sprinkle some dots in your expressions than to define a separate function for each vectorized operation.

34.16 Consider using views for slices

In Julia, an array "slice" expression like `array[1:5, :]` creates a copy of that data (except on the left-hand side of an assignment, where `array[1:5, :] = ...` assigns in-place to that portion of array). If you are doing many operations on the slice, this can be good for performance because it is more efficient to work with a smaller contiguous copy than it would be to index into the original array. On the other hand, if you are just doing a few simple operations on the slice, the cost of the allocation and copy operations can be substantial.

An alternative is to create a "view" of the array, which is an array object (a `SubArray`) that actually references the data of the original array in-place, without making a copy. (If you write to a view, it modifies the original array's data as well.) This can be done for individual slices by calling `view`, or more simply for a whole expression or block of code by putting `@views` in front of that expression. For example:

```
julia> fcopy(x) = sum(x[2:end-1]);

julia> @views fview(x) = sum(x[2:end-1]);

julia> x = rand(10^6);

julia> @time fcopy(x);
0.003051 seconds (3 allocations: 7.629 MB)

julia> @time fview(x);
0.001020 seconds (1 allocation: 16 bytes)
```

Notice both the 3× speedup and the decreased memory allocation of the `fview` version of the function.

34.17 Copying data is not always bad

Arrays are stored contiguously in memory, lending themselves to CPU vectorization and fewer memory accesses due to caching. These are the same reasons that it is recommended to access arrays in column-major order (see above). Irregular access patterns and non-contiguous views can drastically slow down computations on arrays because of non-sequential memory access.

Copying irregularly-accessed data into a contiguous array before repeated access it can result in a large speedup, such as in the example below. Here, a matrix is being accessed at randomly-shuffled indices before being multiplied. Copying into plain arrays speeds up the multiplication even with the added cost of copying and allocation.

```
julia> using Random

julia> A = randn(3000, 3000);

julia> x = randn(2000);
```

```

julia> inds = shuffle(1:3000)[1:2000];

julia> function iterated_neural_network(A, x, depth)
    for _ in 1:depth
        x .= max.(0, A * x)
    end
    argmax(x)
end

julia> @time iterated_neural_network(view(A, inds, inds), x, 10)
0.324903 seconds (12 allocations: 157.562 KiB)
1569

julia> @time iterated_neural_network(A[inds, inds], x, 10)
0.054576 seconds (13 allocations: 30.671 MiB, 13.33% gc time)
1569

```

Provided there is enough memory, the cost of copying the view to an array is outweighed by the speed boost from doing the repeated matrix multiplications on a contiguous array.

34.18 Consider `StaticArrays.jl` for small fixed-size vector/matrix operations

If your application involves many small (< 100 element) arrays of fixed sizes (i.e. the size is known prior to execution), then you might want to consider using the [StaticArrays.jl package](#). This package allows you to represent such arrays in a way that avoids unnecessary heap allocations and allows the compiler to specialize code for the size of the array, e.g. by completely unrolling vector operations (eliminating the loops) and storing elements in CPU registers.

For example, if you are doing computations with 2d geometries, you might have many computations with 2-component vectors. By using the `SVector` type from `StaticArrays.jl`, you can use convenient vector notation and operations like `norm(3v - w)` on vectors `v` and `w`, while allowing the compiler to unroll the code to a minimal computation equivalent to `@inbounds hypot(3v[1]-w[1], 3v[2]-w[2])`.

34.19 Avoid string interpolation for I/O

When writing data to a file (or other I/O device), forming extra intermediate strings is a source of overhead. Instead of:

```
| println(file, "$a $b")
```

use:

```
| println(file, a, " ", b)
```

The first version of the code forms a string, then writes it to the file, while the second version writes values directly to the file. Also notice that in some cases string interpolation can be harder to read. Consider:

```
| println(file, "$(f(a))$(f(b))")
```

versus:

```
| println(file, f(a), f(b))
```

34.20 Optimize network I/O during parallel execution

When executing a remote function in parallel:

```
| using Distributed
|
| responses = Vector{Any}(undef, nworkers())
| @sync begin
|   for (idx, pid) in enumerate(workers())
|     @async responses[idx] = remotecall_fetch(foo, pid, args...)
|   end
| end
```

is faster than:

```
| using Distributed
|
| refs = Vector{Any}(undef, nworkers())
| for (idx, pid) in enumerate(workers())
|   refs[idx] = @spawnat pid foo(args...)
| end
| responses = [fetch(r) for r in refs]
```

The former results in a single network round-trip to every worker, while the latter results in two network calls - first by the `@spawnat` and the second due to the `fetch` (or even a `wait`). The `fetch/wait` is also being executed serially resulting in an overall poorer performance.

34.21 Fix deprecation warnings

A deprecated function internally performs a lookup in order to print a relevant warning only once. This extra lookup can cause a significant slowdown, so all uses of deprecated functions should be modified as suggested by the warnings.

34.22 Tweaks

These are some minor points that might help in tight inner loops.

- Avoid unnecessary arrays. For example, instead of `sum([x,y,z])` use `x+y+z`.
- Use `abs2(z)` instead of `abs(z)^2` for complex `z`. In general, try to rewrite code to use `abs2` instead of `abs` for complex arguments.
- Use `div(x,y)` for truncating division of integers instead of `trunc(x/y)`, `fld(x,y)` instead of `floor(x/y)`, and `cld(x,y)` instead of `ceil(x/y)`.

34.23 Performance Annotations

Sometimes you can enable better optimization by promising certain program properties.

- Use `@inbounds` to eliminate array bounds checking within expressions. Be certain before doing this. If the subscripts are ever out of bounds, you may suffer crashes or silent corruption.
- Use `@fastmath` to allow floating point optimizations that are correct for real numbers, but lead to differences for IEEE numbers. Be careful when doing this, as this may change numerical results. This corresponds to the `-ffast-math` option of clang.
- Write `@simd` in front of for loops to promise that the iterations are independent and may be re-ordered. Note that in many cases, Julia can automatically vectorize code without the `@simd` macro; it is only beneficial in cases where such a transformation would otherwise be illegal, including cases like allowing floating-point re-associativity and ignoring dependent memory accesses (`@simd ivdep`). Again, be very careful when asserting `@simd` as erroneously annotating a loop with dependent iterations may result in unexpected results. In particular, note that `setindex!` on some `AbstractArray` subtypes is inherently dependent upon iteration order. **This feature is experimental** and could change or disappear in future versions of Julia.

The common idiom of using `1:n` to index into an `AbstractArray` is not safe if the `Array` uses unconventional indexing, and may cause a segmentation fault if bounds checking is turned off. Use `LinearIndices(x)` or `eachindex(x)` instead (see also [Arrays with custom indices](#)).

Note

While `@simd` needs to be placed directly in front of an innermost for loop, both `@inbounds` and `@fastmath` can be applied to either single expressions or all the expressions that appear within nested blocks of code, e.g., using `@inbounds begin` or `@inbounds for ...`.

Here is an example with both `@inbounds` and `@simd` markup (we here use `@noinline` to prevent the optimizer from trying to be too clever and defeat our benchmark):

```
@noinline function inner(x, y)
    s = zero(eltype(x))
    for i=eachindex(x)
        @inbounds s += x[i]*y[i]
    end
    return s
end

@noinline function innersimd(x, y)
    s = zero(eltype(x))
    @simd for i = eachindex(x)
        @inbounds s += x[i] * y[i]
    end
    return s
end

function timeit(n, reps)
    x = rand(Float32, n)
```

```

    y = rand(Float32, n)
    s = zero(Float64)
    time = @elapsed for j in 1:reps
        s += inner(x, y)
    end
    println("GFlop/sec      = ", 2n*reps / time*1E-9)
    time = @elapsed for j in 1:reps
        s += innersimd(x, y)
    end
    println("GFlop/sec (SIMD) = ", 2n*reps / time*1E-9)
end

timeit(1000, 1000)

```

On a computer with a 2.4GHz Intel Core i5 processor, this produces:

```

GFlop/sec      = 1.9467069505224963
GFlop/sec (SIMD) = 17.578554163920018

```

(GFlop/sec measures the performance, and larger numbers are better.)

Here is an example with all three kinds of markup. This program first calculates the finite difference of a one-dimensional array, and then evaluates the L2-norm of the result:

```

function init!(u::Vector)
    n = length(u)
    dx = 1.0 / (n-1)
    @fastmath @inbounds @simd for i in 1:n #by asserting that `u` is a `Vector` we can assume it
        ↪ has 1-based indexing
        u[i] = sin(2pi*dx*i)
    end
end

function deriv!(u::Vector, du)
    n = length(u)
    dx = 1.0 / (n-1)
    @fastmath @inbounds du[1] = (u[2] - u[1]) / dx
    @fastmath @inbounds @simd for i in 2:n-1
        du[i] = (u[i+1] - u[i-1]) / (2*dx)
    end
    @fastmath @inbounds du[n] = (u[n] - u[n-1]) / dx
end

function mynorm(u::Vector)
    n = length(u)
    T = eltype(u)
    s = zero(T)
    @fastmath @inbounds @simd for i in 1:n
        s += u[i]^2
    end
    @fastmath @inbounds return sqrt(s)
end

```

```

function main()
    n = 2000
    u = Vector{Float64}(undef, n)
    init!(u)
    du = similar(u)

    deriv!(u, du)
    nu = mynorm(du)

    @time for i in 1:10^6
        deriv!(u, du)
        nu = mynorm(du)
    end

    println(nu)
end

main()

```

On a computer with a 2.7 GHz Intel Core i7 processor, this produces:

```

$ julia wave.jl;
1.207814709 seconds
4.443986180758249

$ julia --math-mode=ieee wave.jl;
4.487083643 seconds
4.443986180758249

```

Here, the option `--math-mode=ieee` disables the `@fastmath` macro, so that we can compare results.

In this case, the speedup due to `@fastmath` is a factor of about 3.7. This is unusually large – in general, the speedup will be smaller. (In this particular example, the working set of the benchmark is small enough to fit into the L1 cache of the processor, so that memory access latency does not play a role, and computing time is dominated by CPU usage. In many real world programs this is not the case.) Also, in this case this optimization does not change the result – in general, the result will be slightly different. In some cases, especially for numerically unstable algorithms, the result can be very different.

The annotation `@fastmath` re-arranges floating point expressions, e.g. changing the order of evaluation, or assuming that certain special cases (`inf`, `nan`) cannot occur. In this case (and on this particular computer), the main difference is that the expression `1 / (2*dx)` in the function `deriv` is hoisted out of the loop (i.e. calculated outside the loop), as if one had written `idx = 1 / (2*dx)`. In the loop, the expression `... / (2*dx)` then becomes `... * idx`, which is much faster to evaluate. Of course, both the actual optimization that is applied by the compiler as well as the resulting speedup depend very much on the hardware. You can examine the change in generated code by using Julia's `code_native` function.

Note that `@fastmath` also assumes that NaNs will not occur during the computation, which can lead to surprising behavior:

```

julia> f(x) = isnan(x);

julia> f(NaN)
true

```

```
julia> f_fast(x) = @fastmath isnan(x);

julia> f_fast(NaN)
false
```

34.24 Treat Subnormal Numbers as Zeros

Subnormal numbers, formerly called **denormal numbers**, are useful in many contexts, but incur a performance penalty on some hardware. A call `set_zero_subnormals(true)` grants permission for floating-point operations to treat subnormal inputs or outputs as zeros, which may improve performance on some hardware. A call `set_zero_subnormals(false)` enforces strict IEEE behavior for subnormal numbers.

Below is an example where subnormals noticeably impact performance on some hardware:

```
function timestep(b::Vector{T}, a::Vector{T}, Δt::T) where T
    @assert length(a)==length(b)
    n = length(b)
    b[1] = 1 # Boundary condition
    for i=2:n-1
        b[i] = a[i] + (a[i-1] - T(2)*a[i] + a[i+1]) * Δt
    end
    b[n] = 0 # Boundary condition
end

function heatflow(a::Vector{T}, nstep::Integer) where T
    b = similar(a)
    for t=1:div(nstep,2) # Assume nstep is even
        timestep(b,a,T(0.1))
        timestep(a,b,T(0.1))
    end
end

heatflow(zeros(Float32,10),2) # Force compilation
for trial=1:6
    a = zeros(Float32,1000)
    set_zero_subnormals(iseven(trial)) # Odd trials use strict IEEE arithmetic
    @time heatflow(a,1000)
end
```

This gives an output similar to

```
0.002202 seconds (1 allocation: 4.063 KiB)
0.001502 seconds (1 allocation: 4.063 KiB)
0.002139 seconds (1 allocation: 4.063 KiB)
0.001454 seconds (1 allocation: 4.063 KiB)
0.002115 seconds (1 allocation: 4.063 KiB)
0.001455 seconds (1 allocation: 4.063 KiB)
```

Note how each even iteration is significantly faster.

This example generates many subnormal numbers because the values in `a` become an exponentially decreasing curve, which slowly flattens out over time.

Treating subnormals as zeros should be used with caution, because doing so breaks some identities, such as $x - y == 0$ implies $x == y$:

```
julia> x = 3f-38; y = 2f-38;

julia> set_zero_subnormals(true); (x - y, x == y)
(0.0f0, false)

julia> set_zero_subnormals(false); (x - y, x == y)
(1.0000001f-38, false)
```

In some applications, an alternative to zeroing subnormal numbers is to inject a tiny bit of noise. For example, instead of initializing `a` with zeros, initialize it with:

```
a = rand(Float32, 1000) * 1.f-9
```

34.25 @code_warntype

The macro `@code_warntype` (or its function variant `code_warntype`) can sometimes be helpful in diagnosing type-related problems. Here's an example:

```
julia> @noinline pos(x) = x < 0 ? 0 : x;

julia> function f(x)
    y = pos(x)
    return sin(y*x + 1)
end;

julia> @code_warntype f(3.2)
MethodInstance for f(::Float64)
  from f(x) @ Main REPL[9]:1
Arguments
  #self#::Core.Const(f)
  x::Float64
Locals
  y::Union{Float64, Int64}
Body::Float64
1 -      (y = Main.pos(x))
|   %2 = (y * x)::Float64
|   %3 = (%2 + 1)::Float64
|   %4 = Main.sin(%3)::Float64
└──      return %4
```

Interpreting the output of `@code_warntype`, like that of its cousins `@code_lowered`, `@code_typed`, `@code_llvm`, and `@code_native`, takes a little practice. Your code is being presented in form that has been heavily digested on its way to generating compiled machine code. Most of the expressions are annotated by a type, indicated by the `::T` (where `T` might be `Float64`, for example). The most important characteristic of `@code_warntype` is that non-concrete types are displayed in red; since this document is written in Markdown, which has no color, in this document, red text is denoted by uppercase.

At the top, the inferred return type of the function is shown as `Body::Float64`. The next lines represent the body of `f` in Julia's SSA IR form. The numbered boxes are labels and represent targets for jumps (via `goto`) in your code. Looking at the body, you can see that the first thing that happens is that `pos` is called and the return value has been inferred as the Union type `Union{Float64, Int64}` shown in uppercase since it is a non-concrete type. This means that we cannot know the exact return type of `pos` based on the input types. However, the result of `y*x` is a `Float64` no matter if `y` is a `Float64` or `Int64`. The net result is that `f(x::Float64)` will not be type-unstable in its output, even if some of the intermediate computations are type-unstable.

How you use this information is up to you. Obviously, it would be far and away best to fix `pos` to be type-stable: if you did so, all of the variables in `f` would be concrete, and its performance would be optimal. However, there are circumstances where this kind of ephemeral type instability might not matter too much: for example, if `pos` is never used in isolation, the fact that `f`'s output is type-stable (for `Float64` inputs) will shield later code from the propagating effects of type instability. This is particularly relevant in cases where fixing the type instability is difficult or impossible. In such cases, the tips above (e.g., adding type annotations and/or breaking up functions) are your best tools to contain the "damage" from type instability. Also, note that even Julia Base has functions that are type unstable. For example, the function `findfirst` returns the index into an array where a key is found, or nothing if it is not found, a clear type instability. In order to make it easier to find the type instabilities that are likely to be important, Unions containing either `missing` or `nothing` are color highlighted in yellow, instead of red.

The following examples may help you interpret expressions marked as containing non-leaf types:

- Function body starting with `Body::Union{T1,T2}`
 - Interpretation: function with unstable return type
 - Suggestion: make the return value type-stable, even if you have to annotate it
- `invoke Main.g(%x::Int64)::Union{Float64, Int64}`
 - Interpretation: call to a type-unstable function `g`.
 - Suggestion: fix the function, or if necessary annotate the return value
- `invoke Base.getindex(%x::Array{Any,1}, 1::Int64)::Any`
 - Interpretation: accessing elements of poorly-typed arrays
 - Suggestion: use arrays with better-defined types, or if necessary annotate the type of individual element accesses
- `Base.getfield(%x, (:data))::Array{Float64,N}` where `N`
 - Interpretation: getting a field that is of non-leaf type. In this case, the type of `x`, say `ArrayContainer`, had a field `data::Array{T}`. But `Array` needs the dimension `N`, too, to be a concrete type.
 - Suggestion: use concrete types like `Array{T,3}` or `Array{T,N}`, where `N` is now a parameter of `ArrayContainer`

34.26 Performance of captured variable

Consider the following example that defines an inner function:

```
function abmult(r::Int)
    if r < 0
        r = -r
    end
    f = x -> x * r
    return f
end
```

Function `abmult` returns a function `f` that multiplies its argument by the absolute value of `r`. The inner function assigned to `f` is called a "closure". Inner functions are also used by the language for `do`-blocks and for generator expressions.

This style of code presents performance challenges for the language. The parser, when translating it into lower-level instructions, substantially reorganizes the above code by extracting the inner function to a separate code block. "Captured" variables such as `r` that are shared by inner functions and their enclosing scope are also extracted into a heap-allocated "box" accessible to both inner and outer functions because the language specifies that `r` in the inner scope must be identical to `r` in the outer scope even after the outer scope (or another inner function) modifies `r`.

The discussion in the preceding paragraph referred to the "parser", that is, the phase of compilation that takes place when the module containing `abmult` is first loaded, as opposed to the later phase when it is first invoked. The parser does not "know" that `Int` is a fixed type, or that the statement `r = -r` transforms an `Int` to another `Int`. The magic of type inference takes place in the later phase of compilation.

Thus, the parser does not know that `r` has a fixed type (`Int`). nor that `r` does not change value once the inner function is created (so that the box is unneeded). Therefore, the parser emits code for box that holds an object with an abstract type such as `Any`, which requires run-time type dispatch for each occurrence of `r`. This can be verified by applying `@code_warntype` to the above function. Both the boxing and the run-time type dispatch can cause loss of performance.

If captured variables are used in a performance-critical section of the code, then the following tips help ensure that their use is performant. First, if it is known that a captured variable does not change its type, then this can be declared explicitly with a type annotation (on the variable, not the right-hand side):

```
function abmult2(r0::Int)
    r::Int = r0
    if r < 0
        r = -r
    end
    f = x -> x * r
    return f
end
```

The type annotation partially recovers lost performance due to capturing because the parser can associate a concrete type to the object in the box. Going further, if the captured variable does not need to be boxed at all (because it will not be reassigned after the closure is created), this can be indicated with `let` blocks as follows.

```

function abmult3(r::Int)
    if r < 0
        r = -r
    end
    f = let r = r
        x -> x * r
    end
    return f
end

```

The `let` block creates a new variable `r` whose scope is only the inner function. The second technique recovers full language performance in the presence of captured variables. Note that this is a rapidly evolving aspect of the compiler, and it is likely that future releases will not require this degree of programmer annotation to attain performance. In the mean time, some user-contributed packages like [FastClosures](#) automate the insertion of `let` statements as in `abmult3`.

34.27 Multithreading and linear algebra

This section applies to multithreaded Julia code which, in each thread, performs linear algebra operations. Indeed, these linear algebra operations involve BLAS / LAPACK calls, which are themselves multithreaded. In this case, one must ensure that cores aren't oversubscribed due to the two different types of multithreading.

Julia compiles and uses its own copy of OpenBLAS for linear algebra, whose number of threads is controlled by the environment variable `OPENBLAS_NUM_THREADS`. It can either be set as a command line option when launching Julia, or modified during the Julia session with `BLAS.set_num_threads(N)` (the submodule `BLAS` is exported by using `LinearAlgebra`). Its current value can be accessed with `BLAS.get_num_threads()`.

When the user does not specify anything, Julia tries to choose a reasonable value for the number of OpenBLAS threads (e.g. based on the platform, the Julia version, etc.). However, it is generally recommended to check and set the value manually. The OpenBLAS behavior is as follows:

- If `OPENBLAS_NUM_THREADS=1`, OpenBLAS uses the calling Julia thread(s), i.e. it "lives in" the Julia thread that runs the computation.
- If `OPENBLAS_NUM_THREADS=N>1`, OpenBLAS creates and manages its own pool of threads (`N` in total). There is just one OpenBLAS thread pool shared among all Julia threads.

When you start Julia in multithreaded mode with `JULIA_NUM_THREADS=X`, it is generally recommended to set `OPENBLAS_NUM_THREADS=1`. Given the behavior described above, increasing the number of BLAS threads to `N>1` can very easily lead to worse performance, in particular when `N<<X`. However this is just a rule of thumb, and the best way to set each number of threads is to experiment on your specific application.

34.28 Alternative linear algebra backends

As an alternative to OpenBLAS, there exist several other backends that can help with linear algebra performance. Prominent examples include [MKL.jl](#) and [AppleAccelerate.jl](#).

These are external packages, so we will not discuss them in detail here. Please refer to their respective documentations (especially because they have different behaviors than OpenBLAS with respect to multithreading).

Chapter 35

Workflow Tips

Here are some tips for working with Julia efficiently.

35.1 REPL-based workflow

As already elaborated in [The Julia REPL](#), Julia's REPL provides rich functionality that facilitates an efficient interactive workflow. Here are some tips that might further enhance your experience at the command line.

A basic editor/REPL workflow

The most basic Julia workflows involve using a text editor in conjunction with the `julia` command line. A common pattern includes the following elements:

- **Put code under development in a temporary module.** Create a file, say `Tmp.jl`, and include within it

```
module Tmp
export say_hello

say_hello() = println("Hello!")

# your other definitions here

end
```

- **Put your test code in another file.** Create another file, say `tst.jl`, which looks like

```
include("Tmp.jl")
import .Tmp
# using .Tmp # we can use `using` to bring the exported symbols in `Tmp` into our namespace

Tmp.say_hello()
# say_hello()

# your other test code here
```

and includes tests for the contents of `Tmp`. Alternatively, you can wrap the contents of your test file in a module, as

```

module Tst
    include("Tmp.jl")
    import .Tmp
    #using .Tmp

    Tmp.say_hello()
    # say_hello()

    # your other test code here
end

```

The advantage is that your testing code is now contained in a module and does not use the global scope in Main for definitions, which is a bit more tidy.

- include the `tst.jl` file in the Julia REPL with `include("tst.jl")`.
- **Lather. Rinse. Repeat.** Explore ideas at the `julia` command prompt. Save good ideas in `tst.jl`. To execute `tst.jl` after it has been changed, just include it again.

35.2 Browser-based workflow

There are a few ways to interact with Julia in a browser:

- Using Pluto notebooks through [Pluto.jl](#)
- Using Jupyter notebooks through [IJulia.jl](#)

35.3 Revise-based workflows

Whether you're at the REPL or in IJulia, you can typically improve your development experience with [Revise](#). It is common to configure Revise to start whenever Julia is started, as per the instructions in the [Revise documentation](#). Once configured, Revise will track changes to files in any loaded modules, and to any files loaded in to the REPL with `includet` (but not with plain `include`); you can then edit the files and the changes take effect without restarting your Julia session. A standard workflow is similar to the REPL-based workflow above, with the following modifications:

1. Put your code in a module somewhere on your load path. There are several options for achieving this, of which two recommended choices are:

- For long-term projects, use [PkgTemplates](#):

```

using PkgTemplates
t = Template()
t("MyPkg")

```

This will create a blank package, "MyPkg", in your `.julia/dev` directory. Note that `PkgTemplates` allows you to control many different options through its `Template` constructor.

In step 2 below, edit `MyPkg/src/MyPkg.jl` to change the source code, and `MyPkg/test/runtests.jl` for the tests.

- For "throw-away" projects, you can avoid any need for cleanup by doing your work in your temporary directory (e.g., `/tmp`).

Navigate to your temporary directory and launch Julia, then do the following:

```
| pkg> generate MyPkg          # type ] to enter pkg mode  
| julia> push!(LOAD_PATH, pwd()) # hit backspace to exit pkg mode
```

If you restart your Julia session you'll have to re-issue that command modifying `LOAD_PATH`.

In step 2 below, edit `MyPkg/src/MyPkg.jl` to change the source code, and create any test file of your choosing.

2. Develop your package

Before loading any code, make sure you're running Revise: say using `Revise` or follow its documentation on configuring it to run automatically.

Then navigate to the directory containing your test file (here assumed to be `"runtests.jl"`) and do the following:

```
| julia> using MyPkg  
| julia> include("runtests.jl")
```

You can iteratively modify the code in `MyPkg` in your editor and re-run the tests with `include("runtests.jl")`. You generally should not need to restart your Julia session to see the changes take effect (subject to a few [limitations](#)).

Chapter 36

Style Guide

The following sections explain a few aspects of idiomatic Julia coding style. None of these rules are absolute; they are only suggestions to help familiarize you with the language and to help you choose among alternative designs.

36.1 Indentation

Use 4 spaces per indentation level.

36.2 Write functions, not just scripts

Writing code as a series of steps at the top level is a quick way to get started solving a problem, but you should try to divide a program into functions as soon as possible. Functions are more reusable and testable, and clarify what steps are being done and what their inputs and outputs are. Furthermore, code inside functions tends to run much faster than top level code, due to how Julia's compiler works.

It is also worth emphasizing that functions should take arguments, instead of operating directly on global variables (aside from constants like `pi`).

36.3 Avoid writing overly-specific types

Code should be as generic as possible. Instead of writing:

```
| Complex{Float64}(x)
```

it's better to use available generic functions:

```
| complex(float(x))
```

The second version will convert `x` to an appropriate type, instead of always the same type.

This style point is especially relevant to function arguments. For example, don't declare an argument to be of type `Int` or `Int32` if it really could be any integer, expressed with the abstract type `Integer`. In fact, in many cases you can omit the argument type altogether, unless it is needed to disambiguate from other

method definitions, since a `MethodError` will be thrown anyway if a type is passed that does not support any of the requisite operations. (This is known as *duck typing*.)

For example, consider the following definitions of a function `addone` that returns one plus its argument:

```
addone(x::Int) = x + 1           # works only for Int
addone(x::Integer) = x + oneunit(x) # any integer type
addone(x::Number) = x + oneunit(x) # any numeric type
addone(x) = x + oneunit(x)      # any type supporting + and oneunit
```

The last definition of `addone` handles any type supporting `oneunit` (which returns 1 in the same type as `x`, which avoids unwanted type promotion) and the `+` function with those arguments. The key thing to realize is that there is no performance penalty to defining only the general `addone(x) = x + oneunit(x)`, because Julia will automatically compile specialized versions as needed. For example, the first time you call `addone(12)`, Julia will automatically compile a specialized `addone` function for `x::Int` arguments, with the call to `oneunit` replaced by its inlined value 1. Therefore, the first three definitions of `addone` above are completely redundant with the fourth definition.

36.4 Handle excess argument diversity in the caller

Instead of:

```
function foo(x, y)
    x = Int(x); y = Int(y)
    ...
end
foo(x, y)
```

use:

```
function foo(x::Int, y::Int)
    ...
end
foo(Int(x), Int(y))
```

This is better style because `foo` does not really accept numbers of all types; it really needs `Int` s.

One issue here is that if a function inherently requires integers, it might be better to force the caller to decide how non-integers should be converted (e.g. floor or ceiling). Another issue is that declaring more specific types leaves more "space" for future method definitions.

36.5 Append ! to names of functions that modify their arguments

Instead of:

```
function double(a::AbstractArray{<:Number})
    for i = firstindex(a):lastindex(a)
        a[i] *= 2
    end
    return a
end
```

use:

```
function double!(a::AbstractArray{<:Number})
    for i = firstindex(a):lastindex(a)
        a[i] *= 2
    end
    return a
end
```

Julia Base uses this convention throughout and contains examples of functions with both copying and modifying forms (e.g., `sort` and `sort!`), and others which are just modifying (e.g., `push!`, `pop!`, `splice!`). It is typical for such functions to also return the modified array for convenience.

Functions related to IO or making use of random number generators (RNG) are notable exceptions: Since these functions almost invariably must mutate the IO or RNG, functions ending with `!` are used to signify a mutation other than mutating the IO or advancing the RNG state. For example, `rand(x)` mutates the RNG, whereas `rand!(x)` mutates both the RNG and `x`; similarly, `read(io)` mutates `io`, whereas `read!(io, x)` mutates both arguments.

36.6 Avoid strange type Unions

Types such as `Union{Function,AbstractString}` are often a sign that some design could be cleaner.

36.7 Avoid elaborate container types

It is usually not much help to construct arrays like the following:

```
a = Vector{Union{Int,AbstractString,Tuple,Array}}(undef, n)
```

In this case `Vector{Any}(undef, n)` is better. It is also more helpful to the compiler to annotate specific uses (e.g. `a[i]::Int`) than to try to pack many alternatives into one type.

36.8 Prefer exported methods over direct field access

Idiomatic Julia code should generally treat a module's exported methods as the interface to its types. An object's fields are generally considered implementation details and user code should only access them directly if this is stated to be the API. This has several benefits:

- Package developers are freer to change the implementation without breaking user code.
- Methods can be passed to higher-order constructs like `map` (e.g. `map(imag, zs)`) rather than `[z.im for z in zs]`.
- Methods can be defined on abstract types.
- Methods can describe a conceptual operation that can be shared across disparate types (e.g. `real(z)` works on Complex numbers or Quaternions).

Julia's dispatch system encourages this style because `play(x::MyType)` only defines the `play` method on that particular type, leaving other types to have their own implementation.

Similarly, non-exported functions are typically internal and subject to change, unless the documentation states otherwise. Names sometimes are given a `_` prefix (or suffix) to further suggest that something is "internal" or an implementation-detail, but it is not a rule.

Counter-examples to this rule include `NamedTuple`, `RegexMatch`, `StatStruct`.

36.9 Use naming conventions consistent with Julia base/

- modules and type names use capitalization and camel case: module `SparseArrays`, struct `UnitRange`.
- functions are lowercase (`maximum`, `convert`) and, when readable, with multiple words squashed together (`isequal`, `haskey`). When necessary, use underscores as word separators. Underscores are also used to indicate a combination of concepts (`remotecall_fetch` as a more efficient implementation of `fetch(remotecall(...))`) or as modifiers.
- functions mutating at least one of their arguments end in `!`.
- conciseness is valued, but avoid abbreviation (`indexin` rather than `indxin`) as it becomes difficult to remember whether and how particular words are abbreviated.

If a function name requires multiple words, consider whether it might represent more than one concept and might be better split into pieces.

36.10 Write functions with argument ordering similar to Julia Base

As a general rule, the Base library uses the following order of arguments to functions, as applicable:

1. **Function argument.** Putting a function argument first permits the use of `do` blocks for passing multiline anonymous functions.
2. **I/O stream.** Specifying the I/O object first permits passing the function to functions such as `sprint`, e.g. `sprint(show, x)`.
3. **Input being mutated.** For example, in `fill!(x, v)`, `x` is the object being mutated and it appears before the value to be inserted into `x`.
4. **Type.** Passing a type typically means that the output will have the given type. In `parse{Int, "1"}`, the type comes before the string to parse. There are many such examples where the type appears first, but it's useful to note that in `read(io, String)`, the I/O argument appears before the type, which is in keeping with the order outlined here.
5. **Input not being mutated.** In `fill!(x, v)`, `v` is not being mutated and it comes after `x`.
6. **Key.** For associative collections, this is the key of the key-value pair(s). For other indexed collections, this is the index.
7. **Value.** For associative collections, this is the value of the key-value pair(s). In cases like `fill!(x, v)`, this is `v`.
8. **Everything else.** Any other arguments.

9. **Varargs.** This refers to arguments that can be listed indefinitely at the end of a function call. For example, in `Matrix{T}(undef, dims)`, the dimensions can be given as a [Tuple](#), e.g. `Matrix{T}(undef, (1,2))`, or as [Varargs](#), e.g. `Matrix{T}(undef, 1, 2)`.
10. **Keyword arguments.** In Julia keyword arguments have to come last anyway in function definitions; they're listed here for the sake of completeness.

The vast majority of functions will not take every kind of argument listed above; the numbers merely denote the precedence that should be used for any applicable arguments to a function.

There are of course a few exceptions. For example, in [convert](#), the type should always come first. In [setindex!](#), the value comes before the indices so that the indices can be provided as varargs.

When designing APIs, adhering to this general order as much as possible is likely to give users of your functions a more consistent experience.

36.11 Don't overuse try-catch

It is better to avoid errors than to rely on catching them.

36.12 Don't parenthesize conditions

Julia doesn't require parens around conditions in `if` and `while`. Write:

```
| if a == b
```

instead of:

```
| if (a == b)
```

36.13 Don't overuse ...

Splicing function arguments can be addictive. Instead of `[a..., b...]`, use simply `[a; b]`, which already concatenates arrays. `collect(a)` is better than `[a...]`, but since `a` is already iterable it is often even better to leave it alone, and not convert it to an array.

36.14 Don't use unnecessary static parameters

A function signature:

```
| foo(x::T) where {T<:Real} = ...
```

should be written as:

```
| foo(x::Real) = ...
```

instead, especially if `T` is not used in the function body. Even if `T` is used, it can be replaced with `typeof(x)` if convenient. There is no performance difference. Note that this is not a general caution against static parameters, just against uses where they are not needed.

Note also that container types, specifically may need type parameters in function calls. See the FAQ [Avoid fields with abstract containers](#) for more information.

36.15 Avoid confusion about whether something is an instance or a type

Sets of definitions like the following are confusing:

```
foo(::Type{MyType}) = ...
foo(::MyType) = foo(MyType)
```

Decide whether the concept in question will be written as `MyType` or `MyType()`, and stick to it.

The preferred style is to use instances by default, and only add methods involving `Type{MyType}` later if they become necessary to solve some problems.

If a type is effectively an enumeration, it should be defined as a single (ideally immutable struct or primitive) type, with the enumeration values being instances of it. Constructors and conversions can check whether values are valid. This design is preferred over making the enumeration an abstract type, with the "values" as subtypes.

36.16 Don't overuse macros

Be aware of when a macro could really be a function instead.

Calling `eval` inside a macro is a particularly dangerous warning sign; it means the macro will only work when called at the top level. If such a macro is written as a function instead, it will naturally have access to the run-time values it needs.

36.17 Don't expose unsafe operations at the interface level

If you have a type that uses a native pointer:

```
mutable struct NativeType
    p::Ptr{UInt8}
    ...
end
```

don't write definitions like the following:

```
getindex(x::NativeType, i) = unsafe_load(x.p, i)
```

The problem is that users of this type can write `x[i]` without realizing that the operation is unsafe, and then be susceptible to memory bugs.

Such a function should either check the operation to ensure it is safe, or have `unsafe` somewhere in its name to alert callers.

36.18 Don't overload methods of base container types

It is possible to write definitions like the following:

```
| show(io::IO, v::Vector{MyType}) = ...
```

This would provide custom showing of vectors with a specific new element type. While tempting, this should be avoided. The trouble is that users will expect a well-known type like `Vector()` to behave in a certain way, and overly customizing its behavior can make it harder to work with.

36.19 Avoid type piracy

"Type piracy" refers to the practice of extending or redefining methods in `Base` or other packages on types that you have not defined. In extreme cases, you can crash Julia (e.g. if your method extension or redefinition causes invalid input to be passed to a `ccall`). Type piracy can complicate reasoning about code, and may introduce incompatibilities that are hard to predict and diagnose.

As an example, suppose you wanted to define multiplication on symbols in a module:

```
| module A
| import Base.*
| *(x::Symbol, y::Symbol) = Symbol(x,y)
| end
```

The problem is that now any other module that uses `Base.*` will also see this definition. Since `Symbol` is defined in `Base` and is used by other modules, this can change the behavior of unrelated code unexpectedly. There are several alternatives here, including using a different function name, or wrapping the `Symbols` in another type that you define.

Sometimes, coupled packages may engage in type piracy to separate features from definitions, especially when the packages were designed by collaborating authors, and when the definitions are reusable. For example, one package might provide some types useful for working with colors; another package could define methods for those types that enable conversions between color spaces. Another example might be a package that acts as a thin wrapper for some C code, which another package might then pirate to implement a higher-level, Julia-friendly API.

36.20 Be careful with type equality

You generally want to use `isa` and `<:` for testing types, not `==`. Checking types for exact equality typically only makes sense when comparing to a known concrete type (e.g. `T == Float64`), or if you really, really know what you're doing.

36.21 Don't write a trivial anonymous function `x->f(x)` for a named function `f`

Since higher-order functions are often called with anonymous functions, it is easy to conclude that this is desirable or even necessary. But any function can be passed directly, without being "wrapped" in an anonymous function. Instead of writing `map(x->f(x), a)`, write `map(f, a)`.

36.22 Avoid using floats for numeric literals in generic code when possible

If you write generic code which handles numbers, and which can be expected to run with many different numeric type arguments, try using literals of a numeric type that will affect the arguments as little as possible through promotion.

For example,

```
julia> f(x) = 2.0 * x
f (generic function with 1 method)

julia> f(1//2)
1.0

julia> f(1/2)
1.0

julia> f(1)
2.0
```

while

```
julia> g(x) = 2 * x
g (generic function with 1 method)

julia> g(1//2)
1//1

julia> g(1/2)
1.0

julia> g(1)
2
```

As you can see, the second version, where we used an `Int` literal, preserved the type of the input argument, while the first didn't. This is because e.g. `promote_type{Int, Float64} == Float64`, and promotion happens with the multiplication. Similarly, `Rational` literals are less type disruptive than `Float64` literals, but more disruptive than `Ints`:

```
julia> h(x) = 2//1 * x
h (generic function with 1 method)

julia> h(1//2)
1//1

julia> h(1/2)
1.0

julia> h(1)
2//1
```

Thus, use `Int` literals when possible, with `Rational{Int}` for literal non-integer numbers, in order to make it easier to use your code.

Chapter 37

Frequently Asked Questions

37.1 General

Is Julia named after someone or something?

No.

Why don't you compile Matlab/Python/R/... code to Julia?

Since many people are familiar with the syntax of other dynamic languages, and lots of code has already been written in those languages, it is natural to wonder why we didn't just plug a Matlab or Python front-end into a Julia back-end (or “transpile” code to Julia) in order to get all the performance benefits of Julia without requiring programmers to learn a new language. Simple, right?

The basic issue is that there is nothing special about Julia's compiler: we use a commonplace compiler (LLVM) with no “secret sauce” that other language developers don't know about. Indeed, Julia's compiler is in many ways much simpler than those of other dynamic languages (e.g. PyPy or LuaJIT). Julia's performance advantage derives almost entirely from its front-end: its language semantics allow a [well-written Julia program](#) to give more opportunities to the compiler to generate efficient code and memory layouts. If you tried to compile Matlab or Python code to Julia, our compiler would be limited by the semantics of Matlab or Python to producing code no better than that of existing compilers for those languages (and probably worse). The key role of semantics is also why several existing Python compilers (like Numba and Pythran) only attempt to optimize a small subset of the language (e.g. operations on Numpy arrays and scalars), and for this subset they are already doing at least as well as we could for the same semantics. The people working on those projects are incredibly smart and have accomplished amazing things, but retrofitting a compiler onto a language that was designed to be interpreted is a very difficult problem.

Julia's advantage is that good performance is not limited to a small subset of “built-in” types and operations, and one can write high-level type-generic code that works on arbitrary user-defined types while remaining fast and memory-efficient. Types in languages like Python simply don't provide enough information to the compiler for similar capabilities, so as soon as you used those languages as a Julia front-end you would be stuck.

For similar reasons, automated translation to Julia would also typically generate unreadable, slow, non-idiomatic code that would not be a good starting point for a native Julia port from another language.

On the other hand, language interoperability is extremely useful: we want to exploit existing high-quality code in other languages from Julia (and vice versa)! The best way to enable this is not a transpiler, but

rather via easy inter-language calling facilities. We have worked hard on this, from the built-in `ccall` intrinsic (to call C and Fortran libraries) to [JuliaInterop](#) packages that connect Julia to Python, Matlab, C++, and more.

37.2 Public API

How does Julia define its public API?

Julia Base and standard library functionality described in the [the documentation](#) that is not marked as unstable (e.g. experimental and internal) is covered by [SemVer](#). Functions, types, and constants are not part of the public API if they are not included in the documentation, even if they have docstrings.

There is a useful undocumented function/type/constant. Can I use it?

Updating Julia may break your code if you use non-public API. If the code is self-contained, it may be a good idea to copy it into your project. If you want to rely on a complex non-public API, especially when using it from a stable package, it is a good idea to open an [issue](#) or [pull request](#) to start a discussion for turning it into a public API. However, we do not discourage the attempt to create packages that expose stable public interfaces while relying on non-public implementation details of Julia and buffering the differences across different Julia versions.

The documentation is not accurate enough. Can I rely on the existing behavior?

Please open an [issue](#) or [pull request](#) to start a discussion for turning the existing behavior into a public API.

37.3 Sessions and the REPL

How do I delete an object in memory?

Julia does not have an analog of MATLAB's `clear` function; once a name is defined in a Julia session (technically, in module `Main`), it is always present.

If memory usage is your concern, you can always replace objects with ones that consume less memory. For example, if `A` is a gigabyte-sized array that you no longer need, you can free the memory with `A = nothing`. The memory will be released the next time the garbage collector runs; you can force this to happen with `GC.gc()`. Moreover, an attempt to use `A` will likely result in an error, because most methods are not defined on type `Nothing`.

How can I modify the declaration of a type in my session?

Perhaps you've defined a type and then realize you need to add a new field. If you try this at the REPL, you get the error:

```
| ERROR: invalid redefinition of constant MyType
```

Types in module `Main` cannot be redefined.

While this can be inconvenient when you are developing new code, there's an excellent workaround. Modules can be replaced by redefining them, and so if you wrap all your new code inside a module you can redefine types and constants. You can't import the type names into `Main` and then expect to be able to redefine them there, but you can use the module name to resolve the scope. In other words, while developing you might use a workflow something like this:

```
include("mynewcode.jl")           # this defines a module MyModule
obj1 = MyModule.ObjConstructor(a, b)
obj2 = MyModule.somefunction(obj1)
# Got an error. Change something in "mynewcode.jl"
include("mynewcode.jl")           # reload the module
obj1 = MyModule.ObjConstructor(a, b) # old objects are no longer valid, must reconstruct
obj2 = MyModule.somefunction(obj1)  # this time it worked!
obj3 = MyModule.someotherfunction(obj2, c)
...
```

37.4 Scripting

How do I check if the current file is being run as the main script?

When a file is run as the main script using `julia file.jl` one might want to activate extra functionality like command line argument handling. A way to determine that a file is run in this fashion is to check if `abspath(PROGRAM_FILE) == @__FILE__` is true.

However, it is recommended to not write files that double as a script and as an importable library. If one needs functionality both available as a library and a script, it is better to write it as a library, then import the functionality into a distinct script.

How do I catch CTRL-C in a script?

Running a Julia script using `julia file.jl` does not throw `InterruptException` when you try to terminate it with CTRL-C (SIGINT). To run a certain code before terminating a Julia script, which may or may not be caused by CTRL-C, use `atexit`. Alternatively, you can use `julia -e 'include(popfirst!(ARGS))' file.jl` to execute a script while being able to catch `InterruptException` in the `try` block. Note that with this strategy `PROGRAM_FILE` will not be set.

How do I pass options to julia using `#!/usr/bin/env`?

Passing options to `julia` in a so-called shebang line, as in `#!/usr/bin/env julia --startup-file=no`, will not work on many platforms (BSD, macOS, Linux) where the kernel, unlike the shell, does not split arguments at space characters. The option `env -S`, which splits a single argument string into multiple arguments at spaces, similar to a shell, offers a simple workaround:

```
#!/usr/bin/env -S julia --color=yes --startup-file=no
@show ARGS # put any Julia code here
```

Note

Option `env -S` appeared in FreeBSD 6.0 (2005), macOS Sierra (2016) and GNU/Linux coreutils 8.30 (2018).

Why doesn't `run` support `*` or pipes for scripting external programs?

Julia's `run` function launches external programs directly, without invoking an `operating-system shell` (unlike the `system("...")` function in other languages like Python, R, or C). That means that `run` does not perform wildcard expansion of `*` ("`globbing`"), nor does it interpret `shell pipelines` like `|` or `>`.

You can still do globbing and pipelines using Julia features, however. For example, the built-in [pipeline](#) function allows you to chain external programs and files, similar to shell pipes, and the [Glob.jl](#) package implements POSIX-compatible globbing.

You can, of course, run programs through the shell by explicitly passing a shell and a command string to run, e.g. `run(`sh -c "ls > files.txt"`)` to use the Unix [Bourne shell](#), but you should generally prefer pure-Julia scripting like `run(pipeline(`ls`, "files.txt"))`. The reason why we avoid the shell by default is that [shelling out sucks](#): launching processes via the shell is slow, fragile to quoting of special characters, has poor error handling, and is problematic for portability. (The Python developers came to a [similar conclusion](#).)

37.5 Variables and Assignments

Why am I getting `UndefVarError` from a simple loop?

You might have something like:

```
x = 0
while x < 10
    x += 1
end
```

and notice that it works fine in an interactive environment (like the Julia REPL), but gives `UndefVarError: `x` not defined` when you try to run it in script or other file. What is going on is that Julia generally requires you to **be explicit about assigning to global variables in a local scope**.

Here, `x` is a global variable, `while` defines a [local scope](#), and `x += 1` is an assignment to a global in that local scope.

As mentioned above, Julia (version 1.5 or later) allows you to omit the `global` keyword for code in the REPL (and many other interactive environments), to simplify exploration (e.g. copy-pasting code from a function to run interactively). However, once you move to code in files, Julia requires a more disciplined approach to global variables. You have at least three options:

1. Put the code into a function (so that `x` is a local variable in a function). In general, it is good software engineering to use functions rather than global scripts (search online for "why global variables bad" to see many explanations). In Julia, global variables are also [slow](#).
2. Wrap the code in a [let](#) block. (This makes `x` a local variable within the `let ... end` statement, again eliminating the need for `global`).
3. Explicitly mark `x` as `global` inside the local scope before assigning to it, e.g. write `global x += 1`.

More explanation can be found in the manual section [on soft scope](#).

37.6 Functions

I passed an argument `x` to a function, modified it inside that function, but on the outside, the variable `x` is still unchanged. Why?

Suppose you call a function like this:

```
julia> x = 10
10

julia> function change_value!(y)
    y = 17
end
change_value! (generic function with 1 method)

julia> change_value!(x)
17

julia> x # x is unchanged!
10
```

In Julia, the binding of a variable `x` cannot be changed by passing `x` as an argument to a function. When calling `change_value!(x)` in the above example, `y` is a newly created variable, bound initially to the value of `x`, i.e. 10; then `y` is rebound to the constant 17, while the variable `x` of the outer scope is left untouched.

However, if `x` is bound to an object of type `Array` (or any other mutable type). From within the function, you cannot "unbind" `x` from this `Array`, but you can change its content. For example:

```
julia> x = [1,2,3]
3-element Vector{Int64}:
 1
 2
 3

julia> function change_array!(A)
    A[1] = 5
end
change_array! (generic function with 1 method)

julia> change_array!(x)
5

julia> x
3-element Vector{Int64}:
 5
 2
 3
```

Here we created a function `change_array!`, that assigns 5 to the first element of the passed array (bound to `x` at the call site, and bound to `A` within the function). Notice that, after the function call, `x` is still bound to the same array, but the content of that array changed: the variables `A` and `x` were distinct bindings referring to the same mutable `Array` object.

Can I use `using` or `import` inside a function?

No, you are not allowed to have a `using` or `import` statement inside a function. If you want to import a module but only use its symbols inside a specific function or set of functions, you have two options:

1. Use `import`:

```
import Foo
function bar(...)
    # ... refer to Foo symbols via Foo.baz ...
end
```

This loads the module `Foo` and defines a variable `Foo` that refers to the module, but does not import any of the other symbols from the module into the current namespace. You refer to the `Foo` symbols by their qualified names `Foo.bar` etc.

2. Wrap your function in a module:

```
module Bar
export bar
using Foo
function bar(...)
    # ... refer to Foo.baz as simply baz ...
end
end
using Bar
```

This imports all the symbols from `Foo`, but only inside the module `Bar`.

What does the `...` operator do?

The two uses of the `...` operator: slurping and splatting

Many newcomers to Julia find the use of `...` operator confusing. Part of what makes the `...` operator confusing is that it means two different things depending on context.

`...` combines many arguments into one argument in function definitions

In the context of function definitions, the `...` operator is used to combine many different arguments into a single argument. This use of `...` for combining many different arguments into a single argument is called slurping:

```
julia> function printargs(args...)
    println(typeof(args))
    for (i, arg) in enumerate(args)
        println("Arg # $i$  =  $\$arg$ ")
    end
end
printargs (generic function with 1 method)

julia> printargs(1, 2, 3)
Tuple{Int64, Int64, Int64}
Arg #1 = 1
Arg #2 = 2
Arg #3 = 3
```

If Julia were a language that made more liberal use of ASCII characters, the slurping operator might have been written as `<-...` instead of `...`.

... splits one argument into many different arguments in function calls

In contrast to the use of the ... operator to denote slurping many different arguments into one argument when defining a function, the ... operator is also used to cause a single function argument to be split apart into many different arguments when used in the context of a function call. This use of ... is called *splatting*:

```
julia> function threeargs(a, b, c)
    println("a = $a::$(typeof(a))")
    println("b = $b::$(typeof(b))")
    println("c = $c::$(typeof(c))")
end
threeargs (generic function with 1 method)

julia> x = [1, 2, 3]
3-element Vector{Int64}:
 1
 2
 3

julia> threeargs(x...)
a = 1::Int64
b = 2::Int64
c = 3::Int64
```

If Julia were a language that made more liberal use of ASCII characters, the splatting operator might have been written as ...-> instead of ...

What is the return value of an assignment?

The operator = always returns the right-hand side, therefore:

```
julia> function threeint()
    x::Int = 3.0
    x # returns variable x
end
threeint (generic function with 1 method)

julia> function threefloat()
    x::Int = 3.0 # returns 3.0
end
threefloat (generic function with 1 method)

julia> threeint()
3

julia> threefloat()
3.0
```

and similarly:

```
julia> function twothreetup()
    x, y = [2, 3] # assigns 2 to x and 3 to y
    x, y # returns a tuple
end
twothreetup (generic function with 1 method)

julia> function twothreearr()
    x, y = [2, 3] # returns an array
end
twothreearr (generic function with 1 method)

julia> twothreetup()
(2, 3)

julia> twothreearr()
2-element Vector{Int64}:
 2
 3
```

37.7 Types, type declarations, and constructors

What does "type-stable" mean?

It means that the type of the output is predictable from the types of the inputs. In particular, it means that the type of the output cannot vary depending on the values of the inputs. The following code is not type-stable:

```
julia> function unstable(flag::Bool)
    if flag
        return 1
    else
        return 1.0
    end
end
unstable (generic function with 1 method)
```

It returns either an `Int` or a `Float64` depending on the value of its argument. Since Julia can't predict the return type of this function at compile-time, any computation that uses it must be able to cope with values of both types, which makes it hard to produce fast machine code.

Why does Julia give a `DomainError` for certain seemingly-sensible operations?

Certain operations make mathematical sense but result in errors:

```
julia> sqrt(-2.0)
ERROR: DomainError with -2.0:
sqrt was called with a negative real argument but will only return a complex result if called
↳ with a complex argument. Try sqrt(Complex(x)).
Stacktrace:
[...]
```

This behavior is an inconvenient consequence of the requirement for type-stability. In the case of `sqrt`, most users want `sqrt(2.0)` to give a real number, and would be unhappy if it produced the complex number `1.4142135623730951 + 0.0im`. One could write the `sqrt` function to switch to a complex-valued output only when passed a negative number (which is what `sqrt` does in some other languages), but then the result would not be `type-stable` and the `sqrt` function would have poor performance.

In these and other cases, you can get the result you want by choosing an input type that conveys your willingness to accept an output type in which the result can be represented:

```
julia> sqrt(-2.0+0im)
0.0 + 1.4142135623730951im
```

How can I constrain or compute type parameters?

The parameters of a `parametric type` can hold either types or bits values, and the type itself chooses how it makes use of these parameters. For example, `Array{Float64, 2}` is parameterized by the type `Float64` to express its element type and the integer value `2` to express its number of dimensions. When defining your own parametric type, you can use subtype constraints to declare that a certain parameter must be a subtype (`<:`) of some abstract type or a previous type parameter. There is not, however, a dedicated syntax to declare that a parameter must be a value of a given type — that is, you cannot directly declare that a dimensionality-like parameter `isa Int` within the struct definition, for example. Similarly, you cannot do computations (including simple things like addition or subtraction) on type parameters. Instead, these sorts of constraints and relationships may be expressed through additional type parameters that are computed and enforced within the type's `constructors`.

As an example, consider

```
struct ConstrainedType{T,N,N+1} # NOTE: INVALID SYNTAX
    A::Array{T,N}
    B::Array{T,N+1}
end
```

where the user would like to enforce that the third type parameter is always the second plus one. This can be implemented with an explicit type parameter that is checked by an `inner constructor method` (where it can be combined with other checks):

```
struct ConstrainedType{T,N,M}
    A::Array{T,N}
    B::Array{T,M}
    function ConstrainedType(A::Array{T,N}, B::Array{T,M}) where {T,N,M}
        N + 1 == M || throw(ArgumentError("second argument should have one more axis" ))
        new{T,N,M}(A, B)
    end
end
```

This check is usually costless, as the compiler can elide the check for valid concrete types. If the second argument is also computed, it may be advantageous to provide an `outer constructor method` that performs this calculation:

```
ConstrainedType(A) = ConstrainedType(A, compute_B(A))
```

Why does Julia use native machine integer arithmetic?

Julia uses machine arithmetic for integer computations. This means that the range of `Int` values is bounded and wraps around at either end so that adding, subtracting and multiplying integers can overflow or underflow, leading to some results that can be unsettling at first:

```
julia> x = typemax{Int}
9223372036854775807

julia> y = x+1
-9223372036854775808

julia> z = -y
-9223372036854775808

julia> 2*z
0
```

Clearly, this is far from the way mathematical integers behave, and you might think it less than ideal for a high-level programming language to expose this to the user. For numerical work where efficiency and transparency are at a premium, however, the alternatives are worse.

One alternative to consider would be to check each integer operation for overflow and promote results to bigger integer types such as `Int128` or `BigInt` in the case of overflow. Unfortunately, this introduces major overhead on every integer operation (think incrementing a loop counter) – it requires emitting code to perform run-time overflow checks after arithmetic instructions and branches to handle potential overflows. Worse still, this would cause every computation involving integers to be type-unstable. As we mentioned above, [type-stability is crucial](#) for effective generation of efficient code. If you can't count on the results of integer operations being integers, it's impossible to generate fast, simple code the way C and Fortran compilers do.

A variation on this approach, which avoids the appearance of type instability is to merge the `Int` and `BigInt` types into a single hybrid integer type, that internally changes representation when a result no longer fits into the size of a machine integer. While this superficially avoids type-instability at the level of Julia code, it just sweeps the problem under the rug by foisting all of the same difficulties onto the C code implementing this hybrid integer type. This approach can be made to work and can even be made quite fast in many cases, but has several drawbacks. One problem is that the in-memory representation of integers and arrays of integers no longer match the natural representation used by C, Fortran and other languages with native machine integers. Thus, to interoperate with those languages, we would ultimately need to introduce native integer types anyway. Any unbounded representation of integers cannot have a fixed number of bits, and thus cannot be stored inline in an array with fixed-size slots – large integer values will always require separate heap-allocated storage. And of course, no matter how clever a hybrid integer implementation one uses, there are always performance traps – situations where performance degrades unexpectedly. Complex representation, lack of interoperability with C and Fortran, the inability to represent integer arrays without additional heap storage, and unpredictable performance characteristics make even the cleverest hybrid integer implementations a poor choice for high-performance numerical work.

An alternative to using hybrid integers or promoting to `BigInts` is to use saturating integer arithmetic, where adding to the largest integer value leaves it unchanged and likewise for subtracting from the smallest integer value. This is precisely what Matlab™ does:

```
>> int64(9223372036854775807)
```

```

ans =

    9223372036854775807

>> int64(9223372036854775807) + 1

ans =

    9223372036854775807

>> int64(-9223372036854775808)

ans =

   -9223372036854775808

>> int64(-9223372036854775808) - 1

ans =

   -9223372036854775808

```

At first blush, this seems reasonable enough since 9223372036854775807 is much closer to 9223372036854775808 than -9223372036854775808 is and integers are still represented with a fixed size in a natural way that is compatible with C and Fortran. Saturated integer arithmetic, however, is deeply problematic. The first and most obvious issue is that this is not the way machine integer arithmetic works, so implementing saturated operations requires emitting instructions after each machine integer operation to check for underflow or overflow and replace the result with `typemin(Int)` or `typemax(Int)` as appropriate. This alone expands each integer operation from a single, fast instruction into half a dozen instructions, probably including branches. Ouch. But it gets worse – saturating integer arithmetic isn't associative. Consider this Matlab computation:

```

>> n = int64(2)^62
4611686018427387904

>> n + (n - 1)
9223372036854775807

>> (n + n) - 1
9223372036854775806

```

This makes it hard to write many basic integer algorithms since a lot of common techniques depend on the fact that machine addition with overflow is associative. Consider finding the midpoint between integer values `lo` and `hi` in Julia using the expression `(lo + hi) >>> 1`:

```

julia> n = 2^62
4611686018427387904

julia> (n + 2n) >>> 1
6917529027641081856

```

See? No problem. That's the correct midpoint between 2^{62} and 2^{63} , despite the fact that $n + 2n$ is -4611686018427387904. Now try it in Matlab:

```
>> (n + 2*n)/2

ans =

    4611686018427387904
```

Oops. Adding a `>>>` operator to Matlab wouldn't help, because saturation that occurs when adding n and $2n$ has already destroyed the information necessary to compute the correct midpoint.

Not only is lack of associativity unfortunate for programmers who cannot rely it for techniques like this, but it also defeats almost anything compilers might want to do to optimize integer arithmetic. For example, since Julia integers use normal machine integer arithmetic, LLVM is free to aggressively optimize simple little functions like $f(k) = 5k - 1$. The machine code for this function is just this:

```
julia> code_native(f, Tuple{Int})
.text
Filename: none
pushq %rbp
movq %rsp, %rbp
Source line: 1
leaq -1(%rdi,%rdi,4), %rax
popq %rbp
retq
nopl (%rax,%rax)
```

The actual body of the function is a single `leaq` instruction, which computes the integer multiply and add at once. This is even more beneficial when `f` gets inlined into another function:

```
julia> function g(k, n)
    for i = 1:n
        k = f(k)
    end
    return k
end
g (generic function with 1 methods)

julia> code_native(g, Tuple{Int,Int})
.text
Filename: none
pushq %rbp
movq %rsp, %rbp
Source line: 2
testq %rsi, %rsi
jle L26
nopl (%rax)
Source line: 3
L16:
leaq -1(%rdi,%rdi,4), %rdi
Source line: 2
```

```

    decq %rsi
    jne L16
Source line: 5
L26:
    movq %rdi, %rax
    popq %rbp
    retq
    nop

```

Since the call to `f` gets inlined, the loop body ends up being just a single `leaq` instruction. Next, consider what happens if we make the number of loop iterations fixed:

```

julia> function g(k)
    for i = 1:10
        k = f(k)
    end
    return k
end
g (generic function with 2 methods)

julia> code_native(g, (Int,))
.text
Filename: none
    pushq %rbp
    movq %rsp, %rbp
Source line: 3
    imulq $9765625, %rdi, %rax    # imm = 0x9502F9
    addq $-2441406, %rax         # imm = 0xFFDABF42
Source line: 5
    popq %rbp
    retq
    nopw %cs:(%rax,%rax)

```

Because the compiler knows that integer addition and multiplication are associative and that multiplication distributes over addition – neither of which is true of saturating arithmetic – it can optimize the entire loop down to just a multiply and an add. Saturated arithmetic completely defeats this kind of optimization since associativity and distributivity can fail at each loop iteration, causing different outcomes depending on which iteration the failure occurs in. The compiler can unroll the loop, but it cannot algebraically reduce multiple operations into fewer equivalent operations.

The most reasonable alternative to having integer arithmetic silently overflow is to do checked arithmetic everywhere, raising errors when adds, subtracts, and multiplies overflow, producing values that are not value-correct. In this [blog post](#), Dan Luu analyzes this and finds that rather than the trivial cost that this approach should in theory have, it ends up having a substantial cost due to compilers (LLVM and GCC) not gracefully optimizing around the added overflow checks. If this improves in the future, we could consider defaulting to checked integer arithmetic in Julia, but for now, we have to live with the possibility of overflow.

In the meantime, overflow-safe integer operations can be achieved through the use of external libraries such as [SaferIntegers.jl](#). Note that, as stated previously, the use of these libraries significantly increases the execution time of code using the checked integer types. However, for limited usage, this is far less of an issue than if it were used for all integer operations. You can follow the status of the discussion [here](#).

What are the possible causes of an `UndefVarError` during remote execution?

As the error states, an immediate cause of an `UndefVarError` on a remote node is that a binding by that name does not exist. Let us explore some of the possible causes.

```
julia> module Foo
    foo() = remotecall_fetch(x->x, 2, "Hello")
end

julia> Foo.foo()
ERROR: On worker 2:
UndefVarError: `Foo` not defined
Stacktrace:
[...]
```

The closure `x->x` carries a reference to `Foo`, and since `Foo` is unavailable on node 2, an `UndefVarError` is thrown.

Globals under modules other than `Main` are not serialized by value to the remote node. Only a reference is sent. Functions which create global bindings (except under `Main`) may cause an `UndefVarError` to be thrown later.

```
julia> @everywhere module Foo
    function foo()
        global gvar = "Hello"
        remotecall_fetch(()->gvar, 2)
    end
end

julia> Foo.foo()
ERROR: On worker 2:
UndefVarError: `gvar` not defined
Stacktrace:
[...]
```

In the above example, `@everywhere module Foo` defined `Foo` on all nodes. However the call to `Foo.foo()` created a new global binding `gvar` on the local node, but this was not found on node 2 resulting in an `UndefVarError` error.

Note that this does not apply to globals created under module `Main`. Globals under module `Main` are serialized and new bindings created under `Main` on the remote node.

```
julia> gvar_self = "Node1"
"Node1"

julia> remotecall_fetch(()->gvar_self, 2)
"Node1"

julia> remotecall_fetch(varinfo, 2)
name      size summary
-----
Base      Module
```

```
Core           Module
Main          Module
gvar_self 13 bytes String
```

This does not apply to function or struct declarations. However, anonymous functions bound to global variables are serialized as can be seen below.

```
julia> bar() = 1
bar (generic function with 1 method)

julia> remotecall_fetch(bar, 2)
ERROR: On worker 2:
UndefVarError: `#bar` not defined
[...]

julia> anon_bar = ()->1
(:#21) (generic function with 1 method)

julia> remotecall_fetch(anon_bar, 2)
1
```

37.8 Troubleshooting "method not matched": parametric type invariance and MethodErrors

Why doesn't it work to declare `foo(bar::Vector{Real}) = 42` and then call `foo([1])`?

As you'll see if you try this, the result is a `MethodError`:

```
julia> foo(x::Vector{Real}) = 42
foo (generic function with 1 method)

julia> foo([1])
ERROR: MethodError: no method matching foo(::Vector{Int64})

Closest candidates are:
  foo(!Matched::Vector{Real})
    @ Main none:1

Stacktrace:
[...]

```

This is because `Vector{Real}` is not a supertype of `Vector{Int}`! You can solve this problem with something like `foo(bar::Vector{T})` where `{T<:Real}` (or the short form `foo(bar::Vector{<:Real})` if the static parameter `T` is not needed in the body of the function). The `T` is a wild card: you first specify that it must be a subtype of `Real`, then specify the function takes a `Vector` of with elements of that type.

This same issue goes for any composite type `Comp`, not just `Vector`. If `Comp` has a parameter declared of type `Y`, then another type `Comp2` with a parameter of type `X<:Y` is not a subtype of `Comp`. This is type-invariance (by contrast, `Tuple` is type-covariant in its parameters). See [Parametric Composite Types](#) for more explanation of these.

Why does Julia use `*` for string concatenation? Why not `+` or something else?

The [main argument](#) against `+` is that string concatenation is not commutative, while `+` is generally used as a commutative operator. While the Julia community recognizes that other languages use different operators and `*` may be unfamiliar for some users, it communicates certain algebraic properties.

Note that you can also use `string(...)` to concatenate strings (and other values converted to strings); similarly, `repeat` can be used instead of `^` to repeat strings. The [interpolation syntax](#) is also useful for constructing strings.

37.9 Packages and Modules

What is the difference between "using" and "import"?

There are several differences between `using` and `import` (see the [Modules section](#)), but there is an important difference that may not seem intuitive at first glance, and on the surface (i.e. syntax-wise) it may seem very minor. When loading modules with `using`, you need to say `function Foo.bar(...` to extend module `Foo`'s function `bar` with a new method, but with `import Foo.bar`, you only need to say `function bar(...` and it automatically extends module `Foo`'s function `bar`.

The reason this is important enough to have been given separate syntax is that you don't want to accidentally extend a function that you didn't know existed, because that could easily cause a bug. This is most likely to happen with a method that takes a common type like a string or integer, because both you and the other module could define a method to handle such a common type. If you use `import`, then you'll replace the other module's implementation of `bar(s::AbstractString)` with your new implementation, which could easily do something completely different (and break all/future usages of the other functions in module `Foo` that depend on calling `bar`).

37.10 Nothingness and missing values

How does "null", "nothingness" or "missingness" work in Julia?

Unlike many languages (for example, C and Java), Julia objects cannot be "null" by default. When a reference (variable, object field, or array element) is uninitialized, accessing it will immediately throw an error. This situation can be detected using the `isdefined` or `isassigned` functions.

Some functions are used only for their side effects, and do not need to return a value. In these cases, the convention is to return the value `nothing`, which is just a singleton object of type `Nothing`. This is an ordinary type with no fields; there is nothing special about it except for this convention, and that the REPL does not print anything for it. Some language constructs that would not otherwise have a value also yield `nothing`, for example `if false; end`.

For situations where a value `x` of type `T` exists only sometimes, the `Union{T, Nothing}` type can be used for function arguments, object fields and array element types as the equivalent of [Nullable](#), [Option](#) or [Maybe](#) in other languages. If the value itself can be `nothing` (notably, when `T` is `Any`), the `Union{Some{T}, Nothing}` type is more appropriate since `x == nothing` then indicates the absence of a value, and `x == Some(nothing)` indicates the presence of a value equal to `nothing`. The [something](#) function allows unwrapping `Some` objects and using a default value instead of `nothing` arguments. Note that the compiler is able to generate efficient code when working with `Union{T, Nothing}` arguments or fields.

To represent missing data in the statistical sense (NA in R or NULL in SQL), use the [missing](#) object. See the [Missing Values](#) section for more details.

In some languages, the empty tuple `()` is considered the canonical form of nothingness. However, in Julia it is best thought of as just a regular tuple that happens to contain zero values.

The empty (or "bottom") type, written as `Union{}` (an empty union type), is a type with no values and no subtypes (except itself). You will generally not need to use this type.

37.11 Memory

Why does `x += y` allocate memory when `x` and `y` are arrays?

In Julia, `x += y` gets replaced during lowering by `x = x + y`. For arrays, this has the consequence that, rather than storing the result in the same location in memory as `x`, it allocates a new array to store the result. If you prefer to mutate `x`, use `x .+= y` to update each element individually.

While this behavior might surprise some, the choice is deliberate. The main reason is the presence of immutable objects within Julia, which cannot change their value once created. Indeed, a number is an immutable object; the statements `x = 5`; `x += 1` do not modify the meaning of 5, they modify the value bound to `x`. For an immutable, the only way to change the value is to reassign it.

To amplify a bit further, consider the following function:

```
function power_by_squaring(x, n::Int)
    ispow2(n) || error("This implementation only works for powers of 2")
    while n >= 2
        x *= x
        n >>= 1
    end
    x
end
```

After a call like `x = 5`; `y = power_by_squaring(x, 4)`, you would get the expected result: `x == 5` && `y == 625`. However, now suppose that `*`, when used with matrices, instead mutated the left hand side. There would be two problems:

- For general square matrices, `A = A*B` cannot be implemented without temporary storage: `A[1,1]` gets computed and stored on the left hand side before you're done using it on the right hand side.
- Suppose you were willing to allocate a temporary for the computation (which would eliminate most of the point of making `*` work in-place); if you took advantage of the mutability of `x`, then this function would behave differently for mutable vs. immutable inputs. In particular, for immutable `x`, after the call you'd have (in general) `y != x`, but for mutable `x` you'd have `y == x`.

Because supporting generic programming is deemed more important than potential performance optimizations that can be achieved by other means (e.g., using broadcasting or explicit loops), operators like `+=` and `*` work by rebinding new values.

37.12 Asynchronous IO and concurrent synchronous writes

Why do concurrent writes to the same stream result in inter-mixed output?

While the streaming I/O API is synchronous, the underlying implementation is fully asynchronous.

Consider the printed output from the following:

```
julia> @sync for i in 1:3
    @async write(stdout, string(i), " Foo ", " Bar ")
end
123 Foo  Foo  Foo  Bar  Bar  Bar
```

This is happening because, while the write call is synchronous, the writing of each argument yields to other tasks while waiting for that part of the I/O to complete.

print and println "lock" the stream during a call. Consequently changing write to println in the above example results in:

```
julia> @sync for i in 1:3
    @async println(stdout, string(i), " Foo ", " Bar ")
end
1 Foo  Bar
2 Foo  Bar
3 Foo  Bar
```

You can lock your writes with a ReentrantLock like this:

```
julia> l = ReentrantLock();

julia> @sync for i in 1:3
    @async begin
        lock(l)
        try
            write(stdout, string(i), " Foo ", " Bar ")
        finally
            unlock(l)
        end
    end
end
1 Foo  Bar 2 Foo  Bar 3 Foo  Bar
```

37.13 Arrays

What are the differences between zero-dimensional arrays and scalars?

Zero-dimensional arrays are arrays of the form `Array{T,0}`. They behave similar to scalars, but there are important differences. They deserve a special mention because they are a special case which makes logical sense given the generic definition of arrays, but might be a bit unintuitive at first. The following line defines a zero-dimensional array:

```
julia> A = zeros()
0-dimensional Array{Float64,0}:
0.0
```

In this example, `A` is a mutable container that contains one element, which can be set by `A[] = 1.0` and retrieved with `A[]`. All zero-dimensional arrays have the same size (`size(A) == ()`), and length (`length(A)`

`== 1`). In particular, zero-dimensional arrays are not empty. If you find this unintuitive, here are some ideas that might help to understand Julia's definition.

- Zero-dimensional arrays are the "point" to vector's "line" and matrix's "plane". Just as a line has no area (but still represents a set of things), a point has no length or any dimensions at all (but still represents a thing).
- We define `prod()` to be 1, and the total number of elements in an array is the product of the size. The size of a zero-dimensional array is `()`, and therefore its length is 1.
- Zero-dimensional arrays don't natively have any dimensions into which you index – they're just `A[]`. We can apply the same "trailing one" rule for them as for all other array dimensionalities, so you can indeed index them as `A[1]`, `A[1,1]`, etc; see [Omitted and extra indices](#).

It is also important to understand the differences to ordinary scalars. Scalars are not mutable containers (even though they are iterable and define things like `length`, `getindex`, e.g. `1[] == 1`). In particular, if `x = 0.0` is defined as a scalar, it is an error to attempt to change its value via `x[] = 1.0`. A scalar `x` can be converted into a zero-dimensional array containing it via `fill(x)`, and conversely, a zero-dimensional array `a` can be converted to the contained scalar via `a[]`. Another difference is that a scalar can participate in linear algebra operations such as `2 * rand(2,2)`, but the analogous operation with a zero-dimensional array `fill(2) * rand(2,2)` is an error.

Why are my Julia benchmarks for linear algebra operations different from other languages?

You may find that simple benchmarks of linear algebra building blocks like

```
using BenchmarkTools
A = randn(1000, 1000)
B = randn(1000, 1000)
@btime $A \ $B
@btime $A * $B
```

can be different when compared to other languages like Matlab or R.

Since operations like this are very thin wrappers over the relevant BLAS functions, the reason for the discrepancy is very likely to be

1. the BLAS library each language is using,
2. the number of concurrent threads.

Julia compiles and uses its own copy of OpenBLAS, with threads currently capped at 8 (or the number of your cores).

Modifying OpenBLAS settings or compiling Julia with a different BLAS library, eg [Intel MKL](#), may provide performance improvements. You can use [MKL.jl](#), a package that makes Julia's linear algebra use Intel MKL BLAS and LAPACK instead of OpenBLAS, or search the discussion forum for suggestions on how to set this up manually. Note that Intel MKL cannot be bundled with Julia, as it is not open source.

37.14 Computing cluster

How do I manage precompilation caches in distributed file systems?

When using Julia in high-performance computing (HPC) facilities with shared filesystems, it is recommended to use a shared depot (via the `JULIA_DEPOT_PATH` environment variable). Since Julia v1.10, multiple Julia processes on functionally similar workers and using the same depot will coordinate via pidfile locks to only spend effort precompiling on one process while the others wait. The precompilation process will indicate when the process is precompiling or waiting for another that is precompiling. If non-interactive the messages are via `@debug`.

However, due to caching of binary code, the cache rejection since v1.9 is more strict and users may need to set the `JULIA_CPU_TARGET` environment variable appropriately to get a single cache that is usable throughout the HPC environment.

37.15 Julia Releases

Do I want to use the Stable, LTS, or nightly version of Julia?

The Stable version of Julia is the latest released version of Julia, this is the version most people will want to run. It has the latest features, including improved performance. The Stable version of Julia is versioned according to [SemVer](#) as v1.x.y. A new minor release of Julia corresponding to a new Stable version is made approximately every 4-5 months after a few weeks of testing as a release candidate. Unlike the LTS version the Stable version will not normally receive bugfixes after another Stable version of Julia has been released. However, upgrading to the next Stable release will always be possible as each release of Julia v1.x will continue to run code written for earlier versions.

You may prefer the LTS (Long Term Support) version of Julia if you are looking for a very stable code base. The current LTS version of Julia is versioned according to SemVer as v1.6.x; this branch will continue to receive bugfixes until a new LTS branch is chosen, at which point the v1.6.x series will no longer receive regular bug fixes and all but the most conservative users will be advised to upgrade to the new LTS version series. As a package developer, you may prefer to develop for the LTS version, to maximize the number of users who can use your package. As per SemVer, code written for v1.0 will continue to work for all future LTS and Stable versions. In general, even if targeting the LTS, one can develop and run code in the latest Stable version, to take advantage of the improved performance; so long as one avoids using new features (such as added library functions or new methods).

You may prefer the nightly version of Julia if you want to take advantage of the latest updates to the language, and don't mind if the version available today occasionally doesn't actually work. As the name implies, releases to the nightly version are made roughly every night (depending on build infrastructure stability). In general nightly released are fairly safe to use—your code will not catch on fire. However, they may be occasional regressions and or issues that will not be found until more thorough pre-release testing. You may wish to test against the nightly version to ensure that such regressions that affect your use case are caught before a release is made.

Finally, you may also consider building Julia from source for yourself. This option is mainly for those individuals who are comfortable at the command line, or interested in learning. If this describes you, you may also be interested in reading our [guidelines for contributing](#).

Links to each of these download types can be found on the download page at <https://julialang.org/downloads/>. Note that not all versions of Julia are available for all platforms.

How can I transfer the list of installed packages after updating my version of Julia?

Each minor version of Julia has its own default [environment](#). As a result, upon installing a new minor version of Julia, the packages you added using the previous minor version will not be available by default. The environment for a given Julia version is defined by the files `Project.toml` and `Manifest.toml` in a folder matching the version number in `.julia/environments/`, for instance, `.julia/environments/v1.3`.

If you install a new minor version of Julia, say 1.4, and want to use in its default environment the same packages as in a previous version (e.g. 1.3), you can copy the contents of the file `Project.toml` from the 1.3 folder to 1.4. Then, in a session of the new Julia version, enter the "package management mode" by typing the key `]`, and run the command `instantiate`.

This operation will resolve a set of feasible packages from the copied file that are compatible with the target Julia version, and will install or update them if suitable. If you want to reproduce not only the set of packages, but also the versions you were using in the previous Julia version, you should also copy the `Manifest.toml` file before running the Pkg command `instantiate`. However, note that packages may define compatibility constraints that may be affected by changing the version of Julia, so the exact set of versions you had in 1.3 may not work for 1.4.

Chapter 38

Noteworthy Differences from other Languages

38.1 Noteworthy differences from MATLAB

Although MATLAB users may find Julia's syntax familiar, Julia is not a MATLAB clone. There are major syntactic and functional differences. The following are some noteworthy differences that may trip up Julia users accustomed to MATLAB:

- Julia arrays are indexed with square brackets, `A[i, j]`.
- Julia arrays are not copied when assigned to another variable. After `A = B`, changing elements of B will modify A as well. To avoid this, use `A = copy(B)`.
- Julia values are not copied when passed to a function. If a function modifies an array, the changes will be visible in the caller.
- Julia does not automatically grow arrays in an assignment statement. Whereas in MATLAB `a(4) = 3.2` can create the array `a = [0 0 0 3.2]` and `a(5) = 7` can grow it into `a = [0 0 0 3.2 7]`, the corresponding Julia statement `a[5] = 7` throws an error if the length of `a` is less than 5 or if this statement is the first use of the identifier `a`. Julia has [push!](#) and [append!](#), which grow Vectors much more efficiently than MATLAB's `a(end+1) = val`.
- The imaginary unit `sqrt(-1)` is represented in Julia as `im`, not `i` or `j` as in MATLAB.
- In Julia, literal numbers without a decimal point (such as 42) create integers instead of floating point numbers. As a result, some operations can throw a domain error if they expect a float; for example, `julia> a = -1; 2^a` throws a domain error, as the result is not an integer (see [the FAQ entry on domain errors](#) for details).
- In Julia, multiple values are returned and assigned as tuples, e.g. `(a, b) = (1, 2)` or `a, b = 1, 2`. MATLAB's `nargout`, which is often used in MATLAB to do optional work based on the number of returned values, does not exist in Julia. Instead, users can use optional and keyword arguments to achieve similar capabilities.
- Julia has true one-dimensional arrays. Column vectors are of size `N`, not `Nx1`. For example, `rand(N)` makes a 1-dimensional array.

- In Julia, `[x,y,z]` will always construct a 3-element array containing `x`, `y` and `z`.
 - To concatenate in the first ("vertical") dimension use either `vcat(x,y,z)` or separate with semicolons (`[x; y; z]`).
 - To concatenate in the second ("horizontal") dimension use either `hcat(x,y,z)` or separate with spaces (`[x y z]`).
 - To construct block matrices (concatenating in the first two dimensions), use either `hvcat` or combine spaces and semicolons (`[a b; c d]`).
- In Julia, `a:b` and `a:b:c` construct `AbstractRange` objects. To construct a full vector like in MATLAB, use `collect(a:b)`. Generally, there is no need to call `collect` though. An `AbstractRange` object will act like a normal array in most cases but is more efficient because it lazily computes its values. This pattern of creating specialized objects instead of full arrays is used frequently, and is also seen in functions such as `range`, or with iterators such as `enumerate`, and `zip`. The special objects can mostly be used as if they were normal arrays.
- Functions in Julia return values from their last expression or the `return` keyword instead of listing the names of variables to return in the function definition (see [The return Keyword](#) for details).
- A Julia script may contain any number of functions, and all definitions will be externally visible when the file is loaded. Function definitions can be loaded from files outside the current working directory.
- In Julia, reductions such as `sum`, `prod`, and `max` are performed over every element of an array when called with a single argument, as in `sum(A)`, even if `A` has more than one dimension.
- In Julia, parentheses must be used to call a function with zero arguments, like in `rand()`.
- Julia discourages the use of semicolons to end statements. The results of statements are not automatically printed (except at the interactive prompt), and lines of code do not need to end with semicolons. `println` or `@printf` can be used to print specific output.
- In Julia, if `A` and `B` are arrays, logical comparison operations like `A == B` do not return an array of booleans. Instead, use `A .== B`, and similarly for the other boolean operators like `<`, `>`.
- In Julia, the operators `&`, `|`, and `⊕` (`xor`) perform the bitwise operations equivalent to `and`, `or`, and `xor` respectively in MATLAB, and have precedence similar to Python's bitwise operators (unlike C). They can operate on scalars or element-wise across arrays and can be used to combine logical arrays, but note the difference in order of operations: parentheses may be required (e.g., to select elements of `A` equal to 1 or 2 use `(A .== 1) .| (A .== 2)`).
- In Julia, the elements of a collection can be passed as arguments to a function using the splat operator `...`, as in `xs=[1,2]; f(xs...)`.
- Julia's `svd` returns singular values as a vector instead of as a dense diagonal matrix.
- In Julia, `...` is not used to continue lines of code. Instead, incomplete expressions automatically continue onto the next line.
- In both Julia and MATLAB, the variable `ans` is set to the value of the last expression issued in an interactive session. In Julia, unlike MATLAB, `ans` is not set when Julia code is run in non-interactive mode.
- Julia's structs do not support dynamically adding fields at runtime, unlike MATLAB's `classes`. Instead, use a `Dict`. `Dict` in Julia isn't ordered.

- In Julia each module has its own global scope/namespace, whereas in MATLAB there is just one global scope.
- In MATLAB, an idiomatic way to remove unwanted values is to use logical indexing, like in the expression `x(x>3)` or in the statement `x(x>3) = []` to modify `x` in-place. In contrast, Julia provides the higher order functions `filter` and `filter!`, allowing users to write `filter(z->z>3, x)` and `filter!(z->z>3, x)` as alternatives to the corresponding transliterations `x[x.>3]` and `x = x[x.>3]`. Using `filter!` reduces the use of temporary arrays.
- The analogue of extracting (or "dereferencing") all elements of a cell array, e.g. in `vertcat(A{:})` in MATLAB, is written using the splat operator in Julia, e.g. as `vc{A...}`.
- In Julia, the adjoint function performs conjugate transposition; in MATLAB, `adjoint` provides the "adjugate" or classical adjoint, which is the transpose of the matrix of cofactors.
- In Julia, `a^b^c` is evaluated `a^(b^c)` while in MATLAB it's `(a^b)^c`.

38.2 Noteworthy differences from R

One of Julia's goals is to provide an effective language for data analysis and statistical programming. For users coming to Julia from R, these are some noteworthy differences:

- Julia's single quotes enclose characters, not strings.
- Julia can create substrings by indexing into strings. In R, strings must be converted into character vectors before creating substrings.
- In Julia, like Python but unlike R, strings can be created with triple quotes `""" ... """`. This syntax is convenient for constructing strings that contain line breaks.
- In Julia, varargs are specified using the splat operator `...`, which always follows the name of a specific variable, unlike R, for which `...` can occur in isolation.
- In Julia, modulus is `mod(a, b)`, not `a %% b`. `%` in Julia is the remainder operator.
- Julia constructs vectors using brackets. Julia's `[1, 2, 3]` is the equivalent of R's `c(1, 2, 3)`.
- In Julia, not all data structures support logical indexing. Furthermore, logical indexing in Julia is supported only with vectors of length equal to the object being indexed. For example:
 - In R, `c(1, 2, 3, 4)[c(TRUE, FALSE)]` is equivalent to `c(1, 3)`.
 - In R, `c(1, 2, 3, 4)[c(TRUE, FALSE, TRUE, FALSE)]` is equivalent to `c(1, 3)`.
 - In Julia, `[1, 2, 3, 4][[true, false]]` throws a `BoundsError`.
 - In Julia, `[1, 2, 3, 4][[true, false, true, false]]` produces `[1, 3]`.
- Like many languages, Julia does not always allow operations on vectors of different lengths, unlike R where the vectors only need to share a common index range. For example, `c(1, 2, 3, 4) + c(1, 2)` is valid R but the equivalent `[1, 2, 3, 4] + [1, 2]` will throw an error in Julia.
- Julia allows an optional trailing comma when that comma does not change the meaning of code. This can cause confusion among R users when indexing into arrays. For example, `x[1,]` in R would return the first row of a matrix; in Julia, however, the comma is ignored, so `x[1,] == x[1]`, and will return the first element. To extract a row, be sure to use `:`, as in `x[1, :]`.

- Julia's `map` takes the function first, then its arguments, unlike `lapply(<structure>, function, ...)` in R. Similarly Julia's equivalent of `apply(X, MARGIN, FUN, ...)` in R is `mapslices` where the function is the first argument.
- Multivariate apply in R, e.g. `mapply(choose, 11:13, 1:3)`, can be written as `broadcast(binomial, 11:13, 1:3)` in Julia. Equivalently Julia offers a shorter dot syntax for vectorizing functions `binomial.(11:13, 1:3)`.
- Julia uses `end` to denote the end of conditional blocks, like `if`, loop blocks, like `while/for`, and functions. In lieu of the one-line `if (cond)` statement, Julia allows statements of the form `if cond; statement; end`, `cond && statement` and `!cond || statement`. Assignment statements in the latter two syntaxes must be explicitly wrapped in parentheses, e.g. `cond && (x = value)`.
- In Julia, `<-`, `<<-` and `->` are not assignment operators.
- Julia's `->` creates an anonymous function.
- Julia's `*` operator can perform matrix multiplication, unlike in R. If `A` and `B` are matrices, then `A * B` denotes a matrix multiplication in Julia, equivalent to R's `A %*% B`. In R, this same notation would perform an element-wise (Hadamard) product. To get the element-wise multiplication operation, you need to write `A .* B` in Julia.
- Julia performs matrix transposition using the `transpose` function and conjugated transposition using the `'` operator or the `adjoint` function. Julia's `transpose(A)` is therefore equivalent to R's `t(A)`. Additionally a non-recursive transpose in Julia is provided by the `permutedims` function.
- Julia does not require parentheses when writing `if` statements or `for/while` loops: use `for i in [1, 2, 3]` instead of `for (i in c(1, 2, 3))` and `if i == 1` instead of `if (i == 1)`.
- Julia does not treat the numbers `0` and `1` as Booleans. You cannot write `if (1)` in Julia, because `if` statements accept only booleans. Instead, you can write `if true`, `if Bool(1)`, or `if 1==1`.
- Julia does not provide `nrow` and `ncol`. Instead, use `size(M, 1)` for `nrow(M)` and `size(M, 2)` for `ncol(M)`.
- Julia is careful to distinguish scalars, vectors and matrices. In R, `1` and `c(1)` are the same. In Julia, they cannot be used interchangeably.
- Julia's `diag` and `diagm` are not like R's.
- Julia cannot assign to the results of function calls on the left hand side of an assignment operation: you cannot write `diag(M) = fill(1, n)`.
- Julia discourages populating the main namespace with functions. Most statistical functionality for Julia is found in [packages](#) under the [JuliaStats organization](#). For example:
 - Functions pertaining to probability distributions are provided by the [Distributions package](#).
 - The [DataFrames package](#) provides data frames.
 - Generalized linear models are provided by the [GLM package](#).
- Julia provides tuples and real hash tables, but not R-style lists. When returning multiple items, you should typically use a tuple or a named tuple: instead of `list(a = 1, b = 2)`, use `(1, 2)` or `(a=1, b=2)`.

- Julia encourages users to write their own types, which are easier to use than S3 or S4 objects in R. Julia's multiple dispatch system means that `table(x::TypeA)` and `table(x::TypeB)` act like R's `table.TypeA(x)` and `table.TypeB(x)`.
- In Julia, values are not copied when assigned or passed to a function. If a function modifies an array, the changes will be visible in the caller. This is very different from R and allows new functions to operate on large data structures much more efficiently.
- In Julia, vectors and matrices are concatenated using `hcat`, `vcat` and `hvcat`, not `c`, `rbind` and `cbind` like in R.
- In Julia, a range like `a:b` is not shorthand for a vector like in R, but is a specialized `AbstractRange` object that is used for iteration. To convert a range into a vector, use `collect(a:b)`.
- The `:` operator has a different precedence in R and Julia. In particular, in Julia arithmetic operators have higher precedence than the `:` operator, whereas the reverse is true in R. For example, `1:n-1` in Julia is equivalent to `1:(n-1)` in R.
- Julia's `max` and `min` are the equivalent of `pmax` and `pmin` respectively in R, but both arguments need to have the same dimensions. While `maximum` and `minimum` replace `max` and `min` in R, there are important differences.
- Julia's `sum`, `prod`, `maximum`, and `minimum` are different from their counterparts in R. They all accept an optional keyword argument `dims`, which indicates the dimensions, over which the operation is carried out. For instance, let `A = [1 2; 3 4]` in Julia and `B <- rbind(c(1,2), c(3,4))` be the same matrix in R. Then `sum(A)` gives the same result as `sum(B)`, but `sum(A, dims=1)` is a row vector containing the sum over each column and `sum(A, dims=2)` is a column vector containing the sum over each row. This contrasts to the behavior of R, where separate `colSums(B)` and `rowSums(B)` functions provide these functionalities. If the `dims` keyword argument is a vector, then it specifies all the dimensions over which the sum is performed, while retaining the dimensions of the summed array, e.g. `sum(A, dims=(1,2)) == hcat(10)`. It should be noted that there is no error checking regarding the second argument.
- Julia has several functions that can mutate their arguments. For example, it has both `sort` and `sort!`.
- In R, performance requires vectorization. In Julia, almost the opposite is true: the best performing code is often achieved by using devectorized loops.
- Julia is eagerly evaluated and does not support R-style lazy evaluation. For most users, this means that there are very few unquoted expressions or column names.
- Julia does not support the `NULL` type. The closest equivalent is `nothing`, but it behaves like a scalar value rather than like a list. Use `x === nothing` instead of `is.null(x)`.
- In Julia, missing values are represented by the `missing` object rather than by `NA`. Use `ismissing(x)` (or `ismissing.(x)` for element-wise operation on vectors) instead of `is.na(x)`. The `skipmissing` function is generally used instead of `na.rm=TRUE` (though in some particular cases functions take a `skipmissing` argument).
- Julia lacks the equivalent of R's `assign` or `get`.
- In Julia, `return` does not require parentheses.

- In R, an idiomatic way to remove unwanted values is to use logical indexing, like in the expression `x[x>3]` or in the statement `x = x[x>3]` to modify `x` in-place. In contrast, Julia provides the higher order functions `filter` and `filter!`, allowing users to write `filter(z->z>3, x)` and `filter!(z->z>3, x)` as alternatives to the corresponding transliterations `x[x.>3]` and `x = x[x.>3]`. Using `filter!` reduces the use of temporary arrays.

38.3 Noteworthy differences from Python

- Julia's `for`, `if`, `while`, etc. blocks are terminated by the `end` keyword. Indentation level is not significant as it is in Python. Unlike Python, Julia has no `pass` keyword.
- Strings are denoted by double quotation marks (`"text"`) in Julia (with three double quotation marks for multi-line strings), whereas in Python they can be denoted either by single (`'text'`) or double quotation marks (`"text"`). Single quotation marks are used for characters in Julia (`'c'`).
- String concatenation is done with `*` in Julia, not `+` like in Python. Analogously, string repetition is done with `^`, not `*`. Implicit string concatenation of string literals like in Python (e.g. `'ab' 'cd' == 'abcd'`) is not done in Julia.
- Python Lists—flexible but slow—correspond to the Julia `Vector{Any}` type or more generally `Vector{T}` where `T` is some non-concrete element type. "Fast" arrays like NumPy arrays that store elements in-place (i.e., `dtype` is `np.float64`, `[('f1', np.uint64), ('f2', np.int32)]`, etc.) can be represented by `Array{T}` where `T` is a concrete, immutable element type. This includes built-in types like `Float64`, `Int32`, `Int64` but also more complex types like `Tuple{UInt64,Float64}` and many user-defined types as well.
- In Julia, indexing of arrays, strings, etc. is 1-based not 0-based.
- Julia's slice indexing includes the last element, unlike in Python. `a[2:3]` in Julia is `a[1:3]` in Python.
- Unlike Python, Julia allows `AbstractArrays` with `arbitrary indexes`. Python's special interpretation of negative indexing, `a[-1]` and `a[-2]`, should be written `a[end]` and `a[end-1]` in Julia.
- Julia requires `end` for indexing until the last element. `x[1:]` in Python is equivalent to `x[2:end]` in Julia.
- In Julia, `:` before any object creates a `Symbol` or quotes an expression; so, `x[:5]` is same as `x[5]`. If you want to get the first `n` elements of an array, then use range indexing.
- Julia's range indexing has the format of `x[start:step:stop]`, whereas Python's format is `x[start:(stop+1):step]`. Hence, `x[0:10:2]` in Python is equivalent to `x[1:2:10]` in Julia. Similarly, `x[::-1]` in Python, which refers to the reversed array, is equivalent to `x[end:-1:1]` in Julia.
- In Julia, ranges can be constructed independently as `start:step:stop`, the same syntax it uses in array-indexing. The `range` function is also supported.
- In Julia, indexing a matrix with arrays like `X[[1,2], [1,3]]` refers to a sub-matrix that contains the intersections of the first and second rows with the first and third columns. In Python, `X[[1,2], [1,3]]` refers to a vector that contains the values of cell `[1,1]` and `[2,3]` in the matrix. `X[[1,2], [1,3]]` in Julia is equivalent with `X[np.ix_([0,1], [0,2])]` in Python. `X[[0,1], [0,2]]` in Python is equivalent with `X[[CartesianIndex(1,1), CartesianIndex(2,3)]]` in Julia.

- Julia has no line continuation syntax: if, at the end of a line, the input so far is a complete expression, it is considered done; otherwise the input continues. One way to force an expression to continue is to wrap it in parentheses.
- Julia arrays are column-major (Fortran-ordered) whereas NumPy arrays are row-major (C-ordered) by default. To get optimal performance when looping over arrays, the order of the loops should be reversed in Julia relative to NumPy (see [relevant section of Performance Tips](#)).
- Julia's updating operators (e.g. `+=`, `-=`, ...) are not in-place whereas NumPy's are. This means `A = [1, 1]; B = A; B += [3, 3]` doesn't change values in A, it rather rebinds the name B to the result of the right-hand side `B = B + 3`, which is a new array. For in-place operation, use `B .+= 3` (see also [dot operators](#)), explicit loops, or `InplaceOps.jl`.
- Julia evaluates default values of function arguments every time the method is invoked, unlike in Python where the default values are evaluated only once when the function is defined. For example, the function `f(x=rand()) = x` returns a new random number every time it is invoked without argument. On the other hand, the function `g(x=[1,2]) = push!(x,3)` returns `[1,2,3]` every time it is called as `g()`.
- In Julia, keyword arguments must be passed using keywords, unlike Python in which it is usually possible to pass them positionally. Attempting to pass a keyword argument positionally alters the method signature leading to a `MethodError` or calling of the wrong method.
- In Julia `%` is the remainder operator, whereas in Python it is the modulus.
- In Julia, the commonly used `Int` type corresponds to the machine integer type (`Int32` or `Int64`), unlike in Python, where `int` is an arbitrary length integer. This means in Julia the `Int` type will overflow, such that `2^64 == 0`. If you need larger values use another appropriate type, such as `Int128`, [BigInt](#) or a floating point type like `Float64`.
- The imaginary unit `sqrt(-1)` is represented in Julia as `im`, not `j` as in Python.
- In Julia, the exponentiation operator is `^`, not `**` as in Python.
- Julia uses nothing of type `Nothing` to represent a null value, whereas Python uses `None` of type `NoneType`.
- In Julia, the standard operators over a matrix type are matrix operations, whereas, in Python, the standard operators are element-wise operations. When both A and B are matrices, `A * B` in Julia performs matrix multiplication, not element-wise multiplication as in Python. `A * B` in Julia is equivalent with `A @ B` in Python, whereas `A * B` in Python is equivalent with `A .* B` in Julia.
- The adjoint operator `'` in Julia returns an adjoint of a vector (a lazy representation of row vector), whereas the transpose operator `.T` over a vector in Python returns the original vector (non-op).
- In Julia, a function may contain multiple concrete implementations (called methods), which are selected via multiple dispatch based on the types of all arguments to the call, as compared to functions in Python, which have a single implementation and no polymorphism (as opposed to Python method calls which use a different syntax and allows dispatch on the receiver of the method).
- There are no classes in Julia. Instead there are structures (mutable or immutable), containing data but no methods.

- Calling a method of a class instance in Python (`x = MyClass(*args); x.f(y)`) corresponds to a function call in Julia, e.g. `x = MyType(args...); f(x, y)`. In general, multiple dispatch is more flexible and powerful than the Python class system.
- Julia structures may have exactly one abstract supertype, whereas Python classes can inherit from one or more (abstract or concrete) superclasses.
- The logical Julia program structure (Packages and Modules) is independent of the file structure (include for additional files), whereas the Python code structure is defined by directories (Packages) and files (Modules).
- The ternary operator `x > 0 ? 1 : -1` in Julia corresponds to a conditional expression in Python `if x > 0 else -1`.
- In Julia the `@` symbol refers to a macro, whereas in Python it refers to a decorator.
- Exception handling in Julia is done using `try — catch — finally`, instead of `try — except — finally`. In contrast to Python, it is not recommended to use exception handling as part of the normal workflow in Julia (compared with Python, Julia is faster at ordinary control flow but slower at exception-catching).
- In Julia loops are fast, there is no need to write "vectorized" code for performance reasons.
- Be careful with non-constant global variables in Julia, especially in tight loops. Since you can write close-to-metal code in Julia (unlike Python), the effect of globals can be drastic (see [Performance Tips](#)).
- In Julia, rounding and truncation are explicit. Python's `int(3.7)` should be `floor(Int, 3.7)` or `Int(floor(3.7))` and is distinguished from `round(Int, 3.7)`. `floor(x)` and `round(x)` on their own return an integer value of the same type as `x` rather than always returning `Int`.
- In Julia, parsing is explicit. Python's `float("3.7")` would be `parse(Float64, "3.7")` in Julia.
- In Python, the majority of values can be used in logical contexts (e.g. `if "a":` means the following block is executed, and `if "":` means it is not). In Julia, you need explicit conversion to `Bool` (e.g. `if "a" throws an exception`). If you want to test for a non-empty string in Julia, you would explicitly write `if !isempty("")`. Perhaps surprisingly, in Python `if "False"` and `bool("False")` both evaluate to `True` (because `"False"` is a non-empty string); in Julia, `parse(Bool, "false")` returns `false`.
- In Julia, a new local scope is introduced by most code blocks, including loops and `try — catch — finally`. Note that comprehensions (list, generator, etc.) introduce a new local scope both in Python and Julia, whereas `if` blocks do not introduce a new local scope in both languages.

38.4 Noteworthy differences from C/C++

- Julia arrays are indexed with square brackets, and can have more than one dimension `A[i, j]`. This syntax is not just syntactic sugar for a reference to a pointer or address as in C/C++. See [the manual entry about array construction](#).
- In Julia, indexing of arrays, strings, etc. is 1-based not 0-based.
- Julia arrays are not copied when assigned to another variable. After `A = B`, changing elements of `B` will modify `A` as well. Updating operators like `+=` do not operate in-place, they are equivalent to `A = A + B` which rebinds the left-hand side to the result of the right-hand side expression.

- Julia arrays are column major (Fortran ordered) whereas C/C++ arrays are row major ordered by default. To get optimal performance when looping over arrays, the order of the loops should be reversed in Julia relative to C/C++ (see [relevant section of Performance Tips](#)).
- Julia values are not copied when assigned or passed to a function. If a function modifies an array, the changes will be visible in the caller.
- In Julia, whitespace is significant, unlike C/C++, so care must be taken when adding/removing whitespace from a Julia program.
- In Julia, literal numbers without a decimal point (such as 42) create signed integers, of type `Int`, but literals too large to fit in the machine word size will automatically be promoted to a larger size type, such as `Int64` (if `Int` is `Int32`), `Int128`, or the arbitrarily large `BigInt` type. There are no numeric literal suffixes, such as `L`, `LL`, `U`, `UL`, `ULL` to indicate unsigned and/or signed vs. unsigned. Decimal literals are always signed, and hexadecimal literals (which start with `0x` like C/C++), are unsigned, unless when they encode more than 128 bits, in which case they are of type `BigInt`. Hexadecimal literals also, unlike C/C++/Java and unlike decimal literals in Julia, have a type based on the length of the literal, including leading 0s. For example, `0x0` and `0x00` have type `UInt8`, `0x000` and `0x0000` have type `UInt16`, then literals with 5 to 8 hex digits have type `UInt32`, 9 to 16 hex digits type `UInt64`, 17 to 32 hex digits type `UInt128`, and more than 32 hex digits type `BigInt`. This needs to be taken into account when defining hexadecimal masks, for example `~0xf == 0xf0` is very different from `~0x000f == 0xfff0`. 64 bit `Float64` and 32 bit `Float32` bit literals are expressed as `1.0` and `1.0f0` respectively. Floating point literals are rounded (and not promoted to the `BigFloat` type) if they can not be exactly represented. Floating point literals are closer in behavior to C/C++. Octal (prefixed with `0o`) and binary (prefixed with `0b`) literals are also treated as unsigned (or `BigInt` for more than 128 bits).
- In Julia, the division operator `/` returns a floating point number when both operands are of integer type. To perform integer division, use `div` or `÷`.
- Indexing an Array with floating point types is generally an error in Julia. The Julia equivalent of the C expression `a[i / 2]` is `a[i ÷ 2 + 1]`, where `i` is of integer type.
- String literals can be delimited with either `"` or `"""`, `"""` delimited literals can contain `"` characters without quoting it like `"\""`. String literals can have values of other variables or expressions interpolated into them, indicated by `$variablename` or `$(expression)`, which evaluates the variable name or the expression in the context of the function.
- `//` indicates a `Rational` number, and not a single-line comment (which is `#` in Julia)
- `#=` indicates the start of a multiline comment, and `#=` ends it.
- Functions in Julia return values from their last expression(s) or the `return` keyword. Multiple values can be returned from functions and assigned as tuples, e.g. `(a, b) = myfunction()` or `a, b = myfunction()`, instead of having to pass pointers to values as one would have to do in C/C++ (i.e. `a = myfunction(&b)`).
- Julia does not require the use of semicolons to end statements. The results of expressions are not automatically printed (except at the interactive prompt, i.e. the REPL), and lines of code do not need to end with semicolons. `println` or `@printf` can be used to print specific output. In the REPL, `;` can be used to suppress output. `;` also has a different meaning within `[]`, something to watch out for. `;` can be used to separate expressions on a single line, but are not strictly necessary in many cases, and are more an aid to readability.

- In Julia, the operator `⊔` (`xor`) performs the bitwise XOR operation, i.e. `^` in C/C++. Also, the bitwise operators do not have the same precedence as C/C++, so parenthesis may be required.
- Julia's `^` is exponentiation (`pow`), not bitwise XOR as in C/C++ (use `⊔`, or `xor`, in Julia)
- Julia has two right-shift operators, `>>` and `>>>`. `>>` performs an arithmetic shift, `>>>` always performs a logical shift, unlike C/C++, where the meaning of `>>` depends on the type of the value being shifted.
- Julia's `->` creates an anonymous function, it does not access a member via a pointer.
- Julia does not require parentheses when writing `if` statements or `for/while` loops: use `for i in [1, 2, 3]` instead of `for (int i=1; i <= 3; i++)` and `if i == 1` instead of `if (i == 1)`.
- Julia does not treat the numbers 0 and 1 as Booleans. You cannot write `if (1)` in Julia, because `if` statements accept only booleans. Instead, you can write `if true`, `if Bool(1)`, or `if 1==1`.
- Julia uses `end` to denote the end of conditional blocks, like `if`, loop blocks, like `while/ for`, and functions. In lieu of the one-line `if (cond) statement`, Julia allows statements of the form `if cond; statement; end`, `cond && statement` and `!cond || statement`. Assignment statements in the latter two syntaxes must be explicitly wrapped in parentheses, e.g. `cond && (x = value)`, because of the operator precedence.
- Julia has no line continuation syntax: if, at the end of a line, the input so far is a complete expression, it is considered done; otherwise the input continues. One way to force an expression to continue is to wrap it in parentheses.
- Julia macros operate on parsed expressions, rather than the text of the program, which allows them to perform sophisticated transformations of Julia code. Macro names start with the `@` character, and have both a function-like syntax, `@mymacro(arg1, arg2, arg3)`, and a statement-like syntax, `@mymacro arg1 arg2 arg3`. The forms are interchangeable; the function-like form is particularly useful if the macro appears within another expression, and is often clearest. The statement-like form is often used to annotate blocks, as in the distributed `for` construct: `@distributed for i in 1:n; #= body =#; end`. Where the end of the macro construct may be unclear, use the function-like form.
- Julia has an enumeration type, expressed using the macro `@enum(name, value1, value2, ...)` For example: `@enum(Fruit, banana=1, apple, pear)`
- By convention, functions that modify their arguments have a `!` at the end of the name, for example `push!`.
- In C++, by default, you have static dispatch, i.e. you need to annotate a function as `virtual`, in order to have dynamic dispatch. On the other hand, in Julia every method is "virtual" (although it's more general than that since methods are dispatched on every argument type, not only this, using the most-specific-declaration rule).

Julia ↔ C/C++: Namespaces

- C/C++ namespaces correspond roughly to Julia modules.
- There are no private globals or fields in Julia. Everything is publicly accessible through fully qualified paths (or relative paths, if desired).
- `using MyNamespace: myfun` (C++) corresponds roughly to `import MyModule: myfun` (Julia).

- `using namespace MyNamespace` (C++) corresponds roughly to `using MyModule` (Julia)
 - In Julia, only exported symbols are made available to the calling module.
 - In C++, only elements found in the included (public) header files are made available.
- Caveat: `import/using` keywords (Julia) also load modules (see below).
- Caveat: `import/using` (Julia) works only at the global scope level (modules)
 - In C++, `using namespace X` works within arbitrary scopes (ex: function scope).

Julia ⇔ C/C++: Module loading

- When you think of a C/C++ "**library**", you are likely looking for a Julia "**package**".
 - Caveat: C/C++ libraries often house multiple "software modules" whereas Julia "packages" typically house one.
 - Reminder: Julia modules are global scopes (not necessarily "software modules").
- **Instead of build/make scripts**, Julia uses "Project Environments" (sometimes called either "Project" or "Environment").
 - Build scripts are only needed for more complex applications (like those needing to compile or download C/C++ executables).
 - To develop application or project in Julia, you can initialize its root directory as a "Project Environment", and house application-specific code/packages there. This provides good control over project dependencies, and future reproducibility.
 - Available packages are added to a "Project Environment" with the `Pkg.add()` function or `Pkg.REPL` mode. (This does not **load** said package, however).
 - The list of available packages (direct dependencies) for a "Project Environment" are saved in its `Project.toml` file.
 - The full dependency information for a "Project Environment" is auto-generated & saved in its `Manifest.toml` file by `Pkg.resolve()`.
- Packages ("software modules") available to the "Project Environment" are loaded with `import` or `using`.
 - In C/C++, you `#include <moduleheader>` to get object/function declarations, and link in libraries when you build the executable.
 - In Julia, calling `using/import` again just brings the existing module into scope, but does not load it again (similar to adding the non-standard `#pragma once` to C/C++).
- **Directory-based package repositories** (Julia) can be made available by adding repository paths to the `Base.LOAD_PATH` array.
 - Packages from directory-based repositories do not require the `Pkg.add()` tool prior to being loaded with `import` or `using`. They are simply available to the project.
 - Directory-based package repositories are the **quickest solution** to developing local libraries of "software modules".

Julia ⇔ C/C++: Assembling modules

- In C/C++, `.c/.cpp` files are compiled & added to a library with build/make scripts.
 - In Julia, `import [PkgName]/using [PkgName]` statements load `[PkgName].jl` located in a package's `[PkgName]/src/` subdirectory.
 - In turn, `[PkgName].jl` typically loads associated source files with calls to `include "[someotherfile].jl"`.
- `include "./path/to/somefile.jl"` (Julia) is very similar to `#include "./path/to/somefile.jl"` (C/C++).
 - However `include "..."` (Julia) is not used to include header files (not required).
 - **Do not use** `include "..."` (Julia) to load code from other "software modules" (use `import/using` instead).
 - `include "path/to/some/module.jl"` (Julia) would instantiate multiple versions of the same code in different modules (creating distinct types (etc.) with the same names).
 - `include "somefile.jl"` is typically used to assemble multiple files within the same Julia package ("software module"). It is therefore relatively straightforward to ensure file are included only once (No `#ifdef` confusion).

Julia ⇔ C/C++: Module interface

- C++ exposes interfaces using "public" `.h/.hpp` files whereas Julia modules mark specific symbols that are intended for their users as public or exported.
 - Often, Julia modules simply add functionality by generating new "methods" to existing functions (ex: `Base.push!`).
 - Developers of Julia packages therefore cannot rely on header files for interface documentation.
 - Interfaces for Julia packages are typically described using docstrings, `README.md`, static web pages, ...
- Some developers choose not to export all symbols required to use their package/module.
 - Users might be expected to access these components by qualifying functions/structs/... with the package/module name (ex: `MyModule.run_this_task(...)`).

Julia ⇔ C/C++: Quick reference

* The Julia package manager supports registering multiple packages from a single Git repository.
 * This allows users to house a library of related packages in a single repository.
 ** Julia registries are primarily designed to provide versioning & distribution of packages.
 ** Custom package registries can be used to create a type of module library.

38.5 Noteworthy differences from Common Lisp

- Julia uses 1-based indexing for arrays by default, and it can also handle arbitrary [index offsets](#).
- Functions and variables share the same namespace ("Lisp-1").

| Software Concept | Julia | C/C++ |
|--------------------------------|---|---|
| unnamed scope | <code>begin ... end</code> | <code>{ ... }</code> |
| function scope | <code>function x() ... end</code> | <code>int x() { ... }</code> |
| global scope | <code>module MyMod ... end</code> | <code>namespace MyNS { ... }</code> |
| software module | A Julia "package" | <code>.h/.hpp</code> files
+compiled <code>somelib.a</code> |
| assembling
software modules | <code>SomePkg.jl:</code>
<code>...
import("subfile1.jl")
import("subfile2.jl")
...</code> | <code>\$(AR) *.o &rArr; somelib.a</code> |
| import
software module | <code>import SomePkg</code> | <code>#include</code>
<code><somelib>
+link in</code>
<code>somelib.a</code> |
| module library | <code>LOAD_PATH[]</code> , *Git repository,
**custom package registry | more <code>.h/.hpp</code> files
+bigger compiled <code>somebiglib.a</code> |

- There is a `Pair` type, but it is not meant to be used as a `COMMON-LISP:CONS`. Various iterable collections can be used interchangeably in most parts of the language (eg splatting, tuples, etc). Tuples are the closest to Common Lisp lists for short collections of heterogeneous elements. Use `NamedTuples` in place of `alists`. For larger collections of homogeneous types, `Arrays` and `Dicts` should be used.
- The typical Julia workflow for prototyping also uses continuous manipulation of the image, implemented with the `Revise.jl` package.
- For performance, Julia prefers that operations have `type stability`. Where Common Lisp abstracts away from the underlying machine operations, Julia cleaves closer to them. For example:
 - Integer division using `/` always returns a floating-point result, even if the computation is exact.
 - * `//` always returns a rational result
 - * `÷` always returns a (truncated) integer result
 - Bignums are supported, but conversion is not automatic; ordinary integers `overflow`.
 - Complex numbers are supported, but to get complex results, `you need complex inputs`.
 - There are multiple Complex and Rational types, with different component types.
- Modules (namespaces) can be hierarchical. `import` and `using` have a dual role: they load the code and make it available in the namespace. `import` for only the module name is possible (roughly equivalent to `ASDF:LOAD-OP`). Slot names don't need to be exported separately. Global variables can't be assigned to from outside the module (except with `eval(mod, :(var = val))` as an escape hatch).
- Macros start with `@`, and are not as seamlessly integrated into the language as Common Lisp; consequently, macro usage is not as widespread as in the latter. A form of hygiene for `macros` is supported by the language. Because of the different surface syntax, there is no equivalent to `COMMON-LISP:&BODY`.
- All functions are generic and use multiple dispatch. Argument lists don't have to follow the same template, which leads to a powerful idiom (see `do`). Optional and keyword arguments are handled differently. Method ambiguities are not resolved like in the Common Lisp Object System, necessitating the definition of a more specific method for the intersection.

- Symbols do not belong to any package, and do not contain any values per se. `M.var` evaluates the symbol `var` in the module `M`.
- A functional programming style is fully supported by the language, including closures, but isn't always the idiomatic solution for Julia. Some [workarounds](#) may be necessary for performance when modifying captured variables.

Chapter 39

Unicode Input

The following table lists Unicode characters that can be entered via tab completion of LaTeX-like abbreviations in the Julia REPL (and in various other editing environments). You can also get information on how to type a symbol by entering it in the REPL help, i.e. by typing `?` and then entering the symbol in the REPL (e.g., by copy-paste from somewhere you saw the symbol).

Warning

This table may appear to contain missing characters in the second column, or even show characters that are inconsistent with the characters as they are rendered in the Julia REPL. In these cases, users are strongly advised to check their choice of fonts in their browser and REPL environment, as there are known issues with glyphs in many fonts.

Chapter 40

Command-line Interface

40.1 Using arguments inside scripts

When running a script using `julia`, you can pass additional arguments to your script:

```
$ julia script.jl arg1 arg2...
```

These additional command-line arguments are passed in the global constant `ARGS`. The name of the script itself is passed in as the global `PROGRAM_FILE`. Note that `ARGS` is also set when a Julia expression is given using the `-e` option on the command line (see the `julia help` output below) but `PROGRAM_FILE` will be empty. For example, to just print the arguments given to a script, you could do this:

```
$ julia -e 'println(PROGRAM_FILE); for x in ARGS; println(x); end' foo bar
foo
bar
```

Or you could put that code into a script and run it:

```
$ echo 'println(PROGRAM_FILE); for x in ARGS; println(x); end' > script.jl
$ julia script.jl foo bar
script.jl
foo
bar
```

The `--` delimiter can be used to separate command-line arguments intended for the script file from arguments intended for Julia:

```
$ julia --color=yes -O -- script.jl arg1 arg2..
```

See also [Scripting](#) for more information on writing Julia scripts.

40.2 Parallel mode

Julia can be started in parallel mode with either the `-p` or the `--machine-file` options. `-p n` will launch an additional `n` worker processes, while `--machine-file file` will launch a worker for each line in file `file`. The machines defined in `file` must be accessible via a password-less `ssh` login, with Julia installed at the same location as the current host. Each machine definition takes the form `[count*][user@]host[:port]`

[bind_addr[:port]]. user defaults to current user, port to the standard ssh port. count is the number of workers to spawn on the node, and defaults to 1. The optional bind-to bind_addr[:port] specifies the IP address and port that other workers should use to connect to this worker.

40.3 Startup file

If you have code that you want executed whenever Julia is run, you can put it in `~/.julia/config/startup.jl`:

```
$ echo 'println("Greetings! ! ?")' > ~/.julia/config/startup.jl
$ julia
Greetings! ! ?
...

```

Note that although you should have a `~/.julia` directory once you've run Julia for the first time, you may need to create the `~/.julia/config` folder and the `~/.julia/config/startup.jl` file if you use it.

To have startup code run only in [The Julia REPL](#) (and not when julia is e.g. run on a script), use `atreplinit` in `startup.jl`:

```
atreplinit() do repl
    # ...
end

```

40.4 Command-line switches for Julia

There are various ways to run Julia code and provide options, similar to those available for the perl and ruby programs:

```
julia [switches] -- [programfile] [args...]
```

The following is a complete list of command-line switches available when launching julia (a '*' marks the default value, if applicable; settings marked '(\$)' may trigger package precompilation):

Julia 1.1

In Julia 1.0, the default `--project=@.` option did not search up from the root directory of a Git repository for the `Project.toml` file. From Julia 1.1 forward, it does.

| Switch | Description |
|----------------------------------|--|
| -v, --version | Display version information |
| -h, --help | Print command-line options (this message). |
| --help-hidden | Uncommon options not shown by -h |
| --project[={<dir> @.}] | Set <dir> as the home project/environment. The default @. option will search through parent directories until a Project.toml or JuliaProject.toml file is found. |
| -J, --sysimage <file> | Start up with the given system image file |
| -H, --home <dir> | Set location of julia executable |
| --startup-file={yes* no} | Load JULIA_DEPOT_PATH/config/startup.jl; if JULIA_DEPOT_PATH environment variable is unset, load ~/.julia/config/startup.jl |
| --handle-signals={yes* no} | Enable or disable Julia's default signal handlers |
| --sysimage-native-code={yes* no} | Use native code from system image if available |
| --compiled-modules={yes* no} | Enable or disable incremental precompilation of modules |
| --pkgimages={yes* no} | Enable or disable usage of native code caching in the form of pkgimages |
| -e, --eval <expr> | Evaluate <expr> |
| -E, --print <expr> | Evaluate <expr> and display the result |
| -L, --load <file> | Load <file> immediately on all processors |
| -t, --threads {N auto} | Enable N threads; auto tries to infer a useful default number of threads to use but the exact behavior might change in the future. Currently, auto uses the number of CPUs assigned to this julia process based on the OS-specific affinity assignment interface, if supported (Linux and Windows). If this is not supported (macOS) or process affinity is not configured, it uses the number of CPU threads. |
| --gcthreads=N[,M] | Use N threads for the mark phase of GC and M (0 or 1) threads for the concurrent sweeping phase of GC. N is set to half of the number of compute threads and M is set to 0 if unspecified. |
| -p, --procs {N auto} | Integer value N launches N additional local worker processes; auto launches as many workers as the number of local CPU threads (logical cores) |
| --machine-file <file> | Run processes on hosts listed in <file> |
| -i | Interactive mode; REPL runs and isinteractive() is true |
| -q, --quiet | Quiet startup: no banner, suppress REPL warnings |
| --banner={yes no auto*} | Enable or disable startup banner |
| --color={yes no auto*} | Enable or disable color text |
| --history-file={yes* no} | Load or save history |
| --depwarn={yes no error} | Enable or disable syntax and method deprecation warnings (error turns warnings into errors) |
| --warn-overwrite={yes no*} | Enable or disable method overwrite warnings |
| --warn-scope={yes* no} | Enable or disable warning for ambiguous top-level scope |
| -C, --cpu-target <target> | Limit usage of CPU features up to <target>; set to help to see the available options |
| -O, --optimize={0,1,2*,3} | Set the optimization level (level is 3 if -O is used without a level) (\$) |
| --min-optlevel={0*,1,2,3} | Set the lower bound on per-module optimization |
| -g, --debug-info={0,1*,2} | Set the level of debug info generation (level is 2 if -g is used without a level) (\$) |
| --inline={yes no} | Control whether inlining is permitted, including overriding @inline declarations |

Part II

Base

Chapter 41

Essentials

41.1 Introduction

Julia Base contains a range of functions and macros appropriate for performing scientific and numerical computing, but is also as broad as those of many general purpose programming languages. Additional functionality is available from a growing collection of [available packages](#). Functions are grouped by topic below.

Some general notes:

- To use module functions, use `import Module` to import the module, and `Module.fn(x)` to use the functions.
- Alternatively, using `Module` will import all exported `Module` functions into the current namespace.
- By convention, function names ending with an exclamation point (!) modify their arguments. Some functions have both modifying (e.g., `sort!`) and non-modifying (`sort`) versions.

The behaviors of Base and standard libraries are stable as defined in [SemVer](#) only if they are documented; i.e., included in the [Julia documentation](#) and not marked as unstable. See [API FAQ](#) for more information.

41.2 Getting Around

`Base.exit` - Function.

```
| exit(code=0)
```

Stop the program with an exit code. The default exit code is zero, indicating that the program completed successfully. In an interactive session, `exit()` can be called with the keyboard shortcut `^D`.

[source](#)

`Base.atexit` - Function.

```
| atexit(f)
```

Register a zero- or one-argument function `f()` to be called at process exit. `atexit()` hooks are called in last in first out (LIFO) order and run before object finalizers.

If `f` has a method defined for one integer argument, it will be called as `f(n::Int32)`, where `n` is the current exit code, otherwise it will be called as `f()`.

Julia 1.9

The one-argument form requires Julia 1.9

Exit hooks are allowed to call `exit(n)`, in which case Julia will exit with exit code `n` (instead of the original exit code). If more than one exit hook calls `exit(n)`, then Julia will exit with the exit code corresponding to the last called exit hook that calls `exit(n)`. (Because exit hooks are called in LIFO order, "last called" is equivalent to "first registered".)

Note: Once all exit hooks have been called, no more exit hooks can be registered, and any call to `atexit(f)` after all hooks have completed will throw an exception. This situation may occur if you are registering exit hooks from background Tasks that may still be executing concurrently during shutdown.

[source](#)

`Base.isinteractive` – Function.

```
| isinteractive() -> Bool
```

Determine whether Julia is running an interactive session.

[source](#)

`Base.summarysize` – Function.

```
| Base.summarysize(obj; exclude=Union{...}, chargeall=Union{...}) -> Int
```

Compute the amount of memory, in bytes, used by all unique objects reachable from the argument.

Keyword Arguments

- `exclude`: specifies the types of objects to exclude from the traversal.
- `chargeall`: specifies the types of objects to always charge the size of all of their fields, even if those fields would normally be excluded.

See also [sizeof](#).

Examples

```
| julia> Base.summarysize(1.0)
8
julia> Base.summarysize(Ref(rand(100)))
848
julia> sizeof(Ref(rand(100)))
8
```

[source](#)

`Base.__precompile__` – Function.

```
| __precompile__(isprecompilable::Bool)
```

Specify whether the file calling this function is precompilable, defaulting to `true`. If a module or file is not safely precompilable, it should call `__precompile__(false)` in order to throw an error if Julia attempts to precompile it.

[source](#)

`Base.include` – Function.

```
| Base.include([mapexpr::Function,] m::Module, path::AbstractString)
```

Evaluate the contents of the input source file in the global scope of module `m`. Every module (except those defined with `baremodule`) has its own definition of `include` omitting the `m` argument, which evaluates the file in that module. Returns the result of the last evaluated expression of the input file. During including, a task-local include path is set to the directory containing the file. Nested calls to `include` will search relative to that path. This function is typically used to load source interactively, or to combine files in packages that are broken into multiple source files.

The optional first argument `mapexpr` can be used to transform the included code before it is evaluated: for each parsed expression `expr` in `path`, the `include` function actually evaluates `mapexpr(expr)`. If it is omitted, `mapexpr` defaults to `identity`.

Julia 1.5

Julia 1.5 is required for passing the `mapexpr` argument.

[source](#)

`Base.MainInclude.include` – Function.

```
| include([mapexpr::Function,] path::AbstractString)
```

Evaluate the contents of the input source file in the global scope of the containing module. Every module (except those defined with `baremodule`) has its own definition of `include`, which evaluates the file in that module. Returns the result of the last evaluated expression of the input file. During including, a task-local include path is set to the directory containing the file. Nested calls to `include` will search relative to that path. This function is typically used to load source interactively, or to combine files in packages that are broken into multiple source files. The argument `path` is normalized using `normpath` which will resolve relative path tokens such as `..` and convert `/` to the appropriate path separator.

The optional first argument `mapexpr` can be used to transform the included code before it is evaluated: for each parsed expression `expr` in `path`, the `include` function actually evaluates `mapexpr(expr)`. If it is omitted, `mapexpr` defaults to `identity`.

Use `Base.include` to evaluate a file into another module.

Julia 1.5

Julia 1.5 is required for passing the `mapexpr` argument.

[source](#)

Base.include_string - Function.

```
| include_string([mapexpr::Function,] m::Module, code::AbstractString,  
| ↪ filename::AbstractString="string")
```

Like `include`, except reads code from the given string rather than from a file.

The optional first argument `mapexpr` can be used to transform the included code before it is evaluated: for each parsed expression `expr` in code, the `include_string` function actually evaluates `mapexpr(expr)`. If it is omitted, `mapexpr` defaults to `identity`.

Julia 1.5

Julia 1.5 is required for passing the `mapexpr` argument.

[source](#)

Base.include_dependency - Function.

```
| include_dependency(path::AbstractString)
```

In a module, declare that the file, directory, or symbolic link specified by `path` (relative or absolute) is a dependency for precompilation; that is, the module will need to be recompiled if the modification time of `path` changes.

This is only needed if your module depends on a path that is not used via `include`. It has no effect outside of compilation.

[source](#)

__init__ - Keyword.

```
| __init__
```

The `__init__()` function in a module executes immediately after the module is loaded at runtime for the first time. It is called once, after all other statements in the module have been executed. Because it is called after fully importing the module, `__init__` functions of submodules will be executed first. Two typical uses of `__init__` are calling runtime initialization functions of external C libraries and initializing global constants that involve pointers returned by external libraries. See the [manual section about modules](#) for more details.

Examples

```
| const foo_data_ptr = Ref{Ptr{Cvoid}}{0}  
| function __init__()  
|     ccall(:foo_init, :libfoo, Cvoid, ())  
|     foo_data_ptr[] = ccall(:foo_data, :libfoo, Ptr{Cvoid}, ())  
|     nothing  
| end
```

[source](#)

Base.which - Method.

```
| which(f, types)
```

Returns the method of `f` (a Method object) that would be called for arguments of the given types.

If `types` is an abstract type, then the method that would be called by `invoke` is returned.

See also: [parentmodule](#), and `@which` and `@edit` in [InteractiveUtils](#).

[source](#)

`Base.methods` – Function.

```
| methods(f, [types], [module])
```

Return the method table for `f`.

If `types` is specified, return an array of methods whose types match. If `module` is specified, return an array of methods defined in that module. A list of modules can also be specified as an array.

Julia 1.4

At least Julia 1.4 is required for specifying a module.

See also: [which](#) and `@which`.

[source](#)

`Base.@show` – Macro.

```
| @show exs...
```

Prints one or more expressions, and their results, to `stdout`, and returns the last result.

See also: [show](#), [@info](#), [println](#).

Examples

```
julia> x = @show 1+2
1 + 2 = 3
3

julia> @show x^2 x/2;
x ^ 2 = 9
x / 2 = 1.5
```

[source](#)

`Base.MainInclude.ans` – Constant.

```
| ans
```

A variable referring to the last computed value, automatically imported to the interactive prompt.

[source](#)

`Base.MainInclude.err` – Constant.

```
| err
```

A variable referring to the last thrown errors, automatically imported to the interactive prompt. The thrown errors are collected in a stack of exceptions.

`source`

`Base.active_project` – Function.

```
| active_project()
```

Return the path of the active `Project.toml` file. See also `Base.set_active_project`.

`source`

`Base.set_active_project` – Function.

```
| set_active_project(projfile::Union{AbstractString,Nothing})
```

Set the active `Project.toml` file to `projfile`. See also `Base.active_project`.

Julia 1.8

This function requires at least Julia 1.8.

`source`

41.3 Keywords

This is the list of reserved keywords in Julia: `baremodule`, `begin`, `break`, `catch`, `const`, `continue`, `do`, `else`, `elseif`, `end`, `export`, `false`, `finally`, `for`, `function`, `global`, `if`, `import`, `let`, `local`, `macro`, `module`, `quote`, `return`, `struct`, `true`, `try`, `using`, `while`. Those keywords are not allowed to be used as variable names.

The following two-word sequences are reserved: `abstract type`, `mutable struct`, `primitive type`. However, you can create variables with names: `abstract`, `mutable`, `primitive` and `type`.

Finally: `where` is parsed as an infix operator for writing parametric method and type definitions; `in` and `isa` are parsed as infix operators; `outer` is parsed as a keyword when used to modify the scope of a variable in an iteration specification of a `for` loop; and `as` is used as a keyword to rename an identifier brought into scope by `import` or `using`. Creation of variables named `where`, `in`, `isa`, `outer` and `as` is allowed, though.

`module` – Keyword.

```
| module
```

`module` declares a `Module`, which is a separate global variable workspace. Within a module, you can control which names from other modules are visible (via importing), and specify which of your names are intended to be public (via exporting). Modules allow you to create top-level definitions without worrying about name conflicts when your code is used together with somebody else's. See the [manual section about modules](#) for more details.

Examples

```
| module Foo
| import Base.show
| export MyType, foo
```

```

struct MyType
    x
end

bar(x) = 2x
foo(a::MyType) = bar(a.x) + 1
show(io::IO, a::MyType) = print(io, "MyType $(a.x)")
end

```

source

export – Keyword.

```
| export
```

export is used within modules to tell Julia which functions should be made available to the user. For example: `export foo` makes the name `foo` available when [using](#) the module. See the [manual section about modules](#) for details.

source

import – Keyword.

```
| import
```

`import Foo` will load the module or package `Foo`. Names from the imported `Foo` module can be accessed with dot syntax (e.g. `Foo.foo` to access the name `foo`). See the [manual section about modules](#) for details.

source

using – Keyword.

```
| using
```

`using Foo` will load the module or package `Foo` and make its [exported](#) names available for direct use. Names can also be used via dot syntax (e.g. `Foo.foo` to access the name `foo`), whether they are exported or not. See the [manual section about modules](#) for details.

source

as – Keyword.

```
| as
```

`as` is used as a keyword to rename an identifier brought into scope by `import` or `using`, for the purpose of working around name conflicts as well as for shortening names. (Outside of `import` or `using` statements, `as` is not a keyword and can be used as an ordinary identifier.)

`import LinearAlgebra as LA` brings the imported `LinearAlgebra` standard library into scope as `LA`.

`import LinearAlgebra: eigen as eig, cholesky as chol` brings the `eigen` and `cholesky` methods from `LinearAlgebra` into scope as `eig` and `chol` respectively.

as works with using only when individual identifiers are brought into scope. For example, using `LinearAlgebra: eigen as eig` or using `LinearAlgebra: eigen as eig, cholesky as chol` works, but using `LinearAlgebra as LA` is invalid syntax, since it is nonsensical to rename all exported names from `LinearAlgebra` to `LA`.

[source](#)

`baremodule` – Keyword.

```
| baremodule
```

`baremodule` declares a module that does not contain using Base or local definitions of `eval` and `include`. It does still import Core. In other words,

```
| module Mod
| ...
| end
```

is equivalent to

```
| baremodule Mod
|
| using Base
|
| eval(x) = Core.eval(Mod, x)
| include(p) = Base.include(Mod, p)
|
| ...
| end
```

[source](#)

`function` – Keyword.

```
| function
```

Functions are defined with the `function` keyword:

```
| function add(a, b)
|     return a + b
| end
```

Or the short form notation:

```
| add(a, b) = a + b
```

The use of the `return` keyword is exactly the same as in other languages, but is often optional. A function without an explicit return statement will return the last expression in the function body.

[source](#)

macro – Keyword.

```
| macro
```

macro defines a method for inserting generated code into a program. A macro maps a sequence of argument expressions to a returned expression, and the resulting expression is substituted directly into the program at the point where the macro is invoked. Macros are a way to run generated code without calling `eval`, since the generated code instead simply becomes part of the surrounding program. Macro arguments may include expressions, literal values, and symbols. Macros can be defined for variable number of arguments (varargs), but do not accept keyword arguments. Every macro also implicitly gets passed the arguments `__source__`, which contains the line number and file name the macro is called from, and `__module__`, which is the module the macro is expanded in.

See the manual section on [Metaprogramming](#) for more information about how to write a macro.

Examples

```
julia> macro sayhello(name)
    return :( println("Hello, ", $name, "!") )
end
@sayhello (macro with 1 method)

julia> @sayhello "Charlie"
Hello, Charlie!

julia> macro saylots(x...)
    return :( println("Say: ", $(x...)) )
end
@saylots (macro with 1 method)

julia> @saylots "hey " "there " "friend"
Say: hey there friend
```

```
source
```

return – Keyword.

```
| return
```

return x causes the enclosing function to exit early, passing the given value x back to its caller. return by itself with no value is equivalent to return nothing (see [nothing](#)).

```
function compare(a, b)
    a == b && return "equal to"
    a < b ? "less than" : "greater than"
end
```

In general you can place a return statement anywhere within a function body, including within deeply nested loops or conditionals, but be careful with do blocks. For example:

```
function test1(xs)
    for x in xs
        iseven(x) && return 2x
    end
end
```

```

    end
end

function test2(xs)
    map(xs) do x
        iseven(x) && return 2x
    end
end

```

In the first example, the return breaks out of test1 as soon as it hits an even number, so test1([5,6,7]) returns 12.

You might expect the second example to behave the same way, but in fact the return there only breaks out of the inner function (inside the do block) and gives a value back to map. test2([5,6,7]) then returns [5,12,7].

When used in a top-level expression (i.e. outside any function), return causes the entire current top-level expression to terminate early.

[source](#)

do – Keyword.

```
do
```

Create an anonymous function and pass it as the first argument to a function call. For example:

```

map(1:10) do x
    2x
end

```

is equivalent to map(x->2x, 1:10).

Use multiple arguments like so:

```

map(1:10, 11:20) do x, y
    x + y
end

```

[source](#)

begin – Keyword.

```
begin
```

begin...end denotes a block of code.

```

begin
    println("Hello, ")
    println("World!")
end

```

Usually `begin` will not be necessary, since keywords such as `function` and `let` implicitly begin blocks of code. See also `;`.

`begin` may also be used when indexing to represent the first index of a collection or the first index of a dimension of an array.

Examples

```
julia> A = [1 2; 3 4]
2×2 Array{Int64,2}:
 1  2
 3  4

julia> A[begin, :]
2-element Array{Int64,1}:
 1
 2
```

[source](#)

`end` – Keyword.

```
| end
```

`end` marks the conclusion of a block of expressions, for example `module`, `struct`, `mutable struct`, `begin`, `let`, `for` etc.

`end` may also be used when indexing to represent the last index of a collection or the last index of a dimension of an array.

Examples

```
julia> A = [1 2; 3 4]
2×2 Array{Int64, 2}:
 1  2
 3  4

julia> A[end, :]
2-element Array{Int64, 1}:
 3
 4
```

[source](#)

`let` – Keyword.

```
| let
```

`let` blocks create a new hard scope and optionally introduce new local bindings.

Just like the [other scope constructs](#), `let` blocks define the block of code where newly introduced local variables are accessible. Additionally, the syntax has a special meaning for comma-separated assignments and variable names that may optionally appear on the same line as the `let`:

```

let var1 = value1, var2, var3 = value3
    code
end

```

The variables introduced on this line are local to the `let` block and the assignments are evaluated in order, with each right-hand side evaluated in the scope without considering the name on the left-hand side. Therefore it makes sense to write something like `let x = x`, since the two `x` variables are distinct with the left-hand side locally shadowing the `x` from the outer scope. This can even be a useful idiom as new local variables are freshly created each time local scopes are entered, but this is only observable in the case of variables that outlive their scope via closures. A `let` variable without an assignment, such as `var2` in the example above, declares a new local variable that is not yet bound to a value.

By contrast, `begin` blocks also group multiple expressions together but do not introduce scope or have the special assignment syntax.

Examples

In the function below, there is a single `x` that is iteratively updated three times by the `map`. The closures returned all reference that one `x` at its final value:

```

julia> function test_outer_x()
    x = 0
    map(1:3) do _
        x += 1
        return ()->x
    end
end

test_outer_x (generic function with 1 method)

julia> [f() for f in test_outer_x()]
3-element Vector{Int64}:
 3
 3
 3

```

If, however, we add a `let` block that introduces a new local variable we will end up with three distinct variables being captured (one at each iteration) even though we chose to use (shadow) the same name.

```

julia> function test_let_x()
    x = 0
    map(1:3) do _
        x += 1
        let x = x
            return ()->x
        end
    end
end

test_let_x (generic function with 1 method)

julia> [f() for f in test_let_x()]
3-element Vector{Int64}:
 1
 2
 3

```

All scope constructs that introduce new local variables behave this way when repeatedly run; the distinctive feature of `let` is its ability to succinctly declare new locals that may shadow outer variables of the same name. For example, directly using the argument of the `do` function similarly captures three distinct variables:

```
julia> function test_do_x()
    map(1:3) do x
        return ()->x
    end
end
test_do_x (generic function with 1 method)

julia> [f() for f in test_do_x()]
3-element Vector{Int64}:
 1
 2
 3
```

[source](#)

`if` – Keyword.

```
| if/elseif/else
```

`if/elseif/else` performs conditional evaluation, which allows portions of code to be evaluated or not evaluated depending on the value of a boolean expression. Here is the anatomy of the `if/elseif/else` conditional syntax:

```
| if x < y
    println("x is less than y")
elseif x > y
    println("x is greater than y")
else
    println("x is equal to y")
end
```

If the condition expression `x < y` is true, then the corresponding block is evaluated; otherwise the condition expression `x > y` is evaluated, and if it is true, the corresponding block is evaluated; if neither expression is true, the `else` block is evaluated. The `elseif` and `else` blocks are optional, and as many `elseif` blocks as desired can be used.

In contrast to some other languages conditions must be of type `Bool`. It does not suffice for conditions to be convertible to `Bool`.

```
julia> if 1 end
ERROR: TypeError: non-boolean (Int64) used in boolean context
```

[source](#)

`for` – Keyword.

```
| for
```

for loops repeatedly evaluate a block of statements while iterating over a sequence of values.

The iteration variable is always a new variable, even if a variable of the same name exists in the enclosing scope. Use `outer` to reuse an existing local variable for iteration.

Examples

```
julia> for i in [1, 4, 0]
    println(i)
end
1
4
0
```

[source](#)

while - Keyword.

```
while
```

while loops repeatedly evaluate a conditional expression, and continue evaluating the body of the while loop as long as the expression remains true. If the condition expression is false when the while loop is first reached, the body is never evaluated.

Examples

```
julia> i = 1
1

julia> while i < 5
    println(i)
    global i += 1
end
1
2
3
4
```

[source](#)

break - Keyword.

```
break
```

Break out of a loop immediately.

Examples

```
julia> i = 0
0

julia> while true
    global i += 1
    i > 5 && break
    println(i)
end
```

```

    end
1
2
3
4
5

```

source

continue - Keyword.

```

| continue

```

Skip the rest of the current loop iteration.

Examples

```

julia> for i = 1:6
        iseven(i) && continue
        println(i)
    end
1
3
5

```

source

try - Keyword.

```

| try/catch

```

A try/catch statement allows intercepting errors (exceptions) thrown by `throw` so that program execution can continue. For example, the following code attempts to write a file, but warns the user and proceeds instead of terminating execution if the file cannot be written:

```

try
    open("/danger", "w") do f
        println(f, "Hello")
    end
catch
    @warn "Could not write file."
end

```

or, when the file cannot be read into a variable:

```

lines = try
    open("/danger", "r") do f
        readlines(f)
    end
catch
    @warn "File not found."
end

```

The syntax `catch e` (where `e` is any variable) assigns the thrown exception object to the given variable within the `catch` block.

The power of the `try/catch` construct lies in the ability to unwind a deeply nested computation immediately to a much higher level in the stack of calling functions.

[source](#)

`finally` – Keyword.

| `finally`

Run some code when a given block of code exits, regardless of how it exits. For example, here is how we can guarantee that an opened file is closed:

```
f = open("file")
try
  operate_on_file(f)
finally
  close(f)
end
```

When control leaves the `try` block (for example, due to a `return`, or just finishing normally), `close(f)` will be executed. If the `try` block exits due to an exception, the exception will continue propagating. A `catch` block may be combined with `try` and `finally` as well. In this case the `finally` block will run after `catch` has handled the error.

[source](#)

`quote` – Keyword.

| `quote`

`quote` creates multiple expression objects in a block without using the explicit `Expr` constructor. For example:

```
ex = quote
  x = 1
  y = 2
  x + y
end
```

Unlike the other means of quoting, `:(...)`, this form introduces `QuoteNode` elements to the expression tree, which must be considered when directly manipulating the tree. For other purposes, `:(...)` and `quote ... end` blocks are treated identically.

[source](#)

`local` – Keyword.

| `local`

`local` introduces a new local variable. See the [manual section on variable scoping](#) for more information.

Examples

```
julia> function foo(n)
    x = 0
    for i = 1:n
        local x # introduce a loop-local x
        x = i
    end
    x
end
foo (generic function with 1 method)

julia> foo(10)
0
```

[source](#)

global – Keyword.

```
| global
```

global x makes x in the current scope and its inner scopes refer to the global variable of that name. See the [manual section on variable scoping](#) for more information.

Examples

```
julia> z = 3
3

julia> function foo()
    global z = 6 # use the z variable defined outside foo
end
foo (generic function with 1 method)

julia> foo()
6

julia> z
6
```

[source](#)

outer – Keyword.

```
| for outer
```

Reuse an existing local variable for iteration in a for loop.

See the [manual section on variable scoping](#) for more information.

See also [for](#).

Examples

```
julia> function f()
    i = 0
    for i = 1:3
```

```

        # empty
    end
    return i
end;

julia> f()
0

julia> function f()
    i = 0
    for outer i = 1:3
        # empty
    end
    return i
end;

julia> f()
3

julia> i = 0 # global variable
    for outer i = 1:3
    end
ERROR: syntax: no outer local variable declaration exists for "for outer"
[...]
```

[source](#)

const – Keyword.

```
| const
```

const is used to declare global variables whose values will not change. In almost all code (and particularly performance sensitive code) global variables should be declared constant in this way.

```
| const x = 5
```

Multiple variables can be declared within a single const:

```
| const y, z = 7, 11
```

Note that const only applies to one = operation, therefore `const x = y = 1` declares x to be constant but not y. On the other hand, `const x = const y = 1` declares both x and y constant.

Note that "constant-ness" does not extend into mutable containers; only the association between a variable and its value is constant. If x is an array or dictionary (for example) you can still modify, add, or remove elements.

In some cases changing the value of a const variable gives a warning instead of an error. However, this can produce unpredictable behavior or corrupt the state of your program, and so should be avoided. This feature is intended only for convenience during interactive use.

[source](#)

struct – Keyword.

```
| struct
```

The most commonly used kind of type in Julia is a struct, specified as a name and a set of fields.

```
| struct Point
|     x
|     y
| end
```

Fields can have type restrictions, which may be parameterized:

```
| struct Point{X}
|     x::X
|     y::Float64
| end
```

A struct can also declare an abstract super type via `<:` syntax:

```
| struct Point <: AbstractPoint
|     x
|     y
| end
```

structs are immutable by default; an instance of one of these types cannot be modified after construction. Use `mutable struct` instead to declare a type whose instances can be modified.

See the manual section on [Composite Types](#) for more details, such as how to define constructors.

[source](#)

`mutable struct` – Keyword.

```
| mutable struct
```

`mutable struct` is similar to `struct`, but additionally allows the fields of the type to be set after construction. See the manual section on [Composite Types](#) for more information.

[source](#)

`Base.@kwdef` – Macro.

```
| @kwdef typedef
```

This is a helper macro that automatically defines a keyword-based constructor for the type declared in the expression `typedef`, which must be a `struct` or `mutable struct` expression. The default argument is supplied by declaring fields of the form `field::T = default` or `field = default`. If no default is provided then the keyword argument becomes a required keyword argument in the resulting type constructor.

Inner constructors can still be defined, but at least one should accept arguments in the same form as the default inner constructor (i.e. one positional argument per field) in order to function correctly with the keyword outer constructor.

Julia 1.1

Base.@kwdef for parametric structs, and structs with supertypes requires at least Julia 1.1.

Julia 1.9

This macro is exported as of Julia 1.9.

Examples

```
julia> @kwdef struct Foo
    a::Int = 1          # specified default
    b::String          # required keyword
end
Foo

julia> Foo(b="hi")
Foo(1, "hi")

julia> Foo()
ERROR: UndefKeywordError: keyword argument `b` not assigned
Stacktrace:
[...]
```

[source](#)

abstract type – Keyword.

```
| abstract type
```

abstract type declares a type that cannot be instantiated, and serves only as a node in the type graph, thereby describing sets of related concrete types: those concrete types which are their descendants. Abstract types form the conceptual hierarchy which makes Julia’s type system more than just a collection of object implementations. For example:

```
| abstract type Number end
| abstract type Real <: Number end
```

Number has no supertype, whereas Real is an abstract subtype of Number.

[source](#)

primitive type – Keyword.

```
| primitive type
```

primitive type declares a concrete type whose data consists only of a series of bits. Classic examples of primitive types are integers and floating-point values. Some example built-in primitive type declarations:

```
| primitive type Char 32 end
| primitive type Bool <: Integer 8 end
```

The number after the name indicates how many bits of storage the type requires. Currently, only sizes that are multiples of 8 bits are supported. The `Bool` declaration shows how a primitive type can be optionally declared to be a subtype of some supertype.

source

where – Keyword.

```
| where
```

The `where` keyword creates a type that is an iterated union of other types, over all values of some variable. For example `Vector{T} where T<:Real` includes all `Vector`s where the element type is some kind of `Real` number.

The variable bound defaults to `Any` if it is omitted:

```
| Vector{T} where T      # short for `where T<:Any`
```

Variables can also have lower bounds:

```
| Vector{T} where T>:Int
| Vector{T} where Int<:T<:Real
```

There is also a concise syntax for nested `where` expressions. For example, this:

```
| Pair{T, S} where S<:Array{T} where T<:Number
```

can be shortened to:

```
| Pair{T, S} where {T<:Number, S<:Array{T}}
```

This form is often found on method signatures.

Note that in this form, the variables are listed outermost-first. This matches the order in which variables are substituted when a type is "applied" to parameter values using the syntax `T{p1, p2, ...}`.

source

... – Keyword.

```
| ...
```

The "splat" operator, `...`, represents a sequence of arguments. `...` can be used in function definitions, to indicate that the function accepts an arbitrary number of arguments. `...` can also be used to apply a function to a sequence of arguments.

Examples

```
| julia> add(xs...) = reduce(+, xs)
| add (generic function with 1 method)
|
| julia> add(1, 2, 3, 4, 5)
| 15
```

```
julia> add([1, 2, 3]...)
6

julia> add(7, 1:100..., 1000:1100...)
111107
```

[source](#)

`;` – Keyword.

```
| ;
```

`;` has a similar role in Julia as in many C-like languages, and is used to delimit the end of the previous statement.

`;` is not necessary at the end of a line, but can be used to separate statements on a single line or to join statements into a single expression.

Adding `;` at the end of a line in the REPL will suppress printing the result of that expression.

In function declarations, and optionally in calls, `;` separates regular arguments from keywords.

In array literals, arguments separated by semicolons have their contents concatenated together. A separator made of a single `;` concatenates vertically (i.e. along the first dimension), `;;` concatenates horizontally (second dimension), `;;;` concatenates along the third dimension, etc. Such a separator can also be used in last position in the square brackets to add trailing dimensions of length 1.

A `;` in first position inside of parentheses can be used to construct a named tuple. The same `(; ...)` syntax on the left side of an assignment allows for property destructuring.

In the standard REPL, typing `;` on an empty line will switch to shell mode.

Examples

```
julia> function foo()
    x = "Hello, "; x *= "World!"
    return x
end
foo (generic function with 1 method)

julia> bar() = (x = "Hello, Mars!"; return x)
bar (generic function with 1 method)

julia> foo();

julia> bar()
"Hello, Mars!"

julia> function plot(x, y; style="solid", width=1, color="black")
    ###
end

julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4
```

```

julia> [1; 3;; 2; 4;;; 10*A]
2×2×2 Array{Int64, 3}:
[:, :, 1] =
 1  2
 3  4

[:, :, 2] =
10 20
30 40

julia> [2; 3;;;]
2×1×1 Array{Int64, 3}:
[:, :, 1] =
 2
 3

julia> nt = (; x=1) # without the ; or a trailing comma this would assign to x
(x = 1,)

julia> key = :a; c = 3;

julia> nt2 = (; key => 1, b=2, c, nt.x)
(a = 1, b = 2, c = 3, x = 1)

julia> (; b, x) = nt2; # set variables b and x using property destructuring

julia> b, x
(2, 1)

shell> echo hello
julia> ; # upon typing ;, the prompt changes (in place) to: shell>
hello

```

source

= - Keyword.

| =

= is the assignment operator.

- For variable a and expression b , $a = b$ makes a refer to the value of b .
- For functions $f(x)$, $f(x) = x$ defines a new function constant f , or adds a new method to f if f is already defined; this usage is equivalent to `function f(x); x; end`.
- $a[i] = v$ calls `setindex!(a,v,i)`.
- $a.b = c$ calls `setproperty!(a,:b,c)`.
- Inside a function call, $f(a=b)$ passes b as the value of keyword argument a .
- Inside parentheses with commas, $(a=1,)$ constructs a `NamedTuple`.

Examples

Assigning a to b does not create a copy of b ; instead use `copy` or `deepcopy`.

```
julia> b = [1]; a = b; b[1] = 2; a
1-element Array{Int64, 1}:
 2

julia> b = [1]; a = copy(b); b[1] = 2; a
1-element Array{Int64, 1}:
 1
```

Collections passed to functions are also not copied. Functions can modify (mutate) the contents of the objects their arguments refer to. (The names of functions which do this are conventionally suffixed with '!'.)

```
julia> function f!(x); x[:] .+= 1; end
f! (generic function with 1 method)

julia> a = [1]; f!(a); a
1-element Array{Int64, 1}:
 2
```

Assignment can operate on multiple variables in parallel, taking values from an iterable:

```
julia> a, b = 4, 5
(4, 5)

julia> a, b = 1:3
1:3

julia> a, b
(1, 2)
```

Assignment can operate on multiple variables in series, and will return the value of the right-hand-most expression:

```
julia> a = [1]; b = [2]; c = [3]; a = b = c
1-element Array{Int64, 1}:
 3

julia> b[1] = 2; a, b, c
([2], [2], [2])
```

Assignment at out-of-bounds indices does not grow a collection. If the collection is a [Vector](#) it can instead be grown with [push!](#) or [append!](#).

```
julia> a = [1, 1]; a[3] = 2
ERROR: BoundsError: attempt to access 2-element Array{Int64, 1} at index [3]
[...]

julia> push!(a, 2, 3)
4-element Array{Int64, 1}:
 1
 1
 2
 3
```

Assigning `[]` does not eliminate elements from a collection; instead use `filter!`.

```
julia> a = collect(1:3); a[a .<= 1] = []
ERROR: DimensionMismatch: tried to assign 0 elements to 1 destinations
[...]

julia> filter!(x -> x > 1, a) # in-place & thus more efficient than a = a[a .> 1]
2-element Array{Int64, 1}:
 2
 3
```

[source](#)

`?:` – Keyword.

```
| a ? b : c
```

Short form for conditionals; read "if a, evaluate b otherwise evaluate c". Also known as the [ternary operator](#).

This syntax is equivalent to `if a; b else c end`, but is often used to emphasize the value b-or-c which is being used as part of a larger expression, rather than the side effects that evaluating b or c may have.

See the manual section on [control flow](#) for more details.

Examples

```
julia> x = 1; y = 2;

julia> x > y ? println("x is larger") : println("y is larger")
y is larger
```

[source](#)

41.4 Standard Modules

Main – Module.

```
| Main
```

Main is the top-level module, and Julia starts with Main set as the current module. Variables defined at the prompt go in Main, and `varinfo` lists variables in Main.

```
julia> @__MODULE__
Main
```

[source](#)

Core – Module.

```
| Core
```

Core is the module that contains all identifiers considered "built in" to the language, i.e. part of the core language and not libraries. Every module implicitly specifies using Core, since you can't do anything without those definitions.

[source](#)

Base – Module.

| Base

The base library of Julia. Base is a module that contains basic functionality (the contents of base/). All modules implicitly contain using Base, since this is needed in the vast majority of cases.

[source](#)

41.5 Base Submodules

Base.Broadcast – Module.

| Base.Broadcast

Module containing the broadcasting implementation.

[source](#)

Base.Docs – Module.

| Docs

The Docs module provides the @doc macro which can be used to set and retrieve documentation meta-data for Julia objects.

Please see the manual section on [documentation](#) for more information.

[source](#)

Base.Iterators – Module.

Methods for working with Iterators.

[source](#)

Base.Libc – Module.

Interface to libc, the C standard library.

[source](#)

Base.Meta – Module.

Convenience functions for metaprogramming.

[source](#)

Base.StackTraces – Module.

Tools for collecting and manipulating stack traces. Mainly used for building errors.

[source](#)

Base.Sys – Module.

Provide methods for retrieving information about hardware and the operating system.

[source](#)

Base.Threads – Module.

Multithreading support.

[source](#)

Base.GC – Module.

| Base.GC

Module with garbage collection utilities.

[source](#)

41.6 All Objects

Core.::== – Function.

```

| == (x, y) -> Bool
| ≡ (x, y) -> Bool

```

Determine whether x and y are identical, in the sense that no program could distinguish them. First the types of x and y are compared. If those are identical, mutable objects are compared by address in memory and immutable objects (such as numbers) are compared by contents at the bit level. This function is sometimes called "egal". It always returns a Bool value.

Examples

```

julia> a = [1, 2]; b = [1, 2];

julia> a == b
true

julia> a === b
false

julia> a === a
true

```

[source](#)

Core.isa – Function.

```

| isa(x, type) -> Bool

```

Determine whether x is of the given type. Can also be used as an infix operator, e.g. x isa type.

Examples

```
julia> isa(1, Int)
true

julia> isa(1, Matrix)
false

julia> isa(1, Char)
false

julia> isa(1, Number)
true

julia> 1 isa Number
true
```

[source](#)

Base.isequal – Function.

```
isequal(x, y) -> Bool
```

Similar to `==`, except for the treatment of floating point numbers and of missing values. `isequal` treats all floating-point NaN values as equal to each other, treats `-0.0` as unequal to `0.0`, and `missing` as equal to `missing`. Always returns a Bool value.

`isequal` is an equivalence relation - it is reflexive (`===` implies `isequal`), symmetric (`isequal(a, b)` implies `isequal(b, a)`) and transitive (`isequal(a, b)` and `isequal(b, c)` implies `isequal(a, c)`).

Implementation

The default implementation of `isequal` calls `==`, so a type that does not involve floating-point values generally only needs to define `==`.

`isequal` is the comparison function used by hash tables (`Dict`). `isequal(x, y)` must imply that `hash(x) == hash(y)`.

This typically means that types for which a custom `==` or `isequal` method exists must implement a corresponding `hash` method (and vice versa). Collections typically implement `isequal` by calling `isequal` recursively on all contents.

Furthermore, `isequal` is linked with `isless`, and they work together to define a fixed total ordering, where exactly one of `isequal(x, y)`, `isless(x, y)`, or `isless(y, x)` must be true (and the other two false).

Scalar types generally do not need to implement `isequal` separate from `==`, unless they represent floating-point numbers amenable to a more efficient implementation than that provided as a generic fallback (based on `isnan`, `signbit`, and `==`).

Examples

```
julia> isequal([1., NaN], [1., NaN])
true

julia> [1., NaN] == [1., NaN]
false
```

```
julia> 0.0 == -0.0
true

julia> isequal(0.0, -0.0)
false

julia> missing == missing
missing

julia> isequal(missing, missing)
true
```

[source](#)

```
isequal(x)
```

Create a function that compares its argument to `x` using `isequal`, i.e. a function equivalent to `y -> isequal(y, x)`.

The returned function is of type `Base.Fix2{typeof(isequal)}`, which can be used to implement specialized methods.

[source](#)

`Base.isless` – Function.

```
isless(x, y)
```

Test whether `x` is less than `y`, according to a fixed total order (defined together with `isequal`). `isless` is not defined for pairs `(x, y)` of all types. However, if it is defined, it is expected to satisfy the following:

- If `isless(x, y)` is defined, then so is `isless(y, x)` and `isequal(x, y)`, and exactly one of those three yields true.
- The relation defined by `isless` is transitive, i.e., `isless(x, y) && isless(y, z)` implies `isless(x, z)`.

Values that are normally unordered, such as NaN, are ordered after regular values. `missing` values are ordered last.

This is the default comparison used by `sort!`.

Implementation

Non-numeric types with a total order should implement this function. Numeric types only need to implement it if they have special values such as NaN. Types with a partial order should implement `<`. See the documentation on [Alternate Orderings](#) for how to define alternate ordering methods that can be used in sorting and related functions.

Examples

```
julia> isless(1, 3)
true

julia> isless("Red", "Blue")
false
```

[source](#)

`Base.isunordered` – Function.

```
| isunordered(x)
```

Return true if `x` is a value that is not orderable according to `<`, such as NaN or missing.

The values that evaluate to true with this predicate may be orderable with respect to other orderings such as `isless`.

Julia 1.7

This function requires Julia 1.7 or later.

[source](#)

`Base.iffelse` – Function.

```
| iffelse(condition::Bool, x, y)
```

Return `x` if `condition` is true, otherwise return `y`. This differs from `?` or `if` in that it is an ordinary function, so all the arguments are evaluated first. In some cases, using `iffelse` instead of an `if` statement can eliminate the branch in generated code and provide higher performance in tight loops.

Examples

```
| julia> iffelse(1 > 2, 1, 2)
| 2
```

[source](#)

`Core.typeassert` – Function.

```
| typeassert(x, type)
```

Throw a `TypeError` unless `x isa type`. The syntax `x::type` calls this function.

Examples

```
| julia> typeassert(2.5, Int)
| ERROR: TypeError: in typeassert, expected Int64, got a value of type Float64
| Stacktrace:
| [...]
|
```

[source](#)

`Core.typeof` – Function.

```
| typeof(x)
```

Get the concrete type of `x`.

See also `eltype`.

Examples

```
julia> a = 1//2;

julia> typeof(a)
Rational{Int64}

julia> M = [1 2; 3.5 4];

julia> typeof(M)
Matrix{Float64} (alias for Array{Float64, 2})
```

[source](#)

Core.tuple – Function.

```
| tuple(xs...)
```

Construct a tuple of the given objects.

See also [Tuple](#), [ntuple](#), [NamedTuple](#).

Examples

```
julia> tuple(1, 'b', pi)
(1, 'b', π)

julia> ans === (1, 'b', π)
true

julia> Tuple{Real[1, 2, pi]} # takes a collection
(1, 2, π)
```

[source](#)

Base.ntuple – Function.

```
| ntuple(f::Function, n::Integer)
```

Create a tuple of length n , computing each element as $f(i)$, where i is the index of the element.

Examples

```
julia> ntuple(i -> 2*i, 4)
(2, 4, 6, 8)
```

[source](#)

```
| ntuple(f, ::Val{N})
```

Create a tuple of length N , computing each element as $f(i)$, where i is the index of the element. By taking a `Val{N}` argument, it is possible that this version of `ntuple` may generate more efficient code than the version taking the length as an integer. But `ntuple(f, N)` is preferable to `ntuple(f, Val{N})` in cases where N cannot be determined at compile time.

Examples

```
julia> ntuple(i -> 2*i, Val{4})
(2, 4, 6, 8)
```

[source](#)

`Base.objectid` – Function.

```
objectid(x) -> UInt
```

Get a hash value for `x` based on object identity.

If `x == y` then `objectid(x) == objectid(y)`, and usually when `x != y`, `objectid(x) != objectid(y)`.

See also [hash](#), [IdDict](#).

[source](#)

`Base.hash` – Function.

```
hash(x[, h::UInt]) -> UInt
```

Compute an integer hash code such that `isequal(x, y)` implies `hash(x) == hash(y)`. The optional second argument `h` is another hash code to be mixed with the result.

New types should implement the 2-argument form, typically by calling the 2-argument hash method recursively in order to mix hashes of the contents with each other (and with `h`). Typically, any type that implements `hash` should also implement its own `==` (hence [isequal](#)) to guarantee the property mentioned above. Types supporting subtraction (operator `-`) should also implement [widen](#), which is required to hash values inside heterogeneous arrays.

The hash value may change when a new Julia process is started.

```
julia> a = hash(10)
0x95ea2955abd45275

julia> hash(10, a) # only use the output of another hash function as the second argument
0xd42bad54a8575b16
```

See also: [objectid](#), [Dict](#), [Set](#).

[source](#)

`Base.finalizer` – Function.

```
finalizer(f, x)
```

Register a function `f(x)` to be called when there are no program-accessible references to `x`, and return `x`. The type of `x` must be a mutable struct, otherwise the function will throw.

`f` must not cause a task switch, which excludes most I/O operations such as `println`. Using the `@async` macro (to defer context switching to outside of the finalizer) or `ccall` to directly invoke IO functions in C can be helpful for debugging purposes.

Note that there is no guaranteed world age for the execution of `f`. It may be called in the world age in which the finalizer was registered or any later world age.

Examples

```

finalizer(my_mutable_struct) do x
    @async println("Finalizing $x.")
end

finalizer(my_mutable_struct) do x
    ccall(:jl_safe_printf, Cvoid, (Cstring, Cstring), "Finalizing %s.", repr(x))
end

```

A finalizer may be registered at object construction. In the following example note that we implicitly rely on the finalizer returning the newly created mutable struct `x`.

Example

```

mutable struct MyMutableStruct
    bar
    function MyMutableStruct(bar)
        x = new{bar}()
        f(t) = @async println("Finalizing $t.")
        finalizer(f, x)
    end
end

```

[source](#)

`Base.finalize` – Function.

```
| finalize(x)
```

Immediately run finalizers registered for object `x`.

[source](#)

`Base.copy` – Function.

```
| copy(x)
```

Create a shallow copy of `x`: the outer structure is copied, but not all internal values. For example, copying an array produces a new array with identically-same elements as the original.

See also [copy!](#), [copyto!](#), [deepcopy](#).

[source](#)

`Base.deepcopy` – Function.

```
| deepcopy(x)
```

Create a deep copy of `x`: everything is copied recursively, resulting in a fully independent object. For example, deep-copying an array produces a new array whose elements are deep copies of the original elements. Calling `deepcopy` on an object should generally have the same effect as serializing and then deserializing it.

While it isn't normally necessary, user-defined types can override the default `deepcopy` behavior by defining a specialized version of the function `deepcopy_internal(x::T, dict::IdDict)` (which shouldn't otherwise be used), where `T` is the type to be specialized for, and `dict` keeps track of objects copied so

far within the recursion. Within the definition, `deepcopy_internal` should be used in place of `deepcopy`, and the `dict` variable should be updated as appropriate before returning.

[source](#)

`Base.getproperty` – Function.

```
getproperty(value, name::Symbol)
getproperty(value, name::Symbol, order::Symbol)
```

The syntax `a.b` calls `getproperty(a, :b)`. The syntax `@atomic order a.b` calls `getproperty(a, :b, :order)` and the syntax `@atomic a.b` calls `getproperty(a, :b, :sequentially_consistent)`.

Examples

```
julia> struct MyType{T <: Number}
    x::T
end

julia> function Base.getproperty(obj::MyType, sym::Symbol)
    if sym === :special
        return obj.x + 1
    else # fallback to getfield
        return getfield(obj, sym)
    end
end

julia> obj = MyType(1);

julia> obj.special
2

julia> obj.x
1
```

One should overload `getproperty` only when necessary, as it can be confusing if the behavior of the syntax `obj.f` is unusual. Also note that using methods is often preferable. See also this style guide documentation for more information: [Prefer exported methods over direct field access](#).

See also [getfield](#), [propertynames](#) and [setproperty!](#).

[source](#)

`Base.setproperty!` – Function.

```
setproperty!(value, name::Symbol, x)
setproperty!(value, name::Symbol, x, order::Symbol)
```

The syntax `a.b = c` calls `setproperty!(a, :b, c)`. The syntax `@atomic order a.b = c` calls `setproperty!(a, :b, c, :order)` and the syntax `@atomic a.b = c` calls `setproperty!(a, :b, c, :sequentially_consistent)`.

Julia 1.8

`setproperty!` on modules requires at least Julia 1.8.

See also [setfield!](#), [propertynames](#) and [getproperty](#).

[source](#)

`Base.replaceproperty!` – Function.

```
| replaceproperty!(x, f::Symbol, expected, desired, success_order::Symbol=:not_atomic,  
| ↪ fail_order::Symbol=success_order)
```

Perform a compare-and-swap operation on `x.f` from `expected` to `desired`, per `egal`. The syntax `@atomic_replace! x.f expected => desired` can be used instead of the function call form.

See also [replacefield!](#) and [setproperty!](#).

[source](#)

`Base.swapproperty!` – Function.

```
| swapproperty!(x, f::Symbol, v, order::Symbol=:not_atomic)
```

The syntax `@atomic a.b, _ = c, a.b` returns `(c, swapproperty!(a, :b, c, :sequentially_consistent))`, where there must be one `getproperty` expression common to both sides.

See also [swapfield!](#) and [setproperty!](#).

[source](#)

`Base.modifyproperty!` – Function.

```
| modifyproperty!(x, f::Symbol, op, v, order::Symbol=:not_atomic)
```

The syntax `@atomic op(x.f, v)` (and its equivalent `@atomic x.f op v`) returns `modifyproperty!(x, :f, op, v, :sequentially_consistent)`, where the first argument must be a `getproperty` expression and is modified atomically.

Invocation of `op(getproperty(x, f), v)` must return a value that can be stored in the field `f` of the object `x` by default. In particular, unlike the default behavior of [setproperty!](#), the `convert` function is not called automatically.

See also [modifyfield!](#) and [setproperty!](#).

[source](#)

`Base.propertynames` – Function.

```
| propertynames(x, private=false)
```

Get a tuple or a vector of the properties (`x.property`) of an object `x`. This is typically the same as [fieldnames\(typeof\(x\)\)](#), but types that overload [getproperty](#) should generally overload `propertynames` as well to get the properties of an instance of the type.

`propertynames(x)` may return only "public" property names that are part of the documented interface of `x`. If you want it to also return "private" property names intended for internal use, pass `true` for the optional second argument. REPL tab completion on `x`. shows only the `private=false` properties.

See also: [hasproperty](#), [hasfield](#).

[source](#)

Base.hasproperty – Function.

```
| hasproperty(x, s::Symbol)
```

Return a boolean indicating whether the object x has s as one of its own properties.

Julia 1.2

This function requires at least Julia 1.2.

See also: [propertynames](#), [hasfield](#).

[source](#)

Core.getfield – Function.

```
| getfield(value, name::Symbol, [order::Symbol])
| getfield(value, i::Int, [order::Symbol])
```

Extract a field from a composite value by name or position. Optionally, an ordering can be defined for the operation. If the field was declared `@atomic`, the specification is strongly recommended to be compatible with the stores to that location. Otherwise, if not declared as `@atomic`, this parameter must be `:not_atomic` if specified. See also [getproperty](#) and [fieldnames](#).

Examples

```
julia> a = 1//2
1//2

julia> getfield(a, :num)
1

julia> a.num
1

julia> getfield(a, 1)
1
```

[source](#)

Core.setfield! – Function.

```
| setfield!(value, name::Symbol, x, [order::Symbol])
| setfield!(value, i::Int, x, [order::Symbol])
```

Assign x to a named field in value of composite type. The value must be mutable and x must be a subtype of `fieldtype(typeof(value), name)`. Additionally, an ordering can be specified for this operation. If the field was declared `@atomic`, this specification is mandatory. Otherwise, if not declared as `@atomic`, it must be `:not_atomic` if specified. See also [setproperty!](#).

Examples

```
julia> mutable struct MyMutableStruct
        field::Int
    end
```

```
julia> a = MyMutableStruct(1);

julia> setfield!(a, :field, 2);

julia> getfield(a, :field)
2

julia> a = 1//2
1//2

julia> setfield!(a, :num, 3);
ERROR: setfield!: immutable struct of type Rational cannot be changed
```

[source](#)

Core.modifyfield! – Function.

```
modifyfield!(value, name::Symbol, op, x, [order::Symbol]) -> Pair
modifyfield!(value, i::Int, op, x, [order::Symbol]) -> Pair
```

These atomically perform the operations to get and set a field after applying the function op.

```
y = getfield(value, name)
z = op(y, x)
setfield!(value, name, z)
return y => z
```

If supported by the hardware (for example, atomic increment), this may be optimized to the appropriate hardware instruction, otherwise it'll use a loop.

[source](#)

Core.replacefield! – Function.

```
replacefield!(value, name::Symbol, expected, desired,
               [success_order::Symbol, [fail_order::Symbol=success_order]] -> (; old,
               ↪ success::Bool)
replacefield!(value, i::Int, expected, desired,
               [success_order::Symbol, [fail_order::Symbol=success_order]] -> (; old,
               ↪ success::Bool)
```

These atomically perform the operations to get and conditionally set a field to a given value.

```
y = getfield(value, name, fail_order)
ok = y === expected
if ok
    setfield!(value, name, desired, success_order)
end
return (; old = y, success = ok)
```

If supported by the hardware, this may be optimized to the appropriate hardware instruction, otherwise it'll use a loop.

[source](#)

Core.swapfield! – Function.

```
swapfield!(value, name::Symbol, x, [order::Symbol])
swapfield!(value, i::Int, x, [order::Symbol])
```

These atomically perform the operations to simultaneously get and set a field:

```
y = getfield(value, name)
setfield!(value, name, x)
return y
```

[source](#)

Core.isdefined – Function.

```
isdefined(m::Module, s::Symbol, [order::Symbol])
isdefined(object, s::Symbol, [order::Symbol])
isdefined(object, index::Int, [order::Symbol])
```

Tests whether a global variable or object field is defined. The arguments can be a module and a symbol or a composite object and field name (as a symbol) or index. Optionally, an ordering can be defined for the operation. If the field was declared `@atomic`, the specification is strongly recommended to be compatible with the stores to that location. Otherwise, if not declared as `@atomic`, this parameter must be `:not_atomic` if specified.

To test whether an array element is defined, use `isassigned` instead.

See also `@isdefined`.

Examples

```
julia> isdefined(Base, :sum)
true

julia> isdefined(Base, :NonExistentMethod)
false

julia> a = 1//2;

julia> isdefined(a, 2)
true

julia> isdefined(a, 3)
false

julia> isdefined(a, :num)
true

julia> isdefined(a, :numerator)
false
```

[source](#)

Core.getglobal – Function.

```
getglobal(module::Module, name::Symbol, [order::Symbol=:monotonic])
```

Retrieve the value of the binding name from the module `module`. Optionally, an atomic ordering can be defined for the operation, otherwise it defaults to monotonic.

While accessing module bindings using `getfield` is still supported to maintain compatibility, using `getglobal` should always be preferred since `getglobal` allows for control over atomic ordering (`getfield` is always monotonic) and better signifies the code's intent both to the user as well as the compiler.

Most users should not have to call this function directly – The `getproperty` function or corresponding syntax (i.e. `module.name`) should be preferred in all but few very specific use cases.

Julia 1.9

This function requires Julia 1.9 or later.

See also `getproperty` and `setglobal!`.

Examples

```
julia> a = 1
1

julia> module M
    a = 2
end;

julia> getglobal(@__MODULE__, :a)
1

julia> getglobal(M, :a)
2
```

[source](#)

Core.setglobal! – Function.

```
setglobal!(module::Module, name::Symbol, x, [order::Symbol=:monotonic])
```

Set or change the value of the binding name in the module `module` to `x`. No type conversion is performed, so if a type has already been declared for the binding, `x` must be of appropriate type or an error is thrown.

Additionally, an atomic ordering can be specified for this operation, otherwise it defaults to monotonic.

Users will typically access this functionality through the `setproperty!` function or corresponding syntax (i.e. `module.name = x`) instead, so this is intended only for very specific use cases.

Julia 1.9

This function requires Julia 1.9 or later.

See also `setproperty!` and `getglobal`

Examples

```
julia> module M end;

julia> M.a # same as `getglobal(M, :a)`
ERROR: UndefVarError: `a` not defined

julia> setglobal!(M, :a, 1)
1

julia> M.a
1
```

[source](#)

Base.@isdefined – Macro.

```
@isdefined s -> Bool
```

Tests whether variable `s` is defined in the current scope.

See also [isdefined](#) for field properties and [isassigned](#) for array indexes or [haskey](#) for other mappings.

Examples

```
julia> @isdefined newvar
false

julia> newvar = 1
1

julia> @isdefined newvar
true

julia> function f()
    println(@isdefined x)
    x = 3
    println(@isdefined x)
end
f (generic function with 1 method)

julia> f()
false
true
```

[source](#)

Base.convert – Function.

```
convert(T, x)
```

Convert `x` to a value of type `T`.

If `T` is an [Integer](#) type, an [InexactError](#) will be raised if `x` is not representable by `T`, for example if `x` is not integer-valued, or is outside the range supported by `T`.

Examples

```
julia> convert{Int}, 3.0)
3

julia> convert{Int}, 3.5)
ERROR: InexactError: Int64(3.5)
Stacktrace:
[...]

```

If `T` is a `AbstractFloat` type, then it will return the closest value to `x` representable by `T`.

```
julia> x = 1/3
0.3333333333333333

julia> convert{Float32}, x)
0.33333334f0

julia> convert{BigFloat}, x)
0.333333333333333314829616256247390992939472198486328125

```

If `T` is a collection type and `x` a collection, the result of `convert(T, x)` may alias all or part of `x`.

```
julia> x = Int[1, 2, 3];

julia> y = convert{Vector{Int}}, x);

julia> y === x
true

```

See also: [round](#), [trunc](#), [oftype](#), [reinterpret](#).

[source](#)

`Base.promote` – Function.

```
| promote(xs...)
```

Convert all arguments to a common type, and return them all (as a tuple). If no arguments can be converted, an error is raised.

See also: [promote_type](#), [promote_rule](#).

Examples

```
julia> promote{Int8}(1), {Float16}(4.5), {Float32}(4.1))
(1.0f0, 4.5f0, 4.1f0)

julia> promote_type{Int8, Float16, Float32}
Float32

julia> reduce(Base.promote_typejoin, ({Int8, Float16, Float32}))
Real

julia> promote(1, "x")
ERROR: promotion of types Int64 and String failed to change any arguments

```

```
[...]  
julia> promote_type{Int, String}  
Any
```

[source](#)

Base.oftype – Function.

```
oftype(x, y)
```

Convert *y* to the type of *x* i.e. `convert(typeof(x), y)`.

Examples

```
julia> x = 4;  
  
julia> y = 3.;  
  
julia> oftype(x, y)  
3  
  
julia> oftype(y, x)  
4.0
```

[source](#)

Base.widen – Function.

```
widen(x)
```

If *x* is a type, return a "larger" type, defined so that arithmetic operations `+` and `-` are guaranteed not to overflow nor lose precision for any combination of values that type *x* can hold.

For fixed-size integer types less than 128 bits, `widen` will return a type with twice the number of bits.

If *x* is a value, it is converted to `widen(typeof(x))`.

Examples

```
julia> widen{Int32}  
Int64  
  
julia> widen(1.5f0)  
1.5
```

[source](#)

Base.identity – Function.

```
identity(x)
```

The identity function. Returns its argument.

See also: [one](#), [oneunit](#), and [LinearAlgebra](#)'s `I`.

Examples

```
julia> identity("Well, what did you expect?")
"Well, what did you expect?"
```

[source](#)

Core.WeakRef – Type.

```
WeakRef(x)
```

`w = WeakRef(x)` constructs a [weak reference](#) to the Julia value `x`: although `w` contains a reference to `x`, it does not prevent `x` from being garbage collected. `w.value` is either `x` (if `x` has not been garbage-collected yet) or `nothing` (if `x` has been garbage-collected).

```
julia> x = "a string"
"a string"

julia> w = WeakRef(x)
WeakRef("a string")

julia> GC.gc()

julia> w           # a reference is maintained via `x`
WeakRef("a string")

julia> x = nothing # clear reference

julia> GC.gc()

julia> w
WeakRef(nothing)
```

[source](#)

41.7 Properties of Types

Type relations

Base.supertype – Function.

```
supertype(T::DataType)
```

Return the supertype of `DataType` `T`.

Examples

```
julia> supertype(Int32)
Signed
```

[source](#)

Core.Type – Type.

```
Core.Type{T}
```

`Core.Type` is an abstract type which has all type objects as its instances. The only instance of the singleton type `Core.Type{T}` is the object `T`.

Examples

```
julia> isa(Type{Float64}, Type)
true

julia> isa(Float64, Type)
true

julia> isa(Real, Type{Float64})
false

julia> isa(Real, Type{Real})
true
```

[source](#)

`Core.DataType` – Type.

```
| DataType <: Type{T}
```

`DataType` represents explicitly declared types that have names, explicitly declared supertypes, and, optionally, parameters. Every concrete value in the system is an instance of some `DataType`.

Examples

```
julia> typeof(Real)
DataType

julia> typeof(Int)
DataType

julia> struct Point
           x::Int
           y
       end

julia> typeof(Point)
DataType
```

[source](#)

`Core.<:` – Function.

```
| <:(T1, T2)
```

Subtype operator: returns `true` if and only if all values of type `T1` are also of type `T2`.

Examples

```
julia> Float64 <: AbstractFloat
true
```

```
julia> Vector{Int} <: AbstractArray
true

julia> Matrix{Float64} <: Matrix{AbstractFloat}
false
```

[source](#)

Base.>: – Function.

```
>:(T1, T2)
```

Supertype operator, equivalent to `T2 <: T1`.

[source](#)

Base.typejoin – Function.

```
typejoin(T, S, ...)
```

Return the closest common ancestor of types `T` and `S`, i.e. the narrowest type from which they both inherit. Recurses on additional varargs.

Examples

```
julia> typejoin(Int, Float64)
Real

julia> typejoin(Int, Float64, ComplexF32)
Number
```

[source](#)

Base.typeintersect – Function.

```
typeintersect(T::Type, S::Type)
```

Compute a type that contains the intersection of `T` and `S`. Usually this will be the smallest such type or one close to it.

[source](#)

Base.promote_type – Function.

```
promote_type(type1, type2, ...)
```

Promotion refers to converting values of mixed types to a single common type. `promote_type` represents the default promotion behavior in Julia when operators (usually mathematical) are given arguments of differing types. `promote_type` generally tries to return a type which can at least approximate most values of either input type without excessively widening. Some loss is tolerated; for example, `promote_type{Int64, Float64}` returns `Float64` even though strictly, not all `Int64` values can be represented exactly as `Float64` values.

See also: [promote](#), [promote_typejoin](#), [promote_rule](#).

Examples

```

julia> promote_type{Int64, Float64}
Float64

julia> promote_type{Int32, Int64}
Int64

julia> promote_type{Float32, BigInt}
BigFloat

julia> promote_type{Int16, Float16}
Float16

julia> promote_type{Int64, Float16}
Float16

julia> promote_type{Int8, UInt16}
UInt16

```

Don't overload this directly

To overload promotion for your own types you should overload `promote_rule`. `promote_type` calls `promote_rule` internally to determine the type. Overloading `promote_type` directly can cause ambiguity errors.

source

`Base.promote_rule` – Function.

```
| promote_rule(type1, type2)
```

Specifies what type should be used by `promote` when given values of types `type1` and `type2`. This function should not be called directly, but should have definitions added to it for new types as appropriate.

source

`Base.promote_typejoin` – Function.

```
| promote_typejoin(T, S)
```

Compute a type that contains both `T` and `S`, which could be either a parent of both types, or a `Union` if appropriate. Falls back to `typejoin`.

See instead `promote`, `promote_type`.

Examples

```

julia> Base.promote_typejoin{Int, Float64}
Real

julia> Base.promote_type{Int, Float64}
Float64

```

source

`Base.isdispatchtuple` – Function.

```
| isdispatchtuple(T)
```

Determine whether type `T` is a tuple "leaf type", meaning it could appear as a type signature in dispatch and has no subtypes (or supertypes) which could appear in a call.

[source](#)

Declared structure

`Base.ismutable` – Function.

```
| ismutable(v) -> Bool
```

Return `true` if and only if value `v` is mutable. See [Mutable Composite Types](#) for a discussion of immutability. Note that this function works on values, so if you give it a `DataType`, it will tell you that a value of the type is mutable.

Note

For technical reasons, `ismutable` returns `true` for values of certain special types (for example `String` and `Symbol`) even though they cannot be mutated in a permissible way.

See also [isbits](#), [isstructtype](#).

Examples

```
julia> ismutable(1)
false

julia> ismutable([1,2])
true
```

Julia 1.5

This function requires at least Julia 1.5.

[source](#)

`Base.isimmutable` – Function.

```
| isimmutable(v) -> Bool
```

Warning

Consider using `!ismutable(v)` instead, as `isimmutable(v)` will be replaced by `!ismutable(v)` in a future release. (Since Julia 1.5)

Return `true` iff value `v` is immutable. See [Mutable Composite Types](#) for a discussion of immutability. Note that this function works on values, so if you give it a type, it will tell you that a value of `DataType` is mutable.

Examples

```
julia> isimmutable(1)
true

julia> isimmutable([1,2])
false
```

[source](#)

Base.ismutabletype – Function.

```
ismutabletype(T) -> Bool
```

Determine whether type T was declared as a mutable type (i.e. using `mutable struct` keyword).

Julia 1.7

This function requires at least Julia 1.7.

[source](#)

Base.isabstracttype – Function.

```
isabstracttype(T)
```

Determine whether type T was declared as an abstract type (i.e. using the `abstract type` syntax).

Examples

```
julia> isabstracttype(AbstractArray)
true

julia> isabstracttype(Vector)
false
```

[source](#)

Base.isprimitivetype – Function.

```
isprimitivetype(T) -> Bool
```

Determine whether type T was declared as a primitive type (i.e. using the `primitive type` syntax).

[source](#)

Base.issingletontype – Function.

```
Base.issingletontype(T)
```

Determine whether type T has exactly one possible instance; for example, a struct type with no fields.

[source](#)

Base.isstructtype – Function.

```
isstructtype(T) -> Bool
```

Determine whether type `T` was declared as a struct type (i.e. using the `struct` or `mutable struct` keyword).

[source](#)

`Base.nameof` – Method.

```
| nameof(t::DataType) -> Symbol
```

Get the name of a (potentially `UnionAll`-wrapped) `DataType` (without its parent module) as a symbol.

Examples

```
julia> module Foo
           struct S{T}
               end
       end
Foo

julia> nameof(Foo.S{T} where T)
:S
```

[source](#)

`Base.fieldnames` – Function.

```
| fieldnames(x::DataType)
```

Get a tuple with the names of the fields of a `DataType`.

See also [propertynames](#), [hasfield](#).

Examples

```
julia> fieldnames(Rational)
(:num, :den)

julia> fieldnames(typeof(1+im))
(:re, :im)
```

[source](#)

`Base.fieldname` – Function.

```
| fieldname(x::DataType, i::Integer)
```

Get the name of field `i` of a `DataType`.

Examples

```
julia> fieldname(Rational, 1)
:num

julia> fieldname(Rational, 2)
:den
```

[source](#)

Core.fieldtype – Function.

```
| fieldtype(T, name::Symbol | index::Int)
```

Determine the declared type of a field (specified by name or index) in a composite DataType T.

Examples

```
julia> struct Foo
           x::Int64
           y::String
       end

julia> fieldtype(Foo, :x)
Int64

julia> fieldtype(Foo, 2)
String
```

[source](#)

Base.fieldtypes – Function.

```
| fieldtypes(T::Type)
```

The declared types of all fields in a composite DataType T as a tuple.

Julia 1.1

This function requires at least Julia 1.1.

Examples

```
julia> struct Foo
           x::Int64
           y::String
       end

julia> fieldtypes(Foo)
(Int64, String)
```

[source](#)

Base.fieldcount – Function.

```
| fieldcount(t::Type)
```

Get the number of fields that an instance of the given type would have. An error is thrown if the type is too abstract to determine this.

[source](#)

Base.hasfield – Function.

```
| hasfield(T::Type, name::Symbol)
```

Return a boolean indicating whether T has name as one of its own fields.

See also [fieldnames](#), [fieldcount](#), [hasproperty](#).

Julia 1.2

This function requires at least Julia 1.2.

Examples

```
julia> struct Foo
           bar::Int
       end

julia> hasfield(Foo, :bar)
true

julia> hasfield(Foo, :x)
false
```

[source](#)

Core.nfields – Function.

```
| nfields(x) -> Int
```

Get the number of fields in the given object.

Examples

```
julia> a = 1//2;

julia> nfields(a)
2

julia> b = 1
1

julia> nfields(b)
0

julia> ex = Exception("I've done a bad thing");

julia> nfields(ex)
1
```

In these examples, a is a [Rational](#), which has two fields. b is an Int, which is a primitive bitstype with no fields at all. ex is an [Exception](#), which has one field.

[source](#)

Base.isconst – Function.

```
| isconst(m::Module, s::Symbol) -> Bool
```

Determine whether a global is declared const in a given module m.

source

```
| isconst(t::DataType, s::Union{Int,Symbol}) -> Bool
```

Determine whether a field s is declared const in a given type t.

source

Base.isfieldatomic – Function.

```
| isfieldatomic(t::DataType, s::Union{Int,Symbol}) -> Bool
```

Determine whether a field s is declared @atomic in a given type t.

source

Memory layout

Base.sizeof – Method.

```
| sizeof(T::DataType)
| sizeof(obj)
```

Size, in bytes, of the canonical binary representation of the given DataType T, if any. Or the size, in bytes, of object obj if it is not a DataType.

See also [Base.summarysize](#).

Examples

```
julia> sizeof(Float32)
4

julia> sizeof(ComplexF64)
16

julia> sizeof(1.0)
8

julia> sizeof(collect(1.0:10.0))
80

julia> struct StructWithPadding
           x::Int64
           flag::Bool
       end

julia> sizeof(StructWithPadding) # not the sum of `sizeof` of fields due to padding
16

julia> sizeof(Int64) + sizeof(Bool) # different from above
9
```

If `DataType` `T` does not have a specific size, an error is thrown.

```
julia> sizeof(AbstractArray)
ERROR: Abstract type AbstractArray does not have a definite size.
Stacktrace:
[...]
```

[source](#)

`Base.isconcretetype` – Function.

```
| isconcretetype(T)
```

Determine whether type `T` is a concrete type, meaning it could have direct instances (values `x` such that `typeof(x) === T`).

See also: [isbits](#), [isabstracttype](#), [issingletontype](#).

Examples

```
julia> isconcretetype(Complex)
false

julia> isconcretetype(Complex{Float32})
true

julia> isconcretetype(Vector{Complex})
true

julia> isconcretetype(Vector{Complex{Float32}})
true

julia> isconcretetype(Union{})
false

julia> isconcretetype(Union{Int,String})
false
```

[source](#)

`Base.isbits` – Function.

```
| isbits(x)
```

Return true if `x` is an instance of an [isbitstype](#) type.

[source](#)

`Base.isbitstype` – Function.

```
| isbitstype(T)
```

Return true if type `T` is a "plain data" type, meaning it is immutable and contains no references to other values, only primitive types and other `isbitstype` types. Typical examples are numeric types such as [UInt8](#), [Float64](#), and [Complex{Float64}](#). This category of types is significant since they are

valid as type parameters, may not track `isdefined` / `isassigned` status, and have a defined layout that is compatible with C.

See also `isbits`, `isprimitivetype`, `ismutable`.

Examples

```
julia> isbitstype{Complex{Float64}}
true

julia> isbitstype{Complex}
false
```

[source](#)

`Base.fielddoffset` – Function.

```
fielddoffset(type, i)
```

The byte offset of field `i` of a type relative to the data start. For example, we could use it in the following manner to summarize information about a struct:

```
julia> structinfo(T) = [(fielddoffset(T,i), fieldname(T,i), fieldtype(T,i)) for i =
↳ 1:fieldcount(T)];

julia> structinfo(Base.Filesystem.StatStruct)
13-element Vector{Tuple{UInt64, Symbol, Type}}:
 (0x0000000000000000, :desc, Union{RawFD, String})
 (0x0000000000000008, :device, UInt64)
 (0x0000000000000010, :inode, UInt64)
 (0x0000000000000018, :mode, UInt64)
 (0x0000000000000020, :nlink, Int64)
 (0x0000000000000028, :uid, UInt64)
 (0x0000000000000030, :gid, UInt64)
 (0x0000000000000038, :rdev, UInt64)
 (0x0000000000000040, :size, Int64)
 (0x0000000000000048, :blksize, Int64)
 (0x0000000000000050, :blocks, Int64)
 (0x0000000000000058, :mtime, Float64)
 (0x0000000000000060, :ctime, Float64)
```

[source](#)

`Base.datatype_alignment` – Function.

```
Base.datatype_alignment(dt::DataType) -> Int
```

Memory allocation minimum alignment for instances of this type. Can be called on any `isconcretetype`.

[source](#)

`Base.datatype_haspadding` – Function.

```
Base.datatype_haspadding(dt::DataType) -> Bool
```

Return whether the fields of instances of this type are packed in memory, with no intervening padding bytes. Can be called on any `isconcretetype`.

[source](#)

`Base.datatype_pointerfree` – Function.

```
| Base.datatype_pointerfree(dt::DataType) -> Bool
```

Return whether instances of this type can contain references to gc-managed memory. Can be called on any `isconcretetype`.

[source](#)

Special values

`Base.typemin` – Function.

```
| typemin(T)
```

The lowest value representable by the given (real) numeric `DataType` `T`.

See also: [floatmin](#), [typemax](#), [eps](#).

Examples

```
julia> typemin{Int8}
-128

julia> typemin{UInt32}
0x00000000

julia> typemin{Float16}
-Inf16

julia> typemin{Float32}
-Inf32

julia> nextfloat(-Inf32) # smallest finite Float32 floating point number
-3.4028235f38
```

[source](#)

`Base.typemax` – Function.

```
| typemax(T)
```

The highest value representable by the given (real) numeric `DataType`.

See also: [floatmax](#), [typemin](#), [eps](#).

Examples

```
julia> typemax{Int8}
127
```

```
julia> typemax(UInt32)
0xffffffff

julia> typemax(Float64)
Inf

julia> typemax(Float32)
Inf32

julia> floatmax(Float32) # largest finite Float32 floating point number
3.4028235f38
```

[source](#)

Base.floatmin – Function.

```
| floatmin(T = Float64)
```

Return the smallest positive normal number representable by the floating-point type T.

Examples

```
julia> floatmin(Float16)
Float16(6.104e-5)

julia> floatmin(Float32)
1.1754944f-38

julia> floatmin()
2.2250738585072014e-308
```

[source](#)

Base.floatmax – Function.

```
| floatmax(T = Float64)
```

Return the largest finite number representable by the floating-point type T.

See also: [typemax](#), [floatmin](#), [eps](#).

Examples

```
julia> floatmax(Float16)
Float16(6.55e4)

julia> floatmax(Float32)
3.4028235f38

julia> floatmax()
1.7976931348623157e308

julia> typemax(Float64)
Inf
```

[source](#)

`Base.maxintfloat` – Function.

```
| maxintfloat(T=Float64)
```

The largest consecutive integer-valued floating-point number that is exactly represented in the given floating-point type `T` (which defaults to `Float64`).

That is, `maxintfloat` returns the smallest positive integer-valued floating-point number `n` such that `n+1` is not exactly representable in the type `T`.

When an Integer-type value is needed, use `Integer(maxintfloat(T))`.

[source](#)

```
| maxintfloat(T, S)
```

The largest consecutive integer representable in the given floating-point type `T` that also does not exceed the maximum integer representable by the integer type `S`. Equivalently, it is the minimum of `maxintfloat(T)` and `typemax(S)`.

[source](#)

`Base.eps` – Method.

```
| eps(::Type{T}) where T<:AbstractFloat  
| eps()
```

Return the machine epsilon of the floating point type `T` (`T = Float64` by default). This is defined as the gap between 1 and the next largest value representable by `typeof(one(T))`, and is equivalent to `eps(one(T))`. (Since `eps(T)` is a bound on the relative error of `T`, it is a "dimensionless" quantity like [one](#).)

Examples

```
julia> eps()  
2.220446049250313e-16  
  
julia> eps(Float32)  
1.1920929f-7  
  
julia> 1.0 + eps()  
1.0000000000000002  
  
julia> 1.0 + eps()/2  
1.0
```

[source](#)

`Base.eps` – Method.

```
| eps(x::AbstractFloat)
```

Return the unit in last place (ulp) of `x`. This is the distance between consecutive representable floating point values at `x`. In most cases, if the distance on either side of `x` is different, then the larger of the two is taken, that is

```
| eps(x) == max(x-prevfloat(x), nextfloat(x)-x)
```

The exceptions to this rule are the smallest and largest finite values (e.g. `nextfloat(-Inf)` and `prevfloat(Inf)` for `Float64`), which round to the smaller of the values.

The rationale for this behavior is that `eps` bounds the floating point rounding error. Under the default `RoundNearest` rounding mode, if y is a real number and x is the nearest floating point number to y , then

$$|y - x| \leq \text{eps}(x)/2.$$

See also: [nextfloat](#), [issubnormal](#), [floatmax](#).

Examples

```
julia> eps(1.0)
2.220446049250313e-16

julia> eps(prevfloat(2.0))
2.220446049250313e-16

julia> eps(2.0)
4.440892098500626e-16

julia> x = prevfloat(Inf)      # largest finite Float64
1.7976931348623157e308

julia> x + eps(x)/2           # rounds up
Inf

julia> x + prevfloat(eps(x)/2) # rounds down
1.7976931348623157e308
```

[source](#)

`Base.instances` – Function.

```
| instances(T::Type)
```

Return a collection of all instances of the given type, if applicable. Mostly used for enumerated types (see `@enum`).

Example

```
julia> @enum Color red blue green

julia> instances(Color)
(red, blue, green)
```

[source](#)

41.8 Special Types

Core.Any – Type.

```
| Any::DataType
```

Any is the union of all types. It has the defining property `isa(x, Any) == true` for any `x`. Any therefore describes the entire universe of possible values. For example `Integer` is a subset of `Any` that includes `Int`, `Int8`, and other integer types.

[source](#)

Core.Union – Type.

```
| Union{Types...}
```

A type union is an abstract type which includes all instances of any of its argument types. The empty union `Union{}` is the bottom type of Julia.

Examples

```
julia> IntOrString = Union{Int,AbstractString}
Union{Int64, AbstractString}

julia> 1 isa IntOrString
true

julia> "Hello!" isa IntOrString
true

julia> 1.0 isa IntOrString
false
```

[source](#)

Union{} – Keyword.

```
| Union{}
```

`Union{}`, the empty `Union` of types, is the type that has no values. That is, it has the defining property `isa(x, Union{}) == false` for any `x`. `Base.Bottom` is defined as its alias and the type of `Union{}` is `Core.TypeofBottom`.

Examples

```
julia> isa(nothing, Union{})
false
```

[source](#)

Core.UnionAll – Type.

```
| UnionAll
```

A union of types over all values of a type parameter. `UnionAll` is used to describe parametric types where the values of some parameters are not known.

Examples

```
julia> typeof(Vector)
UnionAll

julia> typeof(Vector{Int})
DataType
```

[source](#)

`Core.Tuple` – Type.

```
Tuple{Types...}
```

A tuple is a fixed-length container that can hold any values of different types, but cannot be modified (it is immutable). The values can be accessed via indexing. Tuple literals are written with commas and parentheses:

```
julia> (1, 1+1)
(1, 2)

julia> (1,)
(1,)

julia> x = (0.0, "hello", 6*7)
(0.0, "hello", 42)

julia> x[2]
"hello"

julia> typeof(x)
Tuple{Float64, String, Int64}
```

A length-1 tuple must be written with a comma, `(1,)`, since `(1)` would just be a parenthesized value. `()` represents the empty (length-0) tuple.

A tuple can be constructed from an iterator by using a `Tuple` type as constructor:

```
julia> Tuple(["a", 1])
("a", 1)

julia> Tuple{String, Float64}(["a", 1])
("a", 1.0)
```

Tuple types are covariant in their parameters: `Tuple{Int}` is a subtype of `Tuple{Any}`. Therefore `Tuple{Any}` is considered an abstract type, and tuple types are only concrete if their parameters are. Tuples do not have field names; fields are only accessed by index. Tuple types may have any number of parameters.

See the manual section on [Tuple Types](#).

See also [Vararg](#), [NTuple](#), [ntuple](#), [tuple](#), [NamedTuple](#).

[source](#)

Core.NTuple – Type.

```
| NTuple{N, T}
```

A compact way of representing the type for a tuple of length N where all elements are of type T.

Examples

```
| julia> isa((1, 2, 3, 4, 5, 6), NTuple{6, Int})
| true
```

See also [ntuple](#).

[source](#)

Core.NamedTuple – Type.

```
| NamedTuple
```

NamedTuples are, as their name suggests, named [Tuples](#). That is, they're a tuple-like collection of values, where each entry has a unique name, represented as a [Symbol](#). Like Tuples, NamedTuples are immutable; neither the names nor the values can be modified in place after construction.

A named tuple can be created as a tuple literal with keys, e.g. `(a=1, b=2)`, or as a tuple literal with semicolon after the opening parenthesis, e.g. `(; a=1, b=2)` (this form also accepts programmatically generated names as described below), or using a NamedTuple type as constructor, e.g. `NamedTuple{(:a, :b)}((1,2))`.

Accessing the value associated with a name in a named tuple can be done using field access syntax, e.g. `x.a`, or using [getindex](#), e.g. `x[:a]` or `x[(;a, :b)]`. A tuple of the names can be obtained using [keys](#), and a tuple of the values can be obtained using [values](#).

Note

Iteration over NamedTuples produces the values without the names. (See example below.) To iterate over the name-value pairs, use the [pairs](#) function.

The [@NamedTuple](#) macro can be used for conveniently declaring NamedTuple types.

Examples

```
| julia> x = (a=1, b=2)
| (a = 1, b = 2)
|
| julia> x.a
| 1
|
| julia> x[:a]
| 1
|
| julia> x[(;a,)]
| (a = 1,)
```

```

julia> keys(x)
(:a, :b)

julia> values(x)
(1, 2)

julia> collect(x)
2-element Vector{Int64}:
 1
 2

julia> collect(pairs(x))
2-element Vector{Pair{Symbol, Int64}}:
 :a => 1
 :b => 2

```

In a similar fashion as to how one can define keyword arguments programmatically, a named tuple can be created by giving pairs `name::Symbol => value` after a semicolon inside a tuple literal. This and the `name=value` syntax can be mixed:

```

julia> (; :a => 1, :b => 2, c=3)
(a = 1, b = 2, c = 3)

```

The name-value pairs can also be provided by splatting a named tuple or any iterator that yields two-value collections holding each a symbol as first value:

```

julia> keys = (:a, :b, :c); values = (1, 2, 3);

julia> NamedTuple{keys}(values)
(a = 1, b = 2, c = 3)

julia> (; (keys .=> values)...)
(a = 1, b = 2, c = 3)

julia> nt1 = (a=1, b=2);

julia> nt2 = (c=3, d=4);

julia> (; nt1..., nt2..., b=20) # the final b overwrites the value from nt1
(a = 1, b = 20, c = 3, d = 4)

julia> (; zip(keys, values)...) # zip yields tuples such as (:a, 1)
(a = 1, b = 2, c = 3)

```

As in keyword arguments, identifiers and dot expressions imply names:

```

julia> x = 0
0

julia> t = (; x)
(x = 0,)

```

```
julia> (; t.x)
(x = 0,)
```

Julia 1.5

Implicit names from identifiers and dot expressions are available as of Julia 1.5.

Julia 1.7

Use of `getindex` methods with multiple Symbols is available as of Julia 1.7.

source

Base.@NamedTuple – Macro.

```
@NamedTuple{key1::Type1, key2::Type2, ...}
@NamedTuple begin key1::Type1; key2::Type2; ...; end
```

This macro gives a more convenient syntax for declaring `NamedTuple` types. It returns a `NamedTuple` type with the given keys and types, equivalent to `NamedTuple{(:key1, :key2, ...), Tuple{Type1, Type2, ...}}`. If the `::Type` declaration is omitted, it is taken to be `Any`. The `begin ... end` form allows the declarations to be split across multiple lines (similar to a `struct` declaration), but is otherwise equivalent. The `NamedTuple` macro is used when printing `NamedTuple` types to e.g. the REPL.

For example, the tuple `(a=3.1, b="hello")` has a type `NamedTuple{(:a, :b), Tuple{Float64, String}}`, which can also be declared via `@NamedTuple` as:

```
julia> @NamedTuple{a::Float64, b::String}
@NamedTuple{a::Float64, b::String}

julia> @NamedTuple begin
    a::Float64
    b::String
end
@NamedTuple{a::Float64, b::String}
```

Julia 1.5

This macro is available as of Julia 1.5.

source

Base.@Kwargs – Macro.

```
@Kwargs{key1::Type1, key2::Type2, ...}
```

This macro gives a convenient way to construct the type representation of keyword arguments from the same syntax as `@NamedTuple`. For example, when we have a function call like `func([positional arguments]; kw1=1.0, kw2="2")`, we can use this macro to construct the internal type representation of the keyword arguments as `@Kwargs{kw1::Float64, kw2::String}`. The macro syntax is specifically designed to simplify the signature type of a keyword method when it is printed in the stack trace view.

```
julia> @Kwargs{init::Int} # the internal representation of keyword arguments
Base.Pairs{Symbol, Int64, Tuple{Symbol}, @NamedTuple{init::Int64}}

julia> sum("julia"; init=1)

Julia 1.10

This macro is available as of Julia 1.10.

source

Base.Val – Type.

```
| Val(c)
```

Return `Val{c}()`, which contains no run-time data. Types like this can be used to pass the information between functions through the value `c`, which must be an `isbits` value or a `Symbol`. The intent of this construct is to be able to dispatch on constants directly (at compile time) without having to test the value of the constant at run time.

Examples

```
julia> f(::Val{true}) = "Good"
f (generic function with 1 method)

julia> f(::Val{false}) = "Bad"
f (generic function with 2 methods)

julia> f(Val{true})
"Good"
```

[source](#)

Core.Vararg – Constant.

```
| Vararg{T,N}
```

The last parameter of a tuple type `Tuple` can be the special value `Vararg`, which denotes any number of trailing elements. `Vararg{T,N}` corresponds to exactly `N` elements of type `T`. Finally `Vararg{T}` corresponds to zero or more elements of type `T`. `Vararg` tuple types are used to represent the arguments accepted by `varargs` methods (see the section on [Varargs Functions](#) in the manual.)

See also [NTuple](#).

Examples

```
julia> mytupletype = Tuple{AbstractString, Vararg{Int}}
Tuple{AbstractString, Vararg{Int64}}

julia> isa(("1",), mytupletype)
true

julia> isa(("1",1), mytupletype)
true

julia> isa(("1",1,2), mytupletype)
true

julia> isa(("1",1,2,3.0), mytupletype)
false
```

[source](#)

Core.Nothing – Type.

```
| Nothing
```

A type with no fields that is the type of `nothing`.

See also: [isnothing](#), [Some](#), [Missing](#).

[source](#)

Base.isnothing – Function.

```
| isnothing(x)
```

Return true if `x === nothing`, and return false if not.

Julia 1.1

This function requires at least Julia 1.1.

See also [something](#), [Base.notnothing](#), [ismissing](#).

[source](#)

`Base.notnothing` – Function.

```
| notnothing(x)
```

Throw an error if `x === nothing`, and return `x` if not.

[source](#)

`Base.Some` – Type.

```
| Some{T}
```

A wrapper type used in `Union{Some{T}, Nothing}` to distinguish between the absence of a value ([nothing](#)) and the presence of a nothing value (i.e. `Some(nothing)`).

Use [something](#) to access the value wrapped by a `Some` object.

[source](#)

`Base.something` – Function.

```
| something(x...)
```

Return the first value in the arguments which is not equal to [nothing](#), if any. Otherwise throw an error. Arguments of type [Some](#) are unwrapped.

See also [coalesce](#), [skipmissing](#), [@something](#).

Examples

```
julia> something(nothing, 1)
1

julia> something(Some(1), nothing)
1

julia> something(Some(nothing), 2) === nothing
true

julia> something(missing, nothing)
missing

julia> something(nothing, nothing)
ERROR: ArgumentError: No value arguments present
```

[source](#)

`Base.@something` – Macro.

```
| @something(x...)
```

Short-circuiting version of `something`.

Examples

```
julia> f(x) = (println("f($x)"); nothing);

julia> a = 1;

julia> a = @something a f(2) f(3) error("Unable to find default for `a`")
1

julia> b = nothing;

julia> b = @something b f(2) f(3) error("Unable to find default for `b`")
f(2)
f(3)
ERROR: Unable to find default for `b`
[...]

julia> b = @something b f(2) f(3) Some(nothing)
f(2)
f(3)

julia> b === nothing
true
```

Julia 1.7

This macro is available as of Julia 1.7.

[source](#)

Base.Enums.Enum - Type.

```
| Enum{T<:Integer}
```

The abstract supertype of all enumerated types defined with `@enum`.

[source](#)

Base.Enums.@enum - Macro.

```
| @enum EnumName{::BaseType} value1[=x] value2[=y]
```

Create an `Enum{BaseType}` subtype with name `EnumName` and enum member values of `value1` and `value2` with optional assigned values of `x` and `y`, respectively. `EnumName` can be used just like other types and enum member values as regular values, such as

Examples

```
julia> @enum Fruit apple=1 orange=2 kiwi=3

julia> f(x::Fruit) = "I'm a Fruit with value: $(Int(x))"
```

```
f (generic function with 1 method)

julia> f(apple)
"I'm a Fruit with value: 1"

julia> Fruit(1)
apple::Fruit = 1
```

Values can also be specified inside a begin block, e.g.

```
@enum EnumName begin
    value1
    value2
end
```

BaseType, which defaults to `Int32`, must be a primitive subtype of Integer. Member values can be converted between the enum type and BaseType. `read` and `write` perform these conversions automatically. In case the enum is created with a non-default BaseType, `Integer(value1)` will return the integer `value1` with the type BaseType.

To list all the instances of an enum use `instances`, e.g.

```
julia> instances(Fruit)
(apple, orange, kiwi)
```

It is possible to construct a symbol from an enum instance:

```
julia> Symbol(apple)
:apple
```

[source](#)

Core.Expr – Type.

```
Expr(head::Symbol, args...)
```

A type representing compound expressions in parsed julia code (ASTs). Each expression consists of a head Symbol identifying which kind of expression it is (e.g. a call, for loop, conditional statement, etc.), and subexpressions (e.g. the arguments of a call). The subexpressions are stored in a `Vector{Any}` field called `args`.

See the manual chapter on [Metaprogramming](#) and the developer documentation [Julia ASTs](#).

Examples

```
julia> Expr(:call, :+, 1, 2)
:(1 + 2)

julia> dump(:(a ? b : c))
Expr
  head: Symbol if
  args: Array{Any}((3,))
    1: Symbol a
    2: Symbol b
    3: Symbol c
```

source

Core.Symbol – Type.

| **Symbol**

The type of object used to represent identifiers in parsed julia code (ASTs). Also often used as a name or label to identify an entity (e.g. as a dictionary key). Symbols can be entered using the `:` quote operator:

```
julia> :name
:name

julia> typeof(:name)
Symbol

julia> x = 42
42

julia> eval(:x)
42
```

Symbols can also be constructed from strings or other values by calling the constructor `Symbol(x...)`.

Symbols are immutable and their implementation re-uses the same object for all Symbols with the same name.

Unlike strings, Symbols are "atomic" or "scalar" entities that do not support iteration over characters.

source

Core.Symbol – Method.

| **Symbol**(x...) -> **Symbol**

Create a **Symbol** by concatenating the string representations of the arguments together.

Examples

```
julia> Symbol("my", "name")
:myname

julia> Symbol("day", 4)
:day4
```

source

Core.Module – Type.

| **Module**

A Module is a separate global variable workspace. See [module](#) and the [manual section about modules](#) for details.

| `Module(name::Symbol=:anonymous, std_imports=true, default_names=true)`

Return a module with the specified name. A baremodule corresponds to `Module(:ModuleName, false)`

An empty module containing no names at all can be created with `Module(:ModuleName, false, false)`. This module will not import Base or Core and does not contain a reference to itself.

[source](#)

41.9 Generic Functions

Core.Function – Type.

Function

Abstract type of all functions.

Examples

```
julia> isa(+, Function)
true

julia> typeof(sin)
typeof(sin) (singleton type of function sin, subtype of Function)

julia> ans <: Function
true
```

[source](#)

Base.hasmethod – Function.

```
hasmethod(f, t::Type{<:Tuple}[, kwnames]; world=get_world_counter()) -> Bool
```

Determine whether the given generic function has a method matching the given Tuple of argument types with the upper bound of world age given by world.

If a tuple of keyword argument names kwnames is provided, this also checks whether the method of f matching t has the given keyword argument names. If the matching method accepts a variable number of keyword arguments, e.g. with `kwargs...`, any names given in kwnames are considered valid. Otherwise the provided names must be a subset of the method's keyword arguments.

See also [applicable](#).

Julia 1.2

Providing keyword argument names requires Julia 1.2 or later.

Examples

```
julia> hasmethod(length, Tuple{Array})
true

julia> f(; oranges=0) = oranges;

julia> hasmethod(f, Tuple{}, (:oranges,))
true
```

```
julia> hasmethod(f, Tuple{}, (:apples, :bananas))
false

julia> g(; xs...) = 4;

julia> hasmethod(g, Tuple{}, (:a, :b, :c, :d)) # g accepts arbitrary kwargs
true
```

[source](#)

Core.applicable - Function.

```
| applicable(f, args...) -> Bool
```

Determine whether the given generic function has a method applicable to the given arguments.

See also [hasmethod](#).

Examples

```
julia> function f(x, y)
           x + y
       end;

julia> applicable(f, 1)
false

julia> applicable(f, 1, 2)
true
```

[source](#)

Base.isambiguous - Function.

```
| Base.isambiguous(m1, m2; ambiguous_bottom=false) -> Bool
```

Determine whether two methods `m1` and `m2` may be ambiguous for some call signature. This test is performed in the context of other methods of the same function; in isolation, `m1` and `m2` might be ambiguous, but if a third method resolving the ambiguity has been defined, this returns `false`. Alternatively, in isolation `m1` and `m2` might be ordered, but if a third method cannot be sorted with them, they may cause an ambiguity together.

For parametric types, the `ambiguous_bottom` keyword argument controls whether `Union{}` counts as an ambiguous intersection of type parameters – when `true`, it is considered ambiguous, when `false` it is not.

Examples

```
julia> foo(x::Complex{<:Integer}) = 1
foo (generic function with 1 method)

julia> foo(x::Complex{<:Rational}) = 2
foo (generic function with 2 methods)
```

```

julia> m1, m2 = collect(methods(foo));

julia> typeintersect(m1.sig, m2.sig)
Tuple{typeof(foo), Complex{Union{}}}

julia> Base.isambiguous(m1, m2, ambiguous_bottom=true)
true

julia> Base.isambiguous(m1, m2, ambiguous_bottom=false)
false

```

[source](#)

Core.invoke – Function.

```

invoke(f, argtypes::Type, args...; kwargs...)

```

Invoke a method for the given generic function `f` matching the specified types `argtypes` on the specified arguments `args` and passing the keyword arguments `kwargs`. The arguments `args` must conform with the specified types in `argtypes`, i.e. conversion is not automatically performed. This method allows invoking a method other than the most specific matching method, which is useful when the behavior of a more general definition is explicitly needed (often as part of the implementation of a more specific method of the same function).

Be careful when using `invoke` for functions that you don't write. What definition is used for given `argtypes` is an implementation detail unless the function explicitly states that calling with certain `argtypes` is a part of public API. For example, the change between `f1` and `f2` in the example below is usually considered compatible because the change is invisible by the caller with a normal (non-`invoke`) call. However, the change is visible if you use `invoke`.

Examples

```

julia> f(x::Real) = x^2;

julia> f(x::Integer) = 1 + invoke(f, Tuple{Real}, x);

julia> f(2)
5

julia> f1(::Integer) = Integer
          f1(::Real) = Real;

julia> f2(x::Real) = _f2(x)
          _f2(::Integer) = Integer
          _f2(_) = Real;

julia> f1(1)
Integer

julia> f2(1)
Integer

julia> invoke(f1, Tuple{Real}, 1)

```

```
Real
```

```
julia> invoke(f2, Tuple{Real}, 1)
Integer
```

source

Base.@invoke – Macro.

```
@invoke f(arg::T, ...; kwargs...)
```

Provides a convenient way to call `invoke` by expanding `@invoke f(arg1::T1, arg2::T2; kwargs...)` to `invoke(f, Tuple{T1,T2}, arg1, arg2; kwargs...)`. When an argument's type annotation is omitted, it's replaced with `Core.Typeof` that argument. To invoke a method where an argument is untyped or explicitly typed as `Any`, annotate the argument with `::Any`.

It also supports the following syntax:

- `@invoke (x::X).f` expands to `invoke(getproperty, Tuple{X,Symbol}, x, :f)`
- `@invoke (x::X).f = v::V` expands to `invoke(setproperty!, Tuple{X,Symbol,V}, x, :f, v)`
- `@invoke (xs::Xs)[i::I]` expands to `invoke(getindex, Tuple{Xs,I}, xs, i)`
- `@invoke (xs::Xs)[i::I] = v::V` expands to `invoke(setindex!, Tuple{Xs,V,I}, xs, v, i)`

Examples

```
julia> @macroexpand @invoke f(x::T, y)
:(Core.invoke(f, Tuple{T, Core.Typeof(y)}, x, y))

julia> @invoke 420::Integer % Unsigned
0x000000000000001a4

julia> @macroexpand @invoke (x::X).f
:(Core.invoke(Base.getproperty, Tuple{X, Core.Typeof(:f)}, x, :f))

julia> @macroexpand @invoke (x::X).f = v::V
:(Core.invoke(Base.setproperty!, Tuple{X, Core.Typeof(:f), V}, x, :f, v))

julia> @macroexpand @invoke (xs::Xs)[i::I]
:(Core.invoke(Base.getindex, Tuple{Xs, I}, xs, i))

julia> @macroexpand @invoke (xs::Xs)[i::I] = v::V
:(Core.invoke(Base.setindex!, Tuple{Xs, V, I}, xs, v, i))
```

Julia 1.7

This macro requires Julia 1.7 or later.

Julia 1.9

This macro is exported as of Julia 1.9.

Julia 1.10

The additional syntax is supported as of Julia 1.10.

source

`Base.invoke_late_test` – Function.

```
| invoke_late_test(f, args...; kwargs...)
```

Calls `f(args...; kwargs...)`, but guarantees that the most recent method of `f` will be executed. This is useful in specialized circumstances, e.g. long-running event loops or callback functions that may call obsolete versions of a function `f`. (The drawback is that `invoke_late_test` is somewhat slower than calling `f` directly, and the type of the result cannot be inferred by the compiler.)

Julia 1.9

Prior to Julia 1.9, this function was not exported, and was called as `Base.invoke_late_test`.

source

`Base.@invoke_late_test` – Macro.

```
| @invoke_late_test f(args...; kwargs...)
```

Provides a convenient way to call `invoke_late_test`. `@invoke_late_test f(args...; kwargs...)` will simply be expanded into `Base.invoke_late_test(f, args...; kwargs...)`.

It also supports the following syntax:

- `@invoke_late_test x.f` expands to `Base.invoke_late_test(getproperty, x, :f)`
- `@invoke_late_test x.f = v` expands to `Base.invoke_late_test(setproperty!, x, :f, v)`
- `@invoke_late_test xs[i]` expands to `Base.invoke_late_test(getindex, xs, i)`
- `@invoke_late_test xs[i] = v` expands to `Base.invoke_late_test(setindex!, xs, v, i)`

```
julia> @macroexpand @invoke_late_test f(x; kw=kwv)
:(Base.invoke_late_test(f, x; kw = kwv))

julia> @macroexpand @invoke_late_test x.f
:(Base.invoke_late_test(Base.getproperty, x, :f))

julia> @macroexpand @invoke_late_test x.f = v
:(Base.invoke_late_test(Base.setproperty!, x, :f, v))

julia> @macroexpand @invoke_late_test xs[i]
:(Base.invoke_late_test(Base.getindex, xs, i))

julia> @macroexpand @invoke_late_test xs[i] = v
:(Base.invoke_late_test(Base.setindex!, xs, v, i))
```

Julia 1.7

This macro requires Julia 1.7 or later.

Julia 1.9

Prior to Julia 1.9, this macro was not exported, and was called as `Base.@invoke_late_test`.

Julia 1.10

The additional `x.f` and `xs[i]` syntax requires Julia 1.10.

source

`new` – Keyword.

```
| new, or new{A,B,...}
```

Special function available to inner constructors which creates a new object of the type. The form `new{A,B,...}` explicitly specifies values of parameters for parametric types. See the manual section on [Inner Constructor Methods](#) for more information.

source

`Base.:|>` – Function.

```
| |>(x, f)
```

Infix operator which applies function `f` to the argument `x`. This allows `f(g(x))` to be written `x |> g |> f`. When used with anonymous functions, parentheses are typically required around the definition to get the intended chain.

Examples

```
julia> 4 |> inv
0.25

julia> [2, 3, 5] |> sum |> inv
0.1

julia> [0 1; 2 3] .|> (x -> x^2) |> sum
14
```

source

`Base.:∘` – Function.

```
| f ∘ g
```

Compose functions: i.e. `(f ∘ g)(args...; kwargs...)` means `f(g(args...; kwargs...))`. The `∘` symbol can be entered in the Julia REPL (and most editors, appropriately configured) by typing `\circ<tab>`.

Function composition also works in prefix form: `∘(f, g)` is the same as `f ∘ g`. The prefix form supports composition of multiple functions: `∘(f, g, h) = f ∘ g ∘ h` and splatting `∘(fs...)` for composing an iterable collection of functions. The last argument to `∘` execute first.

Julia 1.4

Multiple function composition requires at least Julia 1.4.

Julia 1.5

Composition of one function `∘(f)` requires at least Julia 1.5.

Julia 1.7

Using keyword arguments requires at least Julia 1.7.

Examples

```
julia> map(uppercase∘first, ["apple", "banana", "carrot"])
3-element Vector{Char}:
 'A': ASCII/Unicode U+0041 (category Lu: Letter, uppercase)
 'B': ASCII/Unicode U+0042 (category Lu: Letter, uppercase)
 'C': ASCII/Unicode U+0043 (category Lu: Letter, uppercase)

julia> (==(6)∘length).(["apple", "banana", "carrot"])
3-element BitVector:
 0
 1
 1

julia> fs = [
    x -> 2x
    x -> x-1
    x -> x/2
    x -> x+1
];

julia> ∘(fs...)(3)
2.0
```

See also [ComposedFunction](#), [!f::Function](#).

[source](#)

Base.ComposedFunction – Type.

```
ComposedFunction{Outer,Inner} <: Function
```

Represents the composition of two callable objects `outer::Outer` and `inner::Inner`. That is

```
ComposedFunction(outer, inner)(args...; kw...) == outer(inner(args...; kw...))
```

The preferred way to construct an instance of `ComposedFunction` is to use the composition operator `∘`:

```
julia> sin ∘ cos == ComposedFunction(sin, cos)
true

julia> typeof(sin∘cos)
ComposedFunction{typeof(sin), typeof(cos)}
```

The composed pieces are stored in the fields of `ComposedFunction` and can be retrieved as follows:

```
julia> composition = sin ∘ cos
sin ∘ cos

julia> composition.outer == sin
```

```

true

julia> composition.inner === cos
true

```

Julia 1.6

ComposedFunction requires at least Julia 1.6. In earlier versions ◦ returns an anonymous function instead.

See also ◦.

[source](#)

Base.splat – Function.

```
| splat(f)
```

Equivalent to

```
| my_splat(f) = args->f(args...)
```

i.e. given a function returns a new function that takes one argument and splats it into the original function. This is useful as an adaptor to pass a multi-argument function in a context that expects a single argument, but passes a tuple as that single argument.

Example usage:

```

julia> map(splat(+), zip(1:3,4:6))
3-element Vector{Int64}:
 5
 7
 9

julia> my_add = splat(+)
splat(+)

julia> my_add((1,2,3))
6

```

[source](#)

Base.Fix1 – Type.

```
| Fix1(f, x)
```

A type representing a partially-applied version of the two-argument function `f`, with the first argument fixed to the value `"x"`. In other words, `Fix1(f, x)` behaves similarly to `y->f(x, y)`.

See also [Fix2](#).

[source](#)

Base.Fix2 – Type.

```
| Fix2(f, x)
```

A type representing a partially-applied version of the two-argument function `f`, with the second argument fixed to the value `"x"`. In other words, `Fix2(f, x)` behaves similarly to `y->f(y, x)`.

[source](#)

41.10 Syntax

`Core.eval` – Function.

```
| Core.eval(m::Module, expr)
```

Evaluate an expression in the given module and return the result.

[source](#)

`Base.MainInclude.eval` – Function.

```
| eval(expr)
```

Evaluate an expression in the global scope of the containing module. Every `Module` (except those defined with `baremodule`) has its own 1-argument definition of `eval`, which evaluates expressions in that module.

[source](#)

`Base.@eval` – Macro.

```
| @eval [mod,] ex
```

Evaluate an expression with values interpolated into it using `eval`. If two arguments are provided, the first is the module to evaluate in.

[source](#)

`Base.evalfile` – Function.

```
| evalfile(path::AbstractString, args::Vector{String}=String[])
```

Load the file into an anonymous module using `include`, evaluate all expressions, and return the value of the last expression. The optional `args` argument can be used to set the input arguments of the script (i.e. the global `ARGS` variable). Note that definitions (e.g. methods, globals) are evaluated in the anonymous module and do not affect the current module.

Example

```
julia> write("testfile.jl", """
    @show ARGS
    1 + 1
    """);

julia> x = evalfile("testfile.jl", ["ARG1", "ARG2"]);
ARGS = ["ARG1", "ARG2"]

julia> x
2

julia> rm("testfile.jl")
```

source

Base.esc – Function.

```
| esc(e)
```

Only valid in the context of an [Expr](#) returned from a macro. Prevents the macro hygiene pass from turning embedded variables into gensym variables. See the [Macros](#) section of the Metaprogramming chapter of the manual for more details and examples.

source

Base.@inbounds – Macro.

```
| @inbounds(blk)
```

Eliminates array bounds checking within expressions.

In the example below the in-range check for referencing element *i* of array *A* is skipped to improve performance.

```
function sum(A::AbstractArray)
    r = zero(eltype(A))
    for i in eachindex(A)
        @inbounds r += A[i]
    end
    return r
end
```

Warning

Using `@inbounds` may return incorrect results/crashes/corruption for out-of-bounds indices. The user is responsible for checking it manually. Only use `@inbounds` when it is certain from the information locally available that all accesses are in bounds. In particular, using `1:length(A)` instead of `eachindex(A)` in a function like the one above is not safely in-bounds because the first index of *A* may not be 1 for all user defined types that subtype `AbstractArray`.

source

Base.@boundscheck – Macro.

```
| @boundscheck(blk)
```

Annotates the expression *blk* as a bounds checking block, allowing it to be elided by [@inbounds](#).

Note

The function in which `@boundscheck` is written must be inlined into its caller in order for `@inbounds` to have effect.

Examples

```

julia> @inline function g(A, i)
           @boundscheck checkbounds(A, i)
           return "accessing ($A)[$i]"
       end;

julia> f1() = return g(1:2, -1);

julia> f2() = @inbounds return g(1:2, -1);

julia> f1()
ERROR: BoundsError: attempt to access 2-element UnitRange{Int64} at index [-1]
Stacktrace:
 [1] throw_boundserror(::UnitRange{Int64}, ::Tuple{Int64}) at ./abstractarray.jl:455
 [2] checkbounds at ./abstractarray.jl:420 [inlined]
 [3] g at ./none:2 [inlined]
 [4] f1() at ./none:1
 [5] top-level scope

julia> f2()
"accessing (1:2)[-1]"

```

Warning

The `@boundscheck` annotation allows you, as a library writer, to opt-in to allowing other code to remove your bounds checks with `@inbounds`. As noted there, the caller must verify—using information they can access—that their accesses are valid before using `@inbounds`. For indexing into your `AbstractArray` subclasses, for example, this involves checking the indices against its `axes`. Therefore, `@boundscheck` annotations should only be added to a `getindex` or `setindex!` implementation after you are certain its behavior is correct.

source

Base.@propagate_inbounds – Macro.

```
| @propagate_inbounds
```

Tells the compiler to inline a function while retaining the caller's inbounds context.

source

Base.@inline – Macro.

```
| @inline
```

Give a hint to the compiler that this function is worth inlining.

Small functions typically do not need the `@inline` annotation, as the compiler does it automatically. By using `@inline` on bigger functions, an extra nudge can be given to the compiler to inline it.

`@inline` can be applied immediately before a function definition or within a function body.

```

# annotate long-form definition
@inline function longdef(x)
    ...
end

```

```
# annotate short-form definition
@inline shortdef(x) = ...

# annotate anonymous function that a `do` block creates
f() do
  @inline
  ...
end
```

Julia 1.8

The usage within a function body requires at least Julia 1.8.

@inline block

Give a hint to the compiler that calls within block are worth inlining.

```
# The compiler will try to inline `f`
@inline f(...)

# The compiler will try to inline `f`, `g` and `+`
@inline f(...) + g(...)
```

Note

A callsite annotation always has the precedence over the annotation applied to the definition of the called function:

```
@noinline function explicit_noinline(args...)
  # body
end

let
  @inline explicit_noinline(args...) # will be inlined
end
```

Note

When there are nested callsite annotations, the innermost annotation has the precedence:

```
@noinline let a0, b0 = ...
  a = @inline f(a0) # the compiler will try to inline this call
  b = f(b0)         # the compiler will NOT try to inline this call
  return a, b
end
```

Warning

Although a callsite annotation will try to force inlining in regardless of the cost model, there are still chances it can't succeed in it. Especially, recursive calls can not be inlined even if they are annotated as @inlined.

Julia 1.8

The callsite annotation requires at least Julia 1.8.

source

Base.@noinline – Macro.

| @noinline

Give a hint to the compiler that it should not inline a function.

Small functions are typically inlined automatically. By using @noinline on small functions, auto-inlining can be prevented.

@noinline can be applied immediately before a function definition or within a function body.

```
# annotate long-form definition
@noinline function longdef(x)
    ...
end

# annotate short-form definition
@noinline shortdef(x) = ...

# annotate anonymous function that a `do` block creates
f() do
    @noinline
    ...
end
```

Julia 1.8

The usage within a function body requires at least Julia 1.8.

| @noinline block

Give a hint to the compiler that it should not inline the calls within block.

```
# The compiler will try to not inline `f`
@noinline f(...)

# The compiler will try to not inline `f`, `g` and `+`
@noinline f(...) + g(...)
```

Note

A callsite annotation always has the precedence over the annotation applied to the definition of the called function:

```
@inline function explicit_inline(args...)
    # body
end

let
    @noinline explicit_inline(args...) # will not be inlined
end
```

Note

When there are nested callsite annotations, the innermost annotation has the precedence:

```
@inline let a0, b0 = ...
    a = @noinline f(a0) # the compiler will NOT try to inline this call
    b = f(b0)           # the compiler will try to inline this call
    return a, b
end
```

Julia 1.8

The callsite annotation requires at least Julia 1.8.

Note

If the function is trivial (for example returning a constant) it might get inlined anyway.

[source](#)

Base.@nospecialize – Macro.

```
| @nospecialize
```

Applied to a function argument name, hints to the compiler that the method implementation should not be specialized for different types of that argument, but instead use the declared type for that argument. It can be applied to an argument within a formal argument list, or in the function body. When applied to an argument, the macro must wrap the entire argument expression, e.g., `@nospecialize(x::Real)` or `@nospecialize(i::Integer...)` rather than wrapping just the argument name. When used in a function body, the macro must occur in statement position and before any code.

When used without arguments, it applies to all arguments of the parent scope. In local scope, this means all arguments of the containing function. In global (top-level) scope, this means all methods subsequently defined in the current module.

Specialization can reset back to the default by using `@specialize`.

```
function example_function(@nospecialize x)
    ...
end

function example_function(x, @nospecialize(y = 1))
    ...
end

function example_function(x, y, z)
    @nospecialize x y
    ...
end

@nospecialize
f(y) = [x for x in y]
@specialize
```

Note

`@nospecialize` affects code generation but not inference: it limits the diversity of the resulting native code, but it does not impose any limitations (beyond the standard ones) on type-inference. Use `Base.@nospecializeinfer` together with `@nospecialize` to additionally suppress inference.

Example

```
julia> f(A::AbstractArray) = g(A)
f (generic function with 1 method)

julia> @noinline g(@nospecialize(A::AbstractArray)) = A[1]
g (generic function with 1 method)

julia> @code_typed f([1.0])
CodeInfo(
  1 - %1 = invoke Main.g(_2::AbstractArray)::Float64
    └─      return %1
) => Float64
```

Here, the `@nospecialize` annotation results in the equivalent of

```
f(A::AbstractArray) = invoke(g, Tuple{AbstractArray}, A)
```

ensuring that only one version of native code will be generated for `g`, one that is generic for any `AbstractArray`. However, the specific return type is still inferred for both `g` and `f`, and this is still used in optimizing the callers of `f` and `g`.

[source](#)

`Base.@specialize` – Macro.

```
| @specialize
```

Reset the specialization hint for an argument back to the default. For details, see [@nospecialize](#).

[source](#)

`Base.@nospecializeinfer` – Macro.

```
Base.@nospecializeinfer function f(args...)
    @nospecialize ...
    ...
end
Base.@nospecializeinfer f(@nospecialize args...) = ...
```

Tells the compiler to infer `f` using the declared types of `@nospecialized` arguments. This can be used to limit the number of compiler-generated specializations during inference.

Example

```
julia> f(A::AbstractArray) = g(A)
f (generic function with 1 method)
```

```
julia> @noinline Base.@nospecializeinfer g(@nospecialize(A::AbstractArray)) = A[1]
g (generic function with 1 method)

julia> @code_typed f([1.0])
CodeInfo(
  1 - %1 = invoke Main.g(_2::AbstractArray)::Any
  └─      return %1
) => Any
```

In this example, `f` will be inferred for each specific type of `A`, but `g` will only be inferred once with the declared argument type `A::AbstractArray`, meaning that the compiler will not likely see the excessive inference time on it while it can not infer the concrete return type of it. Without the `@nospecializeinfer`, `f([1.0])` would infer the return type of `g` as `Float64`, indicating that inference ran for `g(::Vector{Float64})` despite the prohibition on specialized code generation.

[source](#)

`Base.@constprop` – Macro.

```
| @constprop setting [ex]
```

Control the mode of interprocedural constant propagation for the annotated function.

Two settings are supported:

- `@constprop :aggressive [ex]`: apply constant propagation aggressively. For a method where the return type depends on the value of the arguments, this can yield improved inference results at the cost of additional compile time.
- `@constprop :none [ex]`: disable constant propagation. This can reduce compile times for functions that Julia might otherwise deem worthy of constant-propagation. Common cases are for functions with `Bool`- or `Symbol`-valued arguments or keyword arguments.

`@constprop` can be applied immediately before a function definition or within a function body.

```
# annotate long-form definition
@constprop :aggressive function longdef(x)
    ...
end

# annotate short-form definition
@constprop :aggressive shortdef(x) = ...

# annotate anonymous function that a `do` block creates
f() do
    @constprop :aggressive
    ...
end
```

Julia 1.10

The usage within a function body requires at least Julia 1.10.

[source](#)

Base.gensym – Function.

```
| gensym([tag])
```

Generates a symbol which will not conflict with other variable names (in the same module).

[source](#)

Base.@gensym – Macro.

```
| @gensym
```

Generates a gensym symbol for a variable. For example, `@gensym x y` is transformed into `x = gensym("x"); y = gensym("y").`

[source](#)

var"name" – Keyword.

```
| var
```

The syntax `var"#example#"` refers to a variable named `Symbol("#example#")`, even though `#example#` is not a valid Julia identifier name.

This can be useful for interoperability with programming languages which have different rules for the construction of valid identifiers. For example, to refer to the R variable `draw.segments`, you can use `var"draw.segments"` in your Julia code.

It is also used to show julia source code which has gone through macro hygiene or otherwise contains variable names which can't be parsed normally.

Note that this syntax requires parser support so it is expanded directly by the parser rather than being implemented as a normal string macro `@var_str`.

Julia 1.3

This syntax requires at least Julia 1.3.

[source](#)

Base.@goto – Macro.

```
| @goto name
```

`@goto name` unconditionally jumps to the statement at the location `@label name`.

`@label` and `@goto` cannot create jumps to different top-level statements. Attempts cause an error. To still use `@goto`, enclose the `@label` and `@goto` in a block.

[source](#)

Base.@label – Macro.

```
| @label name
```

Labels a statement with the symbolic label name. The label marks the end-point of an unconditional jump with `@goto name`.

[source](#)

Base.SimdLoop.@simd – Macro.

| @simd

Annotate a for loop to allow the compiler to take extra liberties to allow loop re-ordering

Warning

This feature is experimental and could change or disappear in future versions of Julia. Incorrect use of the @simd macro may cause unexpected results.

The object iterated over in a @simd for loop should be a one-dimensional range. By using @simd, you are asserting several properties of the loop:

- It is safe to execute iterations in arbitrary or overlapping order, with special consideration for reduction variables.
- Floating-point operations on reduction variables can be reordered or contracted, possibly causing different results than without @simd.

In many cases, Julia is able to automatically vectorize inner for loops without the use of @simd. Using @simd gives the compiler a little extra leeway to make it possible in more situations. In either case, your inner loop should have the following properties to allow vectorization:

- The loop must be an innermost loop
- The loop body must be straight-line code. Therefore, @inbounds is currently needed for all array accesses. The compiler can sometimes turn short &&, ||, and ?: expressions into straight-line code if it is safe to evaluate all operands unconditionally. Consider using the ifelse function instead of ?: in the loop if it is safe to do so.
- Accesses must have a stride pattern and cannot be "gathers" (random-index reads) or "scatters" (random-index writes).
- The stride should be unit stride.

Note

The @simd does not assert by default that the loop is completely free of loop-carried memory dependencies, which is an assumption that can easily be violated in generic code. If you are writing non-generic code, you can use @simd ivdep for ... end to also assert that:

- There exists no loop-carried memory dependencies
- No iteration ever waits on a previous iteration to make forward progress.

source

Base.@polly – Macro.

| @polly

Tells the compiler to apply the polyhedral optimizer Polly to a function.

source

Base.@generated – Macro.

```
| @generated f
```

@generated is used to annotate a function which will be generated. In the body of the generated function, only types of arguments can be read (not the values). The function returns a quoted expression evaluated when the function is called. The @generated macro should not be used on functions mutating the global scope or depending on mutable elements.

See [Metaprogramming](#) for further details.

Examples

```
julia> @generated function bar(x)
    if x <: Integer
        return :(x ^ 2)
    else
        return :(x)
    end
end
bar (generic function with 1 method)

julia> bar(4)
16

julia> bar("baz")
"baz"
```

[source](#)

Base.@assume_effects – Macro.

```
| @assume_effects setting... [ex]
```

Override the compiler's effect modeling for the given method or foreign call. @assume_effects can be applied immediately before a function definition or within a function body. It can also be applied immediately before a @ccall expression.

Julia 1.8

Using Base.@assume_effects requires Julia version 1.8.

Examples

```
julia> Base.@assume_effects :terminates_locally function pow(x)
    # this :terminates_locally allows `pow` to be constant-folded
    res = 1
    1 < x < 20 || error("bad pow")
    while x > 1
        res *= x
        x -= 1
    end
    return res
end
```

```

pow (generic function with 1 method)

julia> code_typed() do
    pow(12)
end
1-element Vector{Any}:
  CodeInfo(
1 -      return 479001600
) => Int64

julia> code_typed() do
    map((2,3,4)) do x
        # this :terminates_locally allows this anonymous function to be
        ↪ constant-folded
        Base.@assume_effects :terminates_locally
        res = 1
        1 < x < 20 || error("bad pow")
        while x > 1
            res *= x
            x -= 1
        end
        return res
    end
end
1-element Vector{Any}:
  CodeInfo(
1 -      return (2, 6, 24)
) => Tuple{Int64, Int64, Int64}

julia> Base.@assume_effects :total !:nothrow @ccall jl_type_intersection(Vector{Int}::Any,
↪ Vector{<:Integer}::Any)::Any
Vector{Int64} (alias for Array{Int64, 1})

```

Julia 1.10

The usage within a function body requires at least Julia 1.10.

Warning

Improper use of this macro causes undefined behavior (including crashes, incorrect answers, or other hard to track bugs). Use with care and only as a last resort if absolutely required. Even in such a case, you SHOULD take all possible steps to minimize the strength of the effect assertion (e.g., do not use `:total` if `:nothrow` would have been sufficient).

In general, each setting value makes an assertion about the behavior of the function, without requiring the compiler to prove that this behavior is indeed true. These assertions are made for all world ages. It is thus advisable to limit the use of generic functions that may later be extended to invalidate the assumption (which would cause undefined behavior).

The following settings are supported.

- `:consistent`
- `:effect_free`

- `:nothrow`
- `:terminates_globally`
- `:terminates_locally`
- `:notaskstate`
- `:inaccessiblememonly`
- `:foldable`
- `:removable`
- `:total`

Extended help

`:consistent`

The `:consistent` setting asserts that for `egal (==)` inputs:

- The manner of termination (return value, exception, non-termination) will always be the same.
- If the method returns, the results will always be `egal`.

Note

This in particular implies that the method must not return a freshly allocated mutable object. Multiple allocations of mutable objects (even with identical contents) are not `egal`.

Note

The `:consistent-cy` assertion is made world-age wise. More formally, write f for the evaluation of f in world-age i , then we require:

$$i, x, y : xy \rightarrow f(x)f(y)$$

However, for two world ages i, j s.t. ij , we may have $f(x)f(y)$.

A further implication is that `:consistent` functions may not make their return value dependent on the state of the heap or any other global state that is not constant for a given world age.

Note

The `:consistent-cy` includes all legal rewrites performed by the optimizer. For example, floating-point fastmath operations are not considered `:consistent`, because the optimizer may rewrite them causing the output to not be `:consistent`, even for the same world age (e.g. because one ran in the interpreter, while the other was optimized).

Note

The `:consistent-cy` assertion currently includes the assertion that the function will not execute any undefined behavior (for any input). Note that undefined behavior may technically cause the function to violate other effect assertions (such as `:nothrow` or `:effect_free`) as well, but we do not model this, and all effects except `:consistent` assume the absence of undefined behavior.

Note

If `:consistent` functions terminate by throwing an exception, that exception itself is not required to meet the equality requirement specified above.

`:effect_free`

The `:effect_free` setting asserts that the method is free of externally semantically visible side effects. The following is an incomplete list of externally semantically visible side effects:

- Changing the value of a global variable.
- Mutating the heap (e.g. an array or mutable value), except as noted below
- Changing the method table (e.g. through calls to `eval`)
- File/Network/etc. I/O
- Task switching

However, the following are explicitly not semantically visible, even if they may be observable:

- Memory allocations (both mutable and immutable)
- Elapsed time
- Garbage collection
- Heap mutations of objects whose lifetime does not exceed the method (i.e. were allocated in the method and do not escape).
- The returned value (which is externally visible, but not a side effect)

The rule of thumb here is that an externally visible side effect is anything that would affect the execution of the remainder of the program if the function were not executed.

Note

The `:effect_free` assertion is made both for the method itself and any code that is executed by the method. Keep in mind that the assertion must be valid for all world ages and limit use of this assertion accordingly.

`:nothrow`

The `:nothrow` settings asserts that this method does not terminate abnormally (i.e. will either always return a value or never return).

Note

It is permissible for `:nothrow` annotated methods to make use of exception handling internally as long as the exception is not rethrown out of the method itself.

Note

`MethodErrors` and similar exceptions count as abnormal termination.

:terminates_globally

The `:terminates_globally` settings asserts that this method will eventually terminate (either normally or abnormally), i.e. does not loop indefinitely.

Note

This `:terminates_globally` assertion covers any other methods called by the annotated method.

Note

The compiler will consider this a strong indication that the method will terminate relatively quickly and may (if otherwise legal), call this method at compile time. I.e. it is a bad idea to annotate this setting on a method that technically, but not practically, terminates.

:terminates_locally

The `:terminates_locally` setting is like `:terminates_globally`, except that it only applies to syntactic control flow within the annotated method. It is thus a much weaker (and thus safer) assertion that allows for the possibility of non-termination if the method calls some other method that does not terminate.

Note

`:terminates_globally` implies `:terminates_locally`.

:notaskstate

The `:notaskstate` setting asserts that the method does not use or modify the local task state (task local storage, RNG state, etc.) and may thus be safely moved between tasks without observable results.

Note

The implementation of exception handling makes use of state stored in the task object. However, this state is currently not considered to be within the scope of `:notaskstate` and is tracked separately using the `:nothrow` effect.

Note

The `:notaskstate` assertion concerns the state of the currently running task. If a reference to a Task object is obtained by some other means that does not consider which task is currently running, the `:notaskstate` effect need not be tainted. This is true, even if said task object happens to be `===` to the currently running task.

Note

Access to task state usually also results in the tainting of other effects, such as `:effect_free` (if task state is modified) or `:consistent` (if task state is used in the computation of the result). In particular, code that is not `:notaskstate`, but is `:effect_free` and `:consistent` may still be dead-code-eliminated and thus promoted to `:total`.

:inaccessiblememonly

The `:inaccessiblememonly` setting asserts that the method does not access or modify externally accessible mutable memory. This means the method can access or modify mutable memory for newly allocated objects that is not accessible by other methods or top-level execution before return from the method, but it can not access or modify any mutable global state or mutable memory pointed to by its arguments.

Note

Below is an incomplete list of examples that invalidate this assumption:

- a global reference or `getglobal` call to access a mutable global variable
- a global assignment or `setglobal!` call to perform assignment to a non-constant global variable
- `setfield!` call that changes a field of a global mutable variable

Note

This `:inaccessiblememonly` assertion covers any other methods called by the annotated method.

:foldable

This setting is a convenient shortcut for the set of effects that the compiler requires to be guaranteed to constant fold a call at compile time. It is currently equivalent to the following settings:

- `:consistent`
- `:effect_free`
- `:terminates_globally`

Note

This list in particular does not include `:nothrow`. The compiler will still attempt constant propagation and note any thrown error at compile time. Note however, that by the `:consistent`-`cy` requirements, any such annotated call must consistently throw given the same argument values.

Note

An explicit `@inbounds` annotation inside the function will also disable constant folding and not be overridden by `:foldable`.

:removable

This setting is a convenient shortcut for the set of effects that the compiler requires to be guaranteed to delete a call whose result is unused at compile time. It is currently equivalent to the following settings:

- `:effect_free`
- `:nothrow`

- `:terminates_globally`

:total

This setting is the maximum possible set of effects. It currently implies the following other settings:

- `:consistent`
- `:effect_free`
- `:nothrow`
- `:terminates_globally`
- `:notaskstate`
- `:inaccessiblememonly`

Warning

`:total` is a very strong assertion and will likely gain additional semantics in future versions of Julia (e.g. if additional effects are added and included in the definition of `:total`). As a result, it should be used with care. Whenever possible, prefer to use the minimum possible set of specific effect assertions required for a particular application. In cases where a large number of effect overrides apply to a set of functions, a custom macro is recommended over the use of `:total`.

Negated effects

Effect names may be prefixed by `!` to indicate that the effect should be removed from an earlier meta effect. For example, `:total !:nothrow` indicates that while the call is generally total, it may however throw.

[source](#)

Base.@deprecate – Macro.

```
| @deprecate old new [export_old=true]
```

Deprecate method `old` and specify the replacement call `new`, defining a new method `old` with the specified signature in the process.

To prevent `old` from being exported, set `export_old` to `false`.

Julia 1.5

As of Julia 1.5, functions defined by `@deprecate` do not print warning when `julia` is run without the `--depwarn=yes` flag set, as the default value of `--depwarn` option is `no`. The warnings are printed from tests run by `Pkg.test()`.

Examples

```
julia> @deprecate old(x) new(x)
old (generic function with 1 method)

julia> @deprecate old(x) new(x) false
old (generic function with 1 method)
```

Calls to `@deprecate` without explicit type-annotations will define deprecated methods accepting any number of positional and keyword arguments of type `Any`.

Julia 1.9

Keyword arguments are forwarded when there is no explicit type annotation as of Julia 1.9. For older versions, you can manually forward positional and keyword arguments by doing `@deprecate old(args...; kwargs...) new(args...; kwargs...)`.

To restrict deprecation to a specific signature, annotate the arguments of `old`. For example,

```
julia> new(x::Int) = x;

julia> new(x::Float64) = 2x;

julia> @deprecate old(x::Int) new(x);

julia> methods(old)
# 1 method for generic function "old" from Main:
[1] old(x::Int64)
      @ deprecated.jl:94
```

will define and deprecate a method `old(x::Int)` that mirrors `new(x::Int)` but will not define nor deprecate the method `old(x::Float64)`.

[source](#)

41.11 Missing Values

`Base.Missing` – Type.

| `Missing`

A type with no fields whose singleton instance `missing` is used to represent missing values.

See also: [skipmissing](#), [nonmissingtype](#), [Nothing](#).

[source](#)

`Base.missing` – Constant.

| `missing`

The singleton instance of type `Missing` representing a missing value.

See also: [NaN](#), [skipmissing](#), [nonmissingtype](#).

[source](#)

`Base.coalesce` – Function.

| `coalesce(x...)`

Return the first value in the arguments which is not equal to `missing`, if any. Otherwise return `missing`.

See also [skipmissing](#), [something](#), [@coalesce](#).

Examples

```
julia> coalesce(missing, 1)
1

julia> coalesce(1, missing)
1

julia> coalesce(nothing, 1) # returns `nothing`

julia> coalesce(missing, missing)
missing
```

[source](#)

Base.@coalesce – Macro.

```
| @coalesce(x...)
```

Short-circuiting version of `coalesce`.

Examples

```
julia> f(x) = (println("f($x)"); missing);

julia> a = 1;

julia> a = @coalesce a f(2) f(3) error("`a` is still missing")
1

julia> b = missing;

julia> b = @coalesce b f(2) f(3) error("`b` is still missing")
f(2)
f(3)
ERROR: `b` is still missing
[...]
```

Julia 1.7

This macro is available as of Julia 1.7.

[source](#)

Base.ismissing – Function.

```
| ismissing(x)
```

Indicate whether `x` is `missing`.

See also: `skipmissing`, `isnothing`, `isnan`.

[source](#)

Base.skipmissing – Function.

```
| skipmissing(itr)
```

Return an iterator over the elements in `itr` skipping `missing` values. The returned object can be indexed using indices of `itr` if the latter is indexable. Indices corresponding to missing values are not valid: they are skipped by `keys` and `eachindex`, and a `MissingException` is thrown when trying to use them.

Use `collect` to obtain an `Array` containing the non-missing values in `itr`. Note that even if `itr` is a multidimensional array, the result will always be a `Vector` since it is not possible to remove missings while preserving dimensions of the input.

See also `coalesce`, `ismissing`, `something`.

Examples

```
julia> x = skipmissing([1, missing, 2])
skipmissing(Union{Missing, Int64}[1, missing, 2])

julia> sum(x)
3

julia> x[1]
1

julia> x[2]
ERROR: MissingException: the value at index (2,) is missing
[...]

julia> argmax(x)
3

julia> collect(keys(x))
2-element Vector{Int64}:
 1
 3

julia> collect(skipmissing([1, missing, 2]))
2-element Vector{Int64}:
 1
 2

julia> collect(skipmissing([1 missing; 2 missing]))
2-element Vector{Int64}:
 1
 2
```

[source](#)

`Base.nonmissingtype` – Function.

```
| nonmissingtype(T::Type)
```

If `T` is a union of types containing `Missing`, return a new type with `Missing` removed.

Examples

```
julia> nonmissingtype(Union{Int64,Missing})
Int64

julia> nonmissingtype(Any)
Any
```

Julia 1.3

This function is exported as of Julia 1.3.

[source](#)

41.12 System

Base.run – Function.

```
| run(command, args...; wait::Bool = true)
```

Run a command object, constructed with backticks (see the [Running External Programs](#) section in the manual). Throws an error if anything goes wrong, including the process exiting with a non-zero status (when wait is true).

The args... allow you to pass through file descriptors to the command, and are ordered like regular unix file descriptors (eg stdin, stdout, stderr, FD(3), FD(4)...).

If wait is false, the process runs asynchronously. You can later wait for it and check its exit status by calling success on the returned process object.

When wait is false, the process' I/O streams are directed to devnull. When wait is true, I/O streams are shared with the parent process. Use [pipeline](#) to control I/O redirection.

[source](#)

Base.devnull – Constant.

```
| devnull
```

Used in a stream redirect to discard all data written to it. Essentially equivalent to /dev/null on Unix or NUL on Windows. Usage:

```
| run(pipeline(`cat test.txt`, devnull))
```

[source](#)

Base.success – Function.

```
| success(command)
```

Run a command object, constructed with backticks (see the [Running External Programs](#) section in the manual), and tell whether it was successful (exited with a code of 0). An exception is raised if the process cannot be started.

[source](#)

Base.process_running – Function.

```
| process_running(p::Process)
```

Determine whether a process is currently running.

[source](#)

Base.process_exited – Function.

```
| process_exited(p::Process)
```

Determine whether a process has exited.

[source](#)

Base.kill – Method.

```
| kill(p::Process, signal=Base.SIGTERM)
```

Send a signal to a process. The default is to terminate the process. Returns successfully if the process has already exited, but throws an error if killing the process failed for other reasons (e.g. insufficient permissions).

[source](#)

Base.Sys.set_process_title – Function.

```
| Sys.set_process_title(title::AbstractString)
```

Set the process title. No-op on some operating systems.

[source](#)

Base.Sys.get_process_title – Function.

```
| Sys.get_process_title()
```

Get the process title. On some systems, will always return an empty string.

[source](#)

Base.ignorestatus – Function.

```
| ignorestatus(command)
```

Mark a command object so that running it will not throw an error if the result code is non-zero.

[source](#)

Base.detach – Function.

```
| detach(command)
```

Mark a command object so that it will be run in a new process group, allowing it to outlive the julia process, and not have Ctrl-C interrupts passed to it.

[source](#)

Base.Cmd – Type.

```
| Cmd(cmd::Cmd; ignorestatus, detach, windows_verbatim, windows_hide, env, dir)
| Cmd(exec::Vector{String})
```

Construct a new `Cmd` object, representing an external program and arguments, from `cmd`, while changing the settings of the optional keyword arguments:

- `ignorestatus::Bool`: If `true` (defaults to `false`), then the `Cmd` will not throw an error if the return code is nonzero.
- `detach::Bool`: If `true` (defaults to `false`), then the `Cmd` will be run in a new process group, allowing it to outlive the `julia` process and not have `Ctrl-C` passed to it.
- `windows_verbatim::Bool`: If `true` (defaults to `false`), then on Windows the `Cmd` will send a command-line string to the process with no quoting or escaping of arguments, even arguments containing spaces. (On Windows, arguments are sent to a program as a single "command-line" string, and programs are responsible for parsing it into arguments. By default, empty arguments and arguments with spaces or tabs are quoted with double quotes " in the command line, and \ or " are preceded by backslashes. `windows_verbatim=true` is useful for launching programs that parse their command line in nonstandard ways.) Has no effect on non-Windows systems.
- `windows_hide::Bool`: If `true` (defaults to `false`), then on Windows no new console window is displayed when the `Cmd` is executed. This has no effect if a console is already open or on non-Windows systems.
- `env`: Set environment variables to use when running the `Cmd`. `env` is either a dictionary mapping strings to strings, an array of strings of the form `"var=val"`, an array or tuple of `"var"=>val` pairs. In order to modify (rather than replace) the existing environment, initialize `env` with `copy(ENV)` and then set `env["var"]=val` as desired. To add to an environment block within a `Cmd` object without replacing all elements, use `addenv()` which will return a `Cmd` object with the updated environment.
- `dir::AbstractString`: Specify a working directory for the command (instead of the current directory).

For any keywords that are not specified, the current settings from `cmd` are used.

Note that the `Cmd(exec)` constructor does not create a copy of `exec`. Any subsequent changes to `exec` will be reflected in the `Cmd` object.

The most common way to construct a `Cmd` object is with command literals (backticks), e.g.

```
| `ls -l`
```

This can then be passed to the `Cmd` constructor to modify its settings, e.g.

```
| Cmd(`echo "Hello world"`, ignorestatus=true, detach=false)
```

source

`Base.setenv` – Function.

```
| setenv(command::Cmd, env; dir)
```

Set environment variables to use when running the given command. `env` is either a dictionary mapping strings to strings, an array of strings of the form `"var=val"`, or zero or more `"var"=>val` pair

arguments. In order to modify (rather than replace) the existing environment, create `env` through `copy(ENV)` and then setting `env["var"]=val` as desired, or use `addenv`.

The `dir` keyword argument can be used to specify a working directory for the command. `dir` defaults to the currently set `dir` for command (which is the current working directory if not specified already).

See also `Cmd`, `addenv`, `ENV`, `pwd`.

[source](#)

`Base.addenv` – Function.

```
| addenv(command::Cmd, env...; inherit::Bool = true)
```

Merge new environment mappings into the given `Cmd` object, returning a new `Cmd` object. Duplicate keys are replaced. If `command` does not contain any environment values set already, it inherits the current environment at time of `addenv()` call if `inherit` is `true`. Keys with value `nothing` are deleted from the `env`.

See also `Cmd`, `setenv`, `ENV`.

Julia 1.6

This function requires Julia 1.6 or later.

[source](#)

`Base.withenv` – Function.

```
| withenv(f, kv::Pair...)
```

Execute `f` in an environment that is temporarily modified (not replaced as in `setenv`) by zero or more "`var`"=>`val` arguments `kv`. `withenv` is generally used via the `withenv(kv...) do ... end` syntax. A value of `nothing` can be used to temporarily unset an environment variable (if it is set). When `withenv` returns, the original environment has been restored.

Warning

Changing the environment is not thread-safe. For running external commands with a different environment from the parent process, prefer using `addenv` over `withenv`.

[source](#)

`Base.setcpuaffinity` – Function.

```
| setcpuaffinity(original_command::Cmd, cpus) -> command::Cmd
```

Set the CPU affinity of the command by a list of CPU IDs (1-based) `cpus`. Passing `cpus = nothing` means to unset the CPU affinity if the `original_command` has any.

This function is supported only in Linux and Windows. It is not supported in macOS because `libuv` does not support affinity setting.

Julia 1.8

This function requires at least Julia 1.8.

Examples

In Linux, the taskset command line program can be used to see how setcpuaffinity works.

```
julia> run(setcpuaffinity(`sh -c 'taskset -p $$$', [1, 2, 5]));
pid 2273's current affinity mask: 13
```

Note that the mask value 13 reflects that the first, second, and the fifth bits (counting from the least significant position) are turned on:

```
julia> 0b010011
0x13
```

source

Base.pipeline – Method.

```
pipeline(from, to, ...)
```

Create a pipeline from a data source to a destination. The source and destination can be commands, I/O streams, strings, or results of other pipeline calls. At least one argument must be a command. Strings refer to filenames. When called with more than two arguments, they are chained together from left to right. For example, pipeline(a,b,c) is equivalent to pipeline(pipeline(a,b),c). This provides a more concise way to specify multi-stage pipelines.

Examples:

```
run(pipeline(`ls`, `grep xyz`))
run(pipeline(`ls`, "out.txt"))
run(pipeline("out.txt", `grep xyz`))
```

source

Base.pipeline – Method.

```
pipeline(command; stdin, stdout, stderr, append=false)
```

Redirect I/O to or from the given command. Keyword arguments specify which of the command's streams should be redirected. append controls whether file output appends to the file. This is a more general version of the 2-argument pipeline function. pipeline(from, to) is equivalent to pipeline(from, stdout=to) when from is a command, and to pipeline(to, stdin=from) when from is another kind of data source.

Examples:

```
run(pipeline(`dothings`, stdout="out.txt", stderr="errs.txt"))
run(pipeline(`update`, stdout="log.txt", append=true))
```

source

Base.Libc.gethostname – Function.

```
gethostname() -> String
```

Get the local machine's host name.

[source](#)

`Base.Libc.getpid` – Function.

```
| getpid() -> Int32
```

Get Julia's process ID.

[source](#)

```
| getpid(process) -> Int32
```

Get the child process ID, if it still exists.

Julia 1.1

This function requires at least Julia 1.1.

[source](#)

`Base.Libc.time` – Method.

```
| time() -> Float64
```

Get the system time in seconds since the epoch, with fairly high (typically, microsecond) resolution.

[source](#)

`Base.time_ns` – Function.

```
| time_ns() -> UInt64
```

Get the time in nanoseconds. The time corresponding to 0 is undefined, and wraps every 5.8 years.

[source](#)

`Base.@time` – Macro.

```
| @time expr
| @time "description" expr
```

A macro to execute an expression, printing the time it took to execute, the number of allocations, and the total number of bytes its execution caused to be allocated, before returning the value of the expression. Any time spent garbage collecting (gc), compiling new code, or recompiling invalidated code is shown as a percentage.

Optionally provide a description string to print before the time report.

In some cases the system will look inside the `@time` expression and compile some of the called code before execution of the top-level expression begins. When that happens, some compilation time will not be counted. To include this time you can run `@time @eval ...`.

See also [@showtime](#), [@timev](#), [@timed](#), [@elapsed](#), [@allocated](#), and [@allocations](#).

Note

For more serious benchmarking, consider the `@btime` macro from the `BenchmarkTools.jl` package which among other things evaluates the function multiple times in order to reduce noise.

Julia 1.8

The option to add a description was introduced in Julia 1.8.

Recompilation time being shown separately from compilation time was introduced in Julia 1.8

```
julia> x = rand(10,10);

julia> @time x * x;
0.606588 seconds (2.19 M allocations: 116.555 MiB, 3.75% gc time, 99.94% compilation time)

julia> @time x * x;
0.000009 seconds (1 allocation: 896 bytes)

julia> @time begin
    sleep(0.3)
    1+1
end
0.301395 seconds (8 allocations: 336 bytes)
2

julia> @time "A one second sleep" sleep(1)
A one second sleep: 1.005750 seconds (5 allocations: 144 bytes)

julia> for loop in 1:3
    @time loop sleep(1)
end
1: 1.006760 seconds (5 allocations: 144 bytes)
2: 1.001263 seconds (5 allocations: 144 bytes)
3: 1.003676 seconds (5 allocations: 144 bytes)
```

[source](#)

Base.@showtime – Macro.

```
| @showtime expr
```

Like `@time` but also prints the expression being evaluated for reference.

Julia 1.8

This macro was added in Julia 1.8.

See also `@time`.

```
julia> @showtime sleep(1)
sleep(1): 1.002164 seconds (4 allocations: 128 bytes)
```

[source](#)

Base.@timev – Macro.

```
| @timev expr
| @timev "description" expr
```

This is a verbose version of the @time macro. It first prints the same information as @time, then any non-zero memory allocation counters, and then returns the value of the expression.

Optionally provide a description string to print before the time report.

Julia 1.8

The option to add a description was introduced in Julia 1.8.

See also [@time](#), [@timed](#), [@elapsed](#), [@allocated](#), and [@allocations](#).

```
julia> x = rand(10,10);

julia> @timev x * x;
0.546770 seconds (2.20 M allocations: 116.632 MiB, 4.23% gc time, 99.94% compilation time)
elapsed time (ns): 546769547
gc time (ns):      23115606
bytes allocated:   122297811
pool allocs:       2197930
non-pool GC allocs:1327
malloc() calls:    36
realloc() calls:    5
GC pauses:         3

julia> @timev x * x;
0.000010 seconds (1 allocation: 896 bytes)
elapsed time (ns): 9848
bytes allocated:   896
pool allocs:       1
```

[source](#)

Base.@timed – Macro.

```
| @timed
```

A macro to execute an expression, and return the value of the expression, elapsed time, total bytes allocated, garbage collection time, and an object with various memory allocation counters.

In some cases the system will look inside the @timed expression and compile some of the called code before execution of the top-level expression begins. When that happens, some compilation time will not be counted. To include this time you can run @timed @eval

See also [@time](#), [@timev](#), [@elapsed](#), [@allocated](#), and [@allocations](#).

```
julia> stats = @timed rand(10^6);

julia> stats.time
0.006634834
```

```
julia> stats.bytes
8000256

julia> stats.gc_time
0.0055765

julia> propertynames(stats.gcstats)
(:allocd, :malloc, :realloc, :poolalloc, :bigalloc, :freecall, :total_time, :pause,
↪ :full_sweep)

julia> stats.gcstats.total_time
5576500
```

Julia 1.5

The return type of this macro was changed from `Tuple` to `NamedTuple` in Julia 1.5.

[source](#)

Base.@elapsed – Macro.

| [@elapsed](#)

A macro to evaluate an expression, discarding the resulting value, instead returning the number of seconds it took to execute as a floating-point number.

In some cases the system will look inside the `@elapsed` expression and compile some of the called code before execution of the top-level expression begins. When that happens, some compilation time will not be counted. To include this time you can run `@elapsed @eval ...`.

See also [@time](#), [@timev](#), [@timed](#), [@allocated](#), and [@allocations](#).

```
julia> @elapsed sleep(0.3)
0.301391426
```

[source](#)

Base.@allocated – Macro.

| [@allocated](#)

A macro to evaluate an expression, discarding the resulting value, instead returning the total number of bytes allocated during evaluation of the expression.

See also [@allocations](#), [@time](#), [@timev](#), [@timed](#), and [@elapsed](#).

```
julia> @allocated rand(10^6)
8000080
```

[source](#)

Base.@allocations – Macro.

| [@allocations](#)

A macro to evaluate an expression, discard the resulting value, and instead return the total number of allocations during evaluation of the expression.

See also [@allocated](#), [@time](#), [@timev](#), [@timed](#), and [@elapsed](#).

```
julia> @allocations rand(10^6)
2
```

Julia 1.9

This macro was added in Julia 1.9.

[source](#)

Base.EnvDict – Type.

```
EnvDict() -> EnvDict
```

A singleton of this type provides a hash table interface to environment variables.

[source](#)

Base.ENV – Constant.

```
ENV
```

Reference to the singleton EnvDict, providing a dictionary interface to system environment variables.

(On Windows, system environment variables are case-insensitive, and ENV correspondingly converts all keys to uppercase for display, iteration, and copying. Portable code should not rely on the ability to distinguish variables by case, and should beware that setting an ostensibly lowercase variable may result in an uppercase ENV key.)

Warning

Mutating the environment is not thread-safe.

Examples

```
julia> ENV
Base.EnvDict with "50" entries:
"SECURITYSESSIONID"  => "123"
"USER"               => "username"
"MallocNanoZone"     => "0"
                     =>

julia> ENV["JULIA_EDITOR"] = "vim"
"vim"

julia> ENV["JULIA_EDITOR"]
"vim"
```

See also: [withenv](#), [addenv](#).

[source](#)

`Base.Sys.STDLIB` – Constant.

```
| Sys.STDLIB::String
```

A string containing the full path to the directory containing the `stdlib` packages.

[source](#)

`Base.Sys.isunix` – Function.

```
| Sys.isunix([os])
```

Predicate for testing if the OS provides a Unix-like interface. See documentation in [Handling Operating System Variation](#).

[source](#)

`Base.Sys.isapple` – Function.

```
| Sys.isapple([os])
```

Predicate for testing if the OS is a derivative of Apple Macintosh OS X or Darwin. See documentation in [Handling Operating System Variation](#).

[source](#)

`Base.Sys.islinux` – Function.

```
| Sys.islinux([os])
```

Predicate for testing if the OS is a derivative of Linux. See documentation in [Handling Operating System Variation](#).

[source](#)

`Base.Sys.isbsd` – Function.

```
| Sys.isbsd([os])
```

Predicate for testing if the OS is a derivative of BSD. See documentation in [Handling Operating System Variation](#).

Note

The Darwin kernel descends from BSD, which means that `Sys.isbsd()` is `true` on macOS systems. To exclude macOS from a predicate, use `Sys.isbsd() && !Sys.isapple()`.

[source](#)

`Base.Sys.isfreebsd` – Function.

```
| Sys.isfreebsd([os])
```

Predicate for testing if the OS is a derivative of FreeBSD. See documentation in [Handling Operating System Variation](#).

Note

Not to be confused with `Sys.isbsd()`, which is `true` on FreeBSD but also on other BSD-based systems. `Sys.isfreebsd()` refers only to FreeBSD.

Julia 1.1

This function requires at least Julia 1.1.

source

`Base.Sys.isopenbsd` – Function.

```
| Sys.isopenbsd([os])
```

Predicate for testing if the OS is a derivative of OpenBSD. See documentation in [Handling Operating System Variation](#).

Note

Not to be confused with `Sys.isbsd()`, which is `true` on OpenBSD but also on other BSD-based systems. `Sys.isopenbsd()` refers only to OpenBSD.

Julia 1.1

This function requires at least Julia 1.1.

source

`Base.Sys.isnetbsd` – Function.

```
| Sys.isnetbsd([os])
```

Predicate for testing if the OS is a derivative of NetBSD. See documentation in [Handling Operating System Variation](#).

Note

Not to be confused with `Sys.isbsd()`, which is `true` on NetBSD but also on other BSD-based systems. `Sys.isnetbsd()` refers only to NetBSD.

Julia 1.1

This function requires at least Julia 1.1.

source

`Base.Sys.isdragonfly` – Function.

```
| Sys.isdragonfly([os])
```

Predicate for testing if the OS is a derivative of DragonFly BSD. See documentation in [Handling Operating System Variation](#).

Note

Not to be confused with `Sys.isbsd()`, which is `true` on DragonFly but also on other BSD-based systems. `Sys.isdragonfly()` refers only to DragonFly.

Julia 1.1

This function requires at least Julia 1.1.

[source](#)

`Base.Sys.iswindows` – Function.

```
| Sys.iswindows([os])
```

Predicate for testing if the OS is a derivative of Microsoft Windows NT. See documentation in [Handling Operating System Variation](#).

[source](#)

`Base.Sys.windows_version` – Function.

```
| Sys.windows_version()
```

Return the version number for the Windows NT Kernel as a `VersionNumber`, i.e. `v"major.minor.build"`, or `v"0.0.0"` if this is not running on Windows.

[source](#)

`Base.Sys.free_memory` – Function.

```
| Sys.free_memory()
```

Get the total free memory in RAM in bytes.

[source](#)

`Base.Sys.total_memory` – Function.

```
| Sys.total_memory()
```

Get the total memory in RAM (including that which is currently used) in bytes. This amount may be constrained, e.g., by Linux control groups. For the unconstrained amount, see `Sys.total_physical_memory()`.

[source](#)

`Base.Sys.free_physical_memory` – Function.

```
| Sys.free_physical_memory()
```

Get the free memory of the system in bytes. The entire amount may not be available to the current process; use `Sys.free_memory()` for the actually available amount.

[source](#)

`Base.Sys.total_physical_memory` – Function.

```
| Sys.total_physical_memory()
```

Get the total memory in RAM (including that which is currently used) in bytes. The entire amount may not be available to the current process; see `Sys.total_memory()`.

[source](#)

`Base.Sys.uptime` – Function.

| `Sys.uptime()`

Gets the current system uptime in seconds.

[source](#)

`Base.Sys.isjsvm` – Function.

| `Sys.isjsvm([os])`

Predicate for testing if Julia is running in a JavaScript VM (JSVM), including e.g. a WebAssembly JavaScript embedding in a web browser.

Julia 1.2

This function requires at least Julia 1.2.

[source](#)

`Base.Sys.loadavg` – Function.

| `Sys.loadavg()`

Get the load average. See: [https://en.wikipedia.org/wiki/Load_\(computing\)](https://en.wikipedia.org/wiki/Load_(computing)).

[source](#)

`Base.Sys.isexecutable` – Function.

| `Sys.isexecutable(path::String)`

Return true if the given path has executable permissions.

Note

Prior to Julia 1.6, this did not correctly interrogate filesystem ACLs on Windows, therefore it would return true for any file. From Julia 1.6 on, it correctly determines whether the file is marked as executable or not.

[source](#)

`Base.@static` – Macro.

| `@static`

Partially evaluate an expression at parse time.

For example, `@static Sys.iswindows() ? foo : bar` will evaluate `Sys.iswindows()` and insert either `foo` or `bar` into the expression. This is useful in cases where a construct would be invalid on other platforms, such as a `ccall` to a non-existent function. `@static if Sys.isapple() foo end` and `@static foo <&& |> bar` are also valid syntax.

[source](#)

41.13 Versioning

Base.VersionNumber – Type.

| [VersionNumber](#)

Version number type which follows the specifications of [semantic versioning \(semver\)](#), composed of major, minor and patch numeric values, followed by pre-release and build alpha-numeric annotations.

VersionNumber objects can be compared with all of the standard comparison operators (`==`, `<`, `<=`, etc.), with the result following semver rules.

See also [@v_str](#) to efficiently construct VersionNumber objects from semver-format literal strings, [VERSION](#) for the VersionNumber of Julia itself, and [Version Number Literals](#) in the manual.

Examples

```
julia> a = VersionNumber(1, 2, 3)
v"1.2.3"

julia> a >= v"1.2"
true

julia> b = VersionNumber("2.0.1-rc1")
v"2.0.1-rc1"

julia> b >= v"2.0.1"
false
```

[source](#)

Base.@v_str – Macro.

| [@v_str](#)

String macro used to parse a string to a [VersionNumber](#).

Examples

```
julia> v"1.2.3"
v"1.2.3"

julia> v"2.0.1-rc1"
v"2.0.1-rc1"
```

[source](#)

41.14 Errors

Base.error – Function.

| `error(message::AbstractString)`

Raise an `ErrorException` with the given message.

[source](#)

```
| error(msg...)
```

Raise an `ErrorException` with the given message.

[source](#)

`Core.throw` – Function.

```
| throw(e)
```

Throw an object as an exception.

See also: [rethrow](#), [error](#).

[source](#)

`Base.rethrow` – Function.

```
| rethrow()
```

Rethrow the current exception from within a catch block. The rethrown exception will continue propagation as if it had not been caught.

Note

The alternative form `rethrow(e)` allows you to associate an alternative exception object `e` with the current `backtrace`. However this misrepresents the program state at the time of the error so you're encouraged to instead throw a new exception using `throw(e)`. In Julia 1.1 and above, using `throw(e)` will preserve the root cause exception on the stack, as described in [current_exceptions](#).

[source](#)

`Base.backtrace` – Function.

```
| backtrace()
```

Get a `backtrace` object for the current program point.

[source](#)

`Base.catch_backtrace` – Function.

```
| catch_backtrace()
```

Get the `backtrace` of the current exception, for use within catch blocks.

[source](#)

`Base.current_exceptions` – Function.

```
| current_exceptions(task::Task=current_task(); [backtrace::Bool=true])
```

Get the stack of exceptions currently being handled. For nested catch blocks there may be more than one current exception in which case the most recently thrown exception is last in the stack. The stack is returned as an `ExceptionStack` which is an `AbstractVector` of named tuples `(exception, backtrace)`. If `backtrace` is false, the `backtrace` in each pair will be set to nothing.

Explicitly passing `task` will return the current exception stack on an arbitrary task. This is useful for inspecting tasks which have failed due to uncaught exceptions.

Julia 1.7

This function went by the experimental name `catch_stack()` in Julia 1.1–1.6, and had a plain Vector-of-tuples as a return type.

[source](#)

`Base.@assert` – Macro.

```
| @assert cond [text]
```

Throw an `AssertionError` if `cond` is false. Preferred syntax for writing assertions. Message text is optionally displayed upon assertion failure.

Warning

An assert might be disabled at various optimization levels. Assert should therefore only be used as a debugging tool and not used for authentication verification (e.g., verifying passwords), nor should side effects needed for the function to work correctly be used inside of asserts.

Examples

```
| julia> @assert iseven(3) "3 is an odd number!"
ERROR: AssertionError: 3 is an odd number!

| julia> @assert isodd(3) "What even are numbers?"
```

[source](#)

`Base.Experimental.register_error_hint` – Function.

```
| Experimental.register_error_hint(handler, exceptiontype)
```

Register a "hinting" function `handler(io, exception)` that can suggest potential ways for users to circumvent errors. `handler` should examine `exception` to see whether the conditions appropriate for a hint are met, and if so generate output to `io`. Packages should call `register_error_hint` from within their `__init__` function.

For specific exception types, `handler` is required to accept additional arguments:

- `MethodError`: provide `handler(io, exc::MethodError, argtypes, kwargs)`, which splits the combined arguments into positional and keyword arguments.

When issuing a hint, the output should typically start with `\n`.

If you define custom exception types, your `showerror` method can support hints by calling `Experimental.show_error_hints`.

Example

```
| julia> module Hinter
|
|     only_int(x::Int)      = 1
|     any_number(x::Number) = 2
```

```

function __init__()
    Base.Experimental.register_error_hint(MethodError) do io, exc, argtypes, kwargs
        if exc.f == only_int
            # Color is not necessary, this is just to show it's possible.
            print(io, "\nDid you mean to call ")
            printstyled(io, "`any_number`?", color=:cyan)
        end
    end
end
end
end
end

```

Then if you call `Hinter.only_int` on something that isn't an `Int` (thereby triggering a `MethodError`), it issues the hint:

```

julia> Hinter.only_int(1.0)
ERROR: MethodError: no method matching only_int(::Float64)
Did you mean to call `any_number`?
Closest candidates are:
...

```

Julia 1.5

Custom error hints are available as of Julia 1.5.

Warning

This interface is experimental and subject to change or removal without notice. To insulate yourself against changes, consider putting any registrations inside an `if isdefined(Base.Experimental, :register_error_hint) ... end` block.

source

`Base.Experimental.show_error_hints` – Function.

```
| Experimental.show_error_hints(io, ex, args...)
```

Invoke all handlers from [Experimental.register_error_hint](#) for the particular exception type `typeof(ex)`. `args` must contain any other arguments expected by the handler for that type.

Julia 1.5

Custom error hints are available as of Julia 1.5.

Warning

This interface is experimental and subject to change or removal without notice.

source

`Core.ArgumentError` – Type.

```
| ArgumentError(msg)
```

The arguments passed to a function are invalid. `msg` is a descriptive error message.

source

Core.AssertionError – Type.

```
| AssertionError([msg])
```

The asserted condition did not evaluate to true. Optional argument msg is a descriptive error string.

Examples

```
| julia> @assert false "this is not true"  
ERROR: AssertionError: this is not true
```

AssertionError is usually thrown from `@assert`.

[source](#)

Core.BoundsError – Type.

```
| BoundsError([a],[i])
```

An indexing operation into an array, a, tried to access an out-of-bounds element at index i.

Examples

```
| julia> A = fill(1.0, 7);  
  
julia> A[8]  
ERROR: BoundsError: attempt to access 7-element Vector{Float64} at index [8]  
  
julia> B = fill(1.0, (2,3));  
  
julia> B[2, 4]  
ERROR: BoundsError: attempt to access 2×3 Matrix{Float64} at index [2, 4]  
  
julia> B[9]  
ERROR: BoundsError: attempt to access 2×3 Matrix{Float64} at index [9]
```

[source](#)

Base.CompositeException – Type.

```
| CompositeException
```

Wrap a Vector of exceptions thrown by a `Task` (e.g. generated from a remote worker over a channel or an asynchronously executing local I/O write or a remote worker under `pmap`) with information about the series of exceptions. For example, if a group of workers are executing several tasks, and multiple workers fail, the resulting `CompositeException` will contain a "bundle" of information from each worker indicating where and why the exception(s) occurred.

[source](#)

Base.DimensionMismatch – Type.

```
| DimensionMismatch([msg])
```

The objects called do not have matching dimensionality. Optional argument `msg` is a descriptive error string.

[source](#)

`Core.DivideError` – Type.

```
| DivideError()
```

Integer division was attempted with a denominator value of 0.

Examples

```
| julia> 2/0
| Inf
|
| julia> div(2, 0)
| ERROR: DivideError: integer division error
| Stacktrace:
| [...]
|
```

[source](#)

`Core.DomainError` – Type.

```
| DomainError(val)
| DomainError(val, msg)
```

The argument `val` to a function or constructor is outside the valid domain.

Examples

```
| julia> sqrt(-1)
| ERROR: DomainError with -1.0:
| sqrt was called with a negative real argument but will only return a complex result if called
| ↪ with a complex argument. Try sqrt(Complex(x)).
| Stacktrace:
| [...]
|
```

[source](#)

`Base.EOFError` – Type.

```
| EOFError()
```

No more data was available to read from a file or stream.

[source](#)

`Core.Exception` – Type.

```
| ErrorException(msg)
```

Generic error type. The error message, in the `.msg` field, may provide more specific details.

Examples

```
julia> ex = ErrorException("I've done a bad thing");

julia> ex.msg
"I've done a bad thing"
```

source

Core.InexactError – Type.

```
| InexactError(name::Symbol, T, val)
```

Cannot exactly convert val to type T in a method of function name.

Examples

```
julia> convert(Float64, 1+2im)
ERROR: InexactError: Float64(1 + 2im)
Stacktrace:
[...]
```

source

Core.InterruptException – Type.

```
| InterruptException()
```

The process was stopped by a terminal interrupt (CTRL+C).

Note that, in Julia script started without `-i` (interactive) option, `InterruptException` is not thrown by default. Calling `Base.exit_on_sigint(false)` in the script can recover the behavior of the REPL. Alternatively, a Julia script can be started with

```
| julia -e "include(popfirst!(ARGS))" script.jl
```

to let `InterruptException` be thrown by CTRL+C during the execution.

source

Base.KeyError – Type.

```
| KeyError(key)
```

An indexing operation into an `AbstractDict` (`Dict`) or `Set` like object tried to access or delete a non-existent element.

source

Core.LoadError – Type.

```
| LoadError(file::AbstractString, line::Int, error)
```

An error occurred while `including`, `requiring`, or `using` a file. The error specifics should be available in the `.error` field.

Julia 1.7

LoadErrors are no longer emitted by `@macroexpand`, `@macroexpand1`, and `macroexpand` as of Julia 1.7.

[source](#)

Core.MethodError – Type.

| **MethodError**(f, args)

A method with the required type signature does not exist in the given generic function. Alternatively, there is no unique most-specific method.

[source](#)

Base.MissingException – Type.

| **MissingException**(msg)

Exception thrown when a [missing](#) value is encountered in a situation where it is not supported. The error message, in the msg field may provide more specific details.

[source](#)

Core.OutOfMemoryError – Type.

| **OutOfMemoryError**()

An operation allocated too much memory for either the system or the garbage collector to handle properly.

[source](#)

Core.ReadOnlyMemoryError – Type.

| **ReadOnlyMemoryError**()

An operation tried to write to memory that is read-only.

[source](#)

Core.OverflowError – Type.

| **OverflowError**(msg)

The result of an expression is too large for the specified type and will cause a wraparound.

[source](#)

Base.ProcessFailedException – Type.

| **ProcessFailedException**

Indicates problematic exit status of a process. When running commands or pipelines, this is thrown to indicate a nonzero exit code was returned (i.e. that the invoked process failed).

[source](#)

Base.TaskFailedException – Type.

| **TaskFailedException**

This exception is thrown by a `wait(t)` call when task `t` fails. `TaskFailedException` wraps the failed task `t`.

[source](#)

`Core.StackOverflowError` – Type.

```
| StackOverflowError()
```

The function call grew beyond the size of the call stack. This usually happens when a call recurses infinitely.

[source](#)

`Base.SystemError` – Type.

```
| SystemError(prefix::AbstractString, [errno::Int32])
```

A system call failed with an error code (in the `errno` global variable).

[source](#)

`Core.TypeError` – Type.

```
| TypeError(func::Symbol, context::AbstractString, expected::Type, got)
```

A type assertion failure, or calling an intrinsic function with an incorrect argument type.

[source](#)

`Core.UndefKeywordError` – Type.

```
| UndefKeywordError(var::Symbol)
```

The required keyword argument `var` was not assigned in a function call.

Examples

```
julia> function my_func(;my_arg)
           return my_arg + 1
       end
my_func (generic function with 1 method)

julia> my_func()
ERROR: UndefKeywordError: keyword argument `my_arg` not assigned
Stacktrace:
 [1] my_func() at ./REPL[1]:2
 [2] top-level scope at REPL[2]:1
```

[source](#)

`Core.UndefRefError` – Type.

```
| UndefRefError()
```

The item or field is not defined for the given object.

Examples

```

julia> struct MyType
           a::Vector{Int}
           MyType() = new()
       end

julia> A = MyType()
MyType{#undef}

julia> A.a
ERROR: UndefRefError: access to undefined reference
Stacktrace:
 [...]

```

[source](#)

Core.UndefVarError – Type.

```

| UndefVarError(var::Symbol)

```

A symbol in the current scope is not defined.

Examples

```

julia> a
ERROR: UndefVarError: `a` not defined

julia> a = 1;

julia> a
1

```

[source](#)

Base.StringIndexError – Type.

```

| StringIndexError(str, i)

```

An error occurred when trying to access `str` at index `i` that is not valid.

[source](#)

Core.InitError – Type.

```

| InitError(mod::Symbol, error)

```

An error occurred when running a module's `__init__` function. The actual error thrown is available in the `.error` field.

[source](#)

Base.retry – Function.

```

| retry(f; delays=ExponentialBackOff(), check=nothing) -> Function

```

Return an anonymous function that calls function `f`. If an exception arises, `f` is repeatedly called again, each time `check` returns `true`, after waiting the number of seconds specified in `delays`. `check` should input `delays`'s current state and the `Exception`.

Julia 1.2

Before Julia 1.2 this signature was restricted to `f::Function`.

Examples

```
retry(f, delays=fill(5.0, 3))
retry(f, delays=rand(5:10, 2))
retry(f, delays=Base.ExponentialBackOff(n=3, first_delay=5, max_delay=1000))
retry(http_get, check=(s,e)->e.status == "503")(url)
retry(read, check=(s,e)->isa(e, IOError))(io, 128; all=false)
```

[source](#)

`Base.ExponentialBackOff` - Type.

```
| ExponentialBackOff(; n=1, first_delay=0.05, max_delay=10.0, factor=5.0, jitter=0.1)
```

A `Float64` iterator of length `n` whose elements exponentially increase at a rate in the interval `factor * (1 ± jitter)`. The first element is `first_delay` and all elements are clamped to `max_delay`.

[source](#)

41.15 Events

`Base.Timer` - Method.

```
| Timer(callback::Function, delay; interval = 0)
```

Create a timer that runs the function `callback` at each timer expiration.

Waiting tasks are woken and the function `callback` is called after an initial delay of `delay` seconds, and then repeating with the given `interval` in seconds. If `interval` is equal to 0, the `callback` is only run once. The function `callback` is called with a single argument, the timer itself. Stop a timer by calling `close`. The `callback` may still be run one final time, if the timer has already expired.

Examples

Here the first number is printed after a delay of two seconds, then the following numbers are printed quickly.

```
julia> begin
    i = 0
    cb(timer) = (global i += 1; println(i))
    t = Timer(cb, 2, interval=0.2)
    wait(t)
    sleep(0.5)
    close(t)
end
1
2
3
```

source

Base.Timer – Type.

```
| Timer(delay; interval = 0)
```

Create a timer that wakes up tasks waiting for it (by calling `wait` on the timer object).

Waiting tasks are woken after an initial delay of at least `delay` seconds, and then repeating after at least `interval` seconds again elapse. If `interval` is equal to 0, the timer is only triggered once. When the timer is closed (by `close`) waiting tasks are woken with an error. Use `isopen` to check whether a timer is still active.

Note

`interval` is subject to accumulating time skew. If you need precise events at a particular absolute time, create a new timer at each expiration with the difference to the next time computed.

Note

A Timer requires yield points to update its state. For instance, `isopen(t::Timer)` cannot be used to timeout a non-yielding while loop.

source

Base.AsyncCondition – Type.

```
| AsyncCondition()
```

Create a async condition that wakes up tasks waiting for it (by calling `wait` on the object) when notified from C by a call to `uv_async_send`. Waiting tasks are woken with an error when the object is closed (by `close`). Use `isopen` to check whether it is still active.

This provides an implicit acquire & release memory ordering between the sending and waiting threads.

source

Base.AsyncCondition – Method.

```
| AsyncCondition(callback::Function)
```

Create a async condition that calls the given callback function. The callback is passed one argument, the async condition object itself.

source**41.16 Reflection**

Base.nameof – Method.

```
| nameof(m::Module) -> Symbol
```

Get the name of a Module as a `Symbol`.

Examples

```
julia> nameof(Base.Broadcast)
:Broadcast
```

source

Base.parentmodule – Function.

```
parentmodule(m::Module) -> Module
```

Get a module's enclosing Module. Main is its own parent.

See also: [names](#), [nameof](#), [fullname](#), [@__MODULE__](#).

Examples

```
julia> parentmodule(Main)
Main

julia> parentmodule(Base.Broadcast)
Base
```

source

```
parentmodule(t::DataType) -> Module
```

Determine the module containing the definition of a (potentially UnionAll-wrapped) DataType.

Examples

```
julia> module Foo
    struct Int end
end
Foo

julia> parentmodule(Int)
Core

julia> parentmodule(Foo.Int)
Foo
```

source

```
parentmodule(f::Function) -> Module
```

Determine the module containing the (first) definition of a generic function.

source

```
parentmodule(f::Function, types) -> Module
```

Determine the module containing the first method of a generic function f matching the specified types.

source

```
parentmodule(m::Method) -> Module
```

Return the module in which the given method m is defined.

Julia 1.9

Passing a Method as an argument requires Julia 1.9 or later.

source

Base.pathof – Method.

```
| pathof(m::Module)
```

Return the path of the `m.jl` file that was used to import module `m`, or nothing if `m` was not imported from a package.

Use `dirname` to get the directory part and `basename` to get the file name part of the path.

source

Base.pkgdir – Method.

```
| pkgdir(m::Module[, paths::String...])
```

Return the root directory of the package that declared module `m`, or nothing if `m` was not declared in a package. Optionally further path component strings can be provided to construct a path within the package root.

To get the root directory of the package that implements the current module the form `pkgdir(@__MODULE__)` can be used.

```
julia> pkgdir(Foo)
"/path/to/Foo.jl"

julia> pkgdir(Foo, "src", "file.jl")
"/path/to/Foo.jl/src/file.jl"
```

Julia 1.7

The optional argument `paths` requires at least Julia 1.7.

source

Base.pkgversion – Method.

```
| pkgversion(m::Module)
```

Return the version of the package that imported module `m`, or nothing if `m` was not imported from a package, or imported from a package without a version field set.

The version is read from the package's `Project.toml` during package load.

To get the version of the package that imported the current module the form `pkgversion(@__MODULE__)` can be used.

Julia 1.9

This function was introduced in Julia 1.9.

source

Base.moduleroot - Function.

```
| moduleroot(m::Module) -> Module
```

Find the root module of a given module. This is the first module in the chain of parent modules of `m` which is either a registered root module or which is its own parent module.

source

__module__ - Keyword.

```
| __module__
```

The argument `__module__` is only visible inside the macro, and it provides information (in the form of a `Module` object) about the expansion context of the macro invocation. See the manual section on [Macro invocation](#) for more information.

source

__source__ - Keyword.

```
| __source__
```

The argument `__source__` is only visible inside the macro, and it provides information (in the form of a `LineNumberNode` object) about the parser location of the `@` sign from the macro invocation. See the manual section on [Macro invocation](#) for more information.

source

Base.@__MODULE__ - Macro.

```
| @__MODULE__ -> Module
```

Get the `Module` of the toplevel eval, which is the `Module` code is currently being read from.

source

Base.@__FILE__ - Macro.

```
| @__FILE__ -> String
```

Expand to a string with the path to the file containing the macrocall, or an empty string if evaluated by `julia -e <expr>`. Return nothing if the macro was missing parser source information. Alternatively see [PROGRAM_FILE](#).

source

Base.@__DIR__ - Macro.

```
| @__DIR__ -> String
```

Expand to a string with the absolute path to the directory of the file containing the macrocall. Return the current working directory if run from a REPL or if evaluated by `julia -e <expr>`.

source

Base.@__LINE__ - Macro.

```
| @__LINE__ -> Int
```

Expand to the line number of the location of the macrocall. Return 0 if the line number could not be determined.

[source](#)

Base.fullname – Function.

```
| fullname(m::Module)
```

Get the fully-qualified name of a module as a tuple of symbols. For example,

Examples

```
julia> fullname(Base.Iterators)
(:Base, :Iterators)

julia> fullname(Main)
(:Main,)
```

[source](#)

Base.names – Function.

```
| names(x::Module; all::Bool = false, imported::Bool = false)
```

Get an array of the names exported by a Module, excluding deprecated names. If `all` is true, then the list also includes non-exported names defined in the module, deprecated names, and compiler-generated names. If `imported` is true, then names explicitly imported from other modules are also included.

As a special case, all names defined in `Main` are considered "exported", since it is not idiomatic to explicitly export names from `Main`.

See also: [@locals](#), [@__MODULE__](#).

[source](#)

Base.nameof – Method.

```
| nameof(f::Function) -> Symbol
```

Get the name of a generic Function as a symbol. For anonymous functions, this is a compiler-generated name. For explicitly-declared subtypes of Function, it is the name of the function's type.

[source](#)

Base.functionloc – Method.

```
| functionloc(f::Function, types)
```

Return a tuple (filename, line) giving the location of a generic Function definition.

[source](#)

Base.functionloc – Method.

```
| functionloc(m::Method)
```

Return a tuple (filename,line) giving the location of a Method definition.

[source](#)

Base.@locals – Macro.

```
| @locals()
```

Construct a dictionary of the names (as symbols) and values of all local variables defined as of the call site.

Julia 1.1

This macro requires at least Julia 1.1.

Examples

```
julia> let x = 1, y = 2
      Base.@locals
    end
Dict{Symbol, Any} with 2 entries:
 :y => 2
 :x => 1

julia> function f(x)
      local y
      show(Base.@locals); println()
      for i = 1:1
        show(Base.@locals); println()
      end
      y = 2
      show(Base.@locals); println()
      nothing
    end;

julia> f(42)
Dict{Symbol, Any}{:x => 42}
Dict{Symbol, Any}{:i => 1, :x => 42}
Dict{Symbol, Any}{:y => 2, :x => 42}
```

[source](#)

41.17 Code loading

Base.identify_package – Function.

```
| Base.identify_package(name::String)::Union{PkgId, Nothing}
| Base.identify_package(where::Union{Module, PkgId}, name::String)::Union{PkgId, Nothing}
```

Identify the package by its name from the current environment stack, returning its PkgId, or nothing if it cannot be found.

If only the name argument is provided, it searches each environment in the stack and its named direct dependencies.

There where argument provides the context from where to search for the package: in this case it first checks if the name matches the context itself, otherwise it searches all recursive dependencies (from the resolved manifest of each environment) until it locates the context where, and from there identifies the dependency with the corresponding name.

```
julia> Base.identify_package("Pkg") # Pkg is a dependency of the default environment
Pkg [44cfe95a-1eb2-52ea-b672-e2afdf69b78f]

julia> using LinearAlgebra

julia> Base.identify_package(LinearAlgebra, "Pkg") # Pkg is not a dependency of LinearAlgebra
```

[source](#)

Base.locate_package – Function.

```
Base.locate_package(pkg::PkgId)::Union{String, Nothing}
```

The path to the entry-point file for the package corresponding to the identifier pkg, or nothing if not found. See also [identify_package](#).

```
julia> pkg = Base.identify_package("Pkg")
Pkg [44cfe95a-1eb2-52ea-b672-e2afdf69b78f]

julia> Base.locate_package(pkg)
"/path/to/julia/stdlib/v1.10/Pkg/src/Pkg.jl"
```

[source](#)

Base.require – Function.

```
require(into::Module, module::Symbol)
```

This function is part of the implementation of [using](#) / [import](#), if a module is not already defined in Main. It can also be called directly to force reloading a module, regardless of whether it has been loaded before (for example, when interactively developing libraries).

Loads a source file, in the context of the Main module, on every active node, searching standard locations for files. `require` is considered a top-level operation, so it sets the current include path but does not use it to search for files (see help for [include](#)). This function is typically used to load library code, and is implicitly called by `using` to load packages.

When searching for files, `require` first looks for package code in the global array [LOAD_PATH](#). `require` is case-sensitive on all platforms, including those with case-insensitive filesystems like macOS and Windows.

For more details regarding code loading, see the manual sections on [modules](#) and [parallel computing](#).

[source](#)

Base.compilecache – Function.

```
| Base.compilecache(module::PkgId)
```

Creates a precompiled cache file for a module and all of its dependencies. This can be used to reduce package load times. Cache files are stored in `DEPOT_PATH[1]/compiled`. See [Module initialization and precompilation](#) for important notes.

[source](#)

`Base.isprecompiled` – Function.

```
| Base.isprecompiled(pkg::PkgId; ignore_loaded::Bool=false)
```

Returns whether a given `PkgId` within the active project is precompiled.

By default this check observes the same approach that code loading takes with respect to when different versions of dependencies are currently loaded to that which is expected. To ignore loaded modules and answer as if in a fresh julia session specify `ignore_loaded=true`.

Julia 1.10

This function requires at least Julia 1.10.

[source](#)

`Base.get_extension` – Function.

```
| get_extension(parent::Module, extension::Symbol)
```

Return the module for extension of parent or return nothing if the extension is not loaded.

[source](#)

41.18 Internals

`Base.GC.gc` – Function.

```
| GC.gc([full=true])
```

Perform garbage collection. The argument `full` determines the kind of collection: A full collection (default) sweeps all objects, which makes the next GC scan much slower, while an incremental collection may only sweep so-called young objects.

Warning

Excessive use will likely lead to poor performance.

[source](#)

`Base.GC.enable` – Function.

```
| GC.enable(on::Bool)
```

Control whether garbage collection is enabled using a boolean argument (`true` for enabled, `false` for disabled). Return previous GC state.

Warning

Disabling garbage collection should be used only with caution, as it can cause memory use to grow without bound.

source

Base.GC.@preserve – Macro.

```
| GC.@preserve x1 x2 ... xn expr
```

Mark the objects `x1`, `x2`, ... as being in use during the evaluation of the expression `expr`. This is only required in unsafe code where `expr` implicitly uses memory or other resources owned by one of the `xs`.

Implicit use of `x` covers any indirect use of resources logically owned by `x` which the compiler cannot see. Some examples:

- Accessing memory of an object directly via a `Ptr`
- Passing a pointer to `x` to `ccall`
- Using resources of `x` which would be cleaned up in the finalizer.

@preserve should generally not have any performance impact in typical use cases where it briefly extends object lifetime. In implementation, @preserve has effects such as protecting dynamically allocated objects from garbage collection.

Examples

When loading from a pointer with `unsafe_load`, the underlying object is implicitly used, for example `x` is implicitly used by `unsafe_load(p)` in the following:

```
julia> let
    x = Ref{Int}(101)
    p = Base.unsafe_convert{Ptr{Int}, x}
    GC.@preserve x unsafe_load(p)
end
101
```

When passing pointers to `ccall`, the pointed-to object is implicitly used and should be preserved. (Note however that you should normally just pass `x` directly to `ccall` which counts as an explicit use.)

```
julia> let
    x = "Hello"
    p = pointer(x)
    Int(GC.@preserve x @ccall strlen(p::Cstring)::Csize_t)
    # Preferred alternative
    Int(@ccall strlen(x::Cstring)::Csize_t)
end
5
```

source

Base.GC.safepoint – Function.

```
| GC.safepoint()
```

Inserts a point in the program where garbage collection may run. This can be useful in rare cases in multi-threaded programs where some threads are allocating memory (and hence may need to run GC) but other threads are doing only simple operations (no allocation, task switches, or I/O). Calling this function periodically in non-allocating threads allows garbage collection to run.

Julia 1.4

This function is available as of Julia 1.4.

[source](#)

Base.GC.enable_logging – Function.

```
| GC.enable_logging(on::Bool)
```

When turned on, print statistics about each GC to stderr.

[source](#)

Base.Meta.lower – Function.

```
| lower(m, x)
```

Takes the expression `x` and returns an equivalent expression in lowered form for executing in module `m`. See also [code_lowered](#).

[source](#)

Base.Meta.@lower – Macro.

```
| @lower [m] x
```

Return lowered form of the expression `x` in module `m`. By default `m` is the module in which the macro is called. See also [lower](#).

[source](#)

Base.Meta.parse – Method.

```
| parse(str, start; greedy=true, raise=true, depwarn=true, filename="none")
```

Parse the expression string and return an expression (which could later be passed to `eval` for execution). `start` is the code unit index into `str` of the first character to start parsing at (as with all string indexing, these are not character indices). If `greedy` is `true` (default), `parse` will try to consume as much input as it can; otherwise, it will stop as soon as it has parsed a valid expression. Incomplete but otherwise syntactically valid expressions will return `Expr(:incomplete, "(error message)")`. If `raise` is `true` (default), syntax errors other than incomplete expressions will raise an error. If `raise` is `false`, `parse` will return an expression that will raise an error upon evaluation. If `depwarn` is `false`, deprecation warnings will be suppressed. The `filename` argument is used to display diagnostics when an error is raised.

```
julia> Meta.parse("(α, β) = 3, 5", 1) # start of string
(:((α, β) = (3, 5)), 16)

julia> Meta.parse("(α, β) = 3, 5", 1, greedy=false)
(:((α, β)), 9)

julia> Meta.parse("(α, β) = 3, 5", 16) # end of string
(nothing, 16)

julia> Meta.parse("(α, β) = 3, 5", 11) # index of 3
(:((3, 5)), 16)

julia> Meta.parse("(α, β) = 3, 5", 11, greedy=false)
(3, 13)
```

[source](#)

Base.Meta.parse - Method.

```
| parse(str; raise=true, depwarn=true, filename="none")
```

Parse the expression string greedily, returning a single expression. An error is thrown if there are additional characters after the first expression. If `raise` is true (default), syntax errors will raise an error; otherwise, parse will return an expression that will raise an error upon evaluation. If `depwarn` is false, deprecation warnings will be suppressed. The `filename` argument is used to display diagnostics when an error is raised.

```
julia> Meta.parse("x = 3")
:(x = 3)

julia> Meta.parse("1.0.2")
ERROR: ParseError:
# Error @ none:1:1
1.0.2
└─ invalid numeric constant
[...]

julia> Meta.parse("1.0.2"; raise = false)
:($Expr(:error, "invalid numeric constant \"1.0.\""))

julia> Meta.parse("x = ")
:($Expr(:incomplete, "incomplete: premature end of input"))
```

[source](#)

Base.Meta.ParseError - Type.

```
| ParseError(msg)
```

The expression passed to the `parse` function could not be interpreted as a valid Julia expression.

[source](#)

Core.QuoteNode - Type.

QuoteNode

A quoted piece of code, that does not support interpolation. See the [manual section about QuoteNodes](#) for details.

[source](#)

Base.`macroexpand` – Function.

```
macroexpand(m::Module, x; recursive=true)
```

Take the expression `x` and return an equivalent expression with all macros removed (expanded) for executing in module `m`. The `recursive` keyword controls whether deeper levels of nested macros are also expanded. This is demonstrated in the example below:

```
julia> module M
    macro m1()
        42
    end
    macro m2()
        :(@m1())
    end
end

M

julia> macroexpand(M, :(@m2()), recursive=true)
42

julia> macroexpand(M, :(@m2()), recursive=false)
: (#= REPL[16]:6 =# M.@m1)
```

[source](#)

Base.`@macroexpand` – Macro.

```
@macroexpand
```

Return equivalent expression with all macros removed (expanded).

There are differences between `@macroexpand` and `macroexpand`.

- While `macroexpand` takes a keyword argument `recursive`, `@macroexpand` is always recursive. For a non recursive macro version, see `@macroexpand1`.
- While `macroexpand` has an explicit `module` argument, `@macroexpand` always expands with respect to the module in which it is called.

This is best seen in the following example:

```
julia> module M
    macro m()
        1
    end
    function f()

```

```

        (@macroexpand(@m),
         macroexpand(M, :(@m)),
         macroexpand(Main, :(@m))
        )
    end
end
M

julia> macro m()
    2
    end
@m (macro with 1 method)

julia> M.f()
(1, 1, 2)

```

With `@macroexpand` the expression expands where `@macroexpand` appears in the code (module `M` in the example). With `macroexpand` the expression expands in the module given as the first argument.

[source](#)

`Base.@macroexpand1` – Macro.

```
| @macroexpand1
```

Non recursive version of `@macroexpand`.

[source](#)

`Base.code_lowered` – Function.

```
| code_lowered(f, types; generated=true, debuginfo=:default)
```

Return an array of the lowered forms (IR) for the methods matching the given generic function and type signature.

If `generated` is `false`, the returned `CodeInfo` instances will correspond to fallback implementations. An error is thrown if no fallback implementation exists. If `generated` is `true`, these `CodeInfo` instances will correspond to the method bodies yielded by expanding the generators.

The keyword `debuginfo` controls the amount of code metadata present in the output.

Note that an error will be thrown if `types` are not leaf types when `generated` is `true` and any of the corresponding methods are an `@generated` method.

[source](#)

`Base.code_typed` – Function.

```
| code_typed(f, types; kw...)
```

Returns an array of type-inferred lowered form (IR) for the methods matching the given generic function and type signature.

Keyword Arguments

- `optimize::Bool = true`: optional, controls whether additional optimizations, such as inlining, are also applied.
- `debuginfo::Symbol = :default`: optional, controls the amount of code metadata present in the output, possible options are `:source` or `:none`.

Internal Keyword Arguments

This section should be considered internal, and is only for who understands Julia compiler internals.

- `world::UInt = Base.get_world_counter()`: optional, controls the world age to use when looking up methods, use current world age if not specified.
- `interp::Core.Compiler.AbstractInterpreter = Core.Compiler.NativeInterpreter(world)`: optional, controls the abstract interpreter to use, use the native interpreter if not specified.

Example

One can put the argument types in a tuple to get the corresponding `code_typed`.

```
julia> code_typed(+, (Float64, Float64))
1-element Vector{Any}:
 CodeInfo(
 1 - %1 = Base.add_float(x, y)::Float64
 └─      return %1
 ) => Float64
```

[source](#)

`Base.precompile` – Function.

```
| precompile(f, argtypes::Tuple{Vararg{Any}})
```

Compile the given function `f` for the argument tuple (of types) `argtypes`, but do not execute it.

[source](#)

```
| precompile(f, argtypes::Tuple{Vararg{Any}}, m::Method)
```

Precompile a specific method for the given argument types. This may be used to precompile a different method than the one that would ordinarily be chosen by dispatch, thus mimicking `invoke`.

[source](#)

`Base.jit_total_bytes` – Function.

```
| Base.jit_total_bytes()
```

Return the total amount (in bytes) allocated by the just-in-time compiler for e.g. native code and data.

[source](#)

41.19 Meta

Base.Meta.quot – Function.

```
| Meta.quot(ex) :: Expr
```

Quote expression `ex` to produce an expression with head quote. This can for instance be used to represent objects of type `Expr` in the AST. See also the manual section about [QuoteNode](#).

Examples

```
julia> eval(Meta.quot(:x))
:x

julia> dump(Meta.quot(:x))
Expr
  head: Symbol quote
  args: Array{Any}((1,))
    1: Symbol x

julia> eval(Meta.quot(: (1+2)))
:(1 + 2)
```

[source](#)

Base.isexpr – Function.

```
| Meta.isexpr(ex, head[, n]) :: Bool
```

Return true if `ex` is an `Expr` with the given type `head` and optionally that the argument list is of length `n`. `head` may be a `Symbol` or collection of `Symbols`. For example, to check that a macro was passed a function call expression, you might use `isexpr(ex, :call)`.

Examples

```
julia> ex = :(f(x))
:(f(x))

julia> Meta.isexpr(ex, :block)
false

julia> Meta.isexpr(ex, :call)
true

julia> Meta.isexpr(ex, [:block, :call]) # multiple possible heads
true

julia> Meta.isexpr(ex, :call, 1)
false

julia> Meta.isexpr(ex, :call, 2)
true
```

[source](#)

`Base.isidentifier` – Function.

```
| isidentifier(s) -> Bool
```

Return whether the symbol or string `s` contains characters that are parsed as a valid ordinary identifier (not a binary/unary operator) in Julia code; see also [Base.isoperator](#).

Internally Julia allows any sequence of characters in a `Symbol` (except `\0s`), and macros automatically use variable names containing `#` in order to avoid naming collision with the surrounding code. In order for the parser to recognize a variable, it uses a limited set of characters (greatly extended by Unicode). `isidentifier()` makes it possible to query the parser directly whether a symbol contains valid characters.

Examples

```
| julia> Meta.isidentifier(:x), Meta.isidentifier("1x")  
| (true, false)
```

[source](#)

`Base.isoperator` – Function.

```
| isoperator(s::Symbol)
```

Return true if the symbol can be used as an operator, false otherwise.

Examples

```
| julia> Meta.isoperator(:+), Meta.isoperator(:f)  
| (true, false)
```

[source](#)

`Base.isunaryoperator` – Function.

```
| isunaryoperator(s::Symbol)
```

Return true if the symbol can be used as a unary (prefix) operator, false otherwise.

Examples

```
| julia> Meta.isunaryoperator(:-), Meta.isunaryoperator(:√), Meta.isunaryoperator(:f)  
| (true, true, false)
```

[source](#)

`Base.isbinaryoperator` – Function.

```
| isbinaryoperator(s::Symbol)
```

Return true if the symbol can be used as a binary (infix) operator, false otherwise.

Examples

```
| julia> Meta.isbinaryoperator(:-), Meta.isbinaryoperator(:√), Meta.isbinaryoperator(:f)  
| (true, false, false)
```

[source](#)

`Base.Meta.show_sexpr` – Function.

```
| Meta.show_sexpr([io::IO,], ex)
```

Show expression `ex` as a lisp style S-expression.

Examples

```
| julia> Meta.show_sexpr(:(f(x, g(y,z))))  
| (:call, :f, :x, (:call, :g, :y, :z))
```

[source](#)

Chapter 42

Collections and Data Structures

42.1 Iteration

Sequential iteration is implemented by the `iterate` function. The general for loop:

```
for i in iter  # or "for i = iter"
  # body
end
```

is translated into:

```
next = iterate(iter)
while next != nothing
  (i, state) = next
  # body
  next = iterate(iter, state)
end
```

The state object may be anything, and should be chosen appropriately for each iterable type. See the [manual section on the iteration interface](#) for more details about defining a custom iterable type.

Base.iterate - Function.

```
iterate(iter [, state]) -> Union{Nothing, Tuple{Any, Any}}
```

Advance the iterator to obtain the next element. If no elements remain, nothing should be returned. Otherwise, a 2-tuple of the next element and the new iteration state should be returned.

[source](#)

Base.IteratorSize - Type.

```
IteratorSize(itype::Type) -> IteratorSize
```

Given the type of an iterator, return one of the following values:

- `SizeUnknown()` if the length (number of elements) cannot be determined in advance.

- `HasLength()` if there is a fixed, finite length.
- `HasShape{N}()` if there is a known length plus a notion of multidimensional shape (as for an array). In this case `N` should give the number of dimensions, and the `axes` function is valid for the iterator.
- `IsInfinite()` if the iterator yields values forever.

The default value (for iterators that do not define this function) is `HasLength()`. This means that most iterators are assumed to implement `length`.

This trait is generally used to select between algorithms that pre-allocate space for their result, and algorithms that resize their result incrementally.

```
julia> Base.IteratorSize(1:5)
Base.HasShape{1}()

julia> Base.IteratorSize((2,3))
Base.HasLength()
```

[source](#)

`Base.IteratorEltType` – Type.

```
| IteratorEltType(itertype::Type) -> IteratorEltType
```

Given the type of an iterator, return one of the following values:

- `EltTypeUnknown()` if the type of elements yielded by the iterator is not known in advance.
- `HasEltType()` if the element type is known, and `eltype` would return a meaningful value.

`HasEltType()` is the default, since iterators are assumed to implement `eltype`.

This trait is generally used to select between algorithms that pre-allocate a specific type of result, and algorithms that pick a result type based on the types of yielded values.

```
julia> Base.IteratorEltType(1:5)
Base.HasEltType()
```

[source](#)

Fully implemented by:

- `AbstractRange`
- `UnitRange`
- `Tuple`
- `Number`
- `AbstractArray`
- `BitSet`

- [IdDict](#)
- [Dict](#)
- [WeakKeyDict](#)
- [EachLine](#)
- [AbstractString](#)
- [Set](#)
- [Pair](#)
- [NamedTuple](#)

42.2 Constructors and Types

Base.AbstractRange – Type.

```
| AbstractRange{T}
```

Supertype for ranges with elements of type T. [UnitRange](#) and other types are subtypes of this.

[source](#)

Base.OrdinalRange – Type.

```
| OrdinalRange{T, S} <: AbstractRange{T}
```

Supertype for ordinal ranges with elements of type T with spacing(s) of type S. The steps should be always-exact multiples of [oneunit](#), and T should be a "discrete" type, which cannot have values smaller than oneunit. For example, Integer or Date types would qualify, whereas Float64 would not (since this type can represent values smaller than oneunit(Float64)). [UnitRange](#), [StepRange](#), and other types are subtypes of this.

[source](#)

Base.AbstractUnitRange – Type.

```
| AbstractUnitRange{T} <: OrdinalRange{T, T}
```

Supertype for ranges with a step size of [oneunit\(T\)](#) with elements of type T. [UnitRange](#) and other types are subtypes of this.

[source](#)

Base.StepRange – Type.

```
| StepRange{T, S} <: OrdinalRange{T, S}
```

Ranges with elements of type T with spacing of type S. The step between each element is constant, and the range is defined in terms of a start and stop of type T and a step of type S. Neither T nor S should be floating point types. The syntax `a:b:c` with `b != 0` and `a`, `b`, and `c` all integers creates a StepRange.

Examples

```
julia> collect(StepRange(1, Int8(2), 10))
5-element Vector{Int64}:
 1
 3
 5
 7
 9

julia> typeof(StepRange(1, Int8(2), 10))
StepRange{Int64, Int8}

julia> typeof(1:3:6)
StepRange{Int64, Int64}
```

[source](#)

Base.UnitRange – Type.

```
| UnitRange{T<:Real}
```

A range parameterized by a start and stop of type T, filled with elements spaced by 1 from start until stop is exceeded. The syntax a:b with a and b both Integers creates a UnitRange.

Examples

```
julia> collect(UnitRange(2.3, 5.2))
3-element Vector{Float64}:
 2.3
 3.3
 4.3

julia> typeof(1:10)
UnitRange{Int64}
```

[source](#)

Base.LinRange – Type.

```
| LinRange{T,L}
```

A range with len linearly spaced elements between its start and stop. The size of the spacing is controlled by len, which must be an Integer.

Examples

```
julia> LinRange(1.5, 5.5, 9)
9-element LinRange{Float64, Int64}:
 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5
```

Compared to using [range](#), directly constructing a LinRange should have less overhead but won't try to correct for floating point errors:

```

julia> collect(range(-0.1, 0.3, length=5))
5-element Vector{Float64}:
-0.1
 0.0
 0.1
 0.2
 0.3

julia> collect(LinRange(-0.1, 0.3, 5))
5-element Vector{Float64}:
-0.1
-1.3877787807814457e-17
 0.09999999999999999
 0.19999999999999998
 0.3

```

[source](#)

42.3 General Collections

`Base.isempty` – Function.

```
| isempty(collection) -> Bool
```

Determine whether a collection is empty (has no elements).

Warning

`isempty(itr)` may consume the next element of a stateful iterator `itr` unless an appropriate `Base.isdone(itr)` or `isempty` method is defined. Use of `isempty` should therefore be avoided when writing generic code which should support any iterator type.

Examples

```

julia> isempty([])
true

julia> isempty([1 2 3])
false

```

[source](#)

```
| isempty(condition)
```

Return true if no tasks are waiting on the condition, false otherwise.

[source](#)

`Base.empty!` – Function.

```
| empty!(collection) -> collection
```

Remove all elements from a collection.

Examples

```
julia> A = Dict{"a" => 1, "b" => 2}
Dict{String, Int64} with 2 entries:
  "b" => 2
  "a" => 1

julia> empty!(A);

julia> A
Dict{String, Int64}()
```

[source](#)

Base.length – Function.

```
| length(collection) -> Integer
```

Return the number of elements in the collection.

Use [lastindex](#) to get the last valid index of an indexable collection.

See also: [size](#), [ndims](#), [eachindex](#).

Examples

```
julia> length(1:5)
5

julia> length([1, 2, 3, 4])
4

julia> length([1 2; 3 4])
4
```

[source](#)

Base.checked_length – Function.

```
| Base.checked_length(r)
```

Calculates `length(r)`, but may check for overflow errors where applicable when the result doesn't fit into `Union{Integer(elttype(r)),Int}`.

[source](#)

Fully implemented by:

- [AbstractRange](#)
- [UnitRange](#)
- `Tuple`
- `Number`
- [AbstractArray](#)

- [BitSet](#)
- [IdDict](#)
- [Dict](#)
- [WeakKeyDict](#)
- [AbstractString](#)
- [Set](#)
- [NamedTuple](#)

42.4 Iterable Collections

Base.in – Function.

```
in(item, collection) -> Bool
∈(item, collection) -> Bool
```

Determine whether an item is in the given collection, in the sense that it is `==` to one of the values generated by iterating over the collection. Return a `Bool` value, except if item is [missing](#) or collection contains missing but not item, in which case missing is returned ([three-valued logic](#), matching the behavior of [any](#) and `==`).

Some collections follow a slightly different definition. For example, [Sets](#) check whether the item [isequal](#) to one of the elements; [Dicts](#) look for key=>value pairs, and the key is compared using [isequal](#).

To test for the presence of a key in a dictionary, use [haskey](#) or `k in keys(dict)`. For the collections mentioned above, the result is always a `Bool`.

When broadcasting with `in.(items, collection)` or `items .∈ collection`, both item and collection are broadcasted over, which is often not what is intended. For example, if both arguments are vectors (and the dimensions match), the result is a vector indicating whether each value in collection items is in the value at the corresponding position in collection. To get a vector indicating whether each value in items is in collection, wrap collection in a tuple or a Ref like this: `in.(items, Ref(collection))` or `items .∈ Ref(collection)`.

See also: [∈](#), [insorted](#), [contains](#), [occursin](#), [issubset](#).

Examples

```
julia> a = 1:3:20
1:3:19

julia> 4 in a
true

julia> 5 in a
false

julia> missing in [1, 2]
missing
```

```

julia> 1 in [2, missing]
missing

julia> 1 in [1, missing]
true

julia> missing in Set{Int}([1, 2])
false

julia> (1==missing) in Dict{Int, Int}([1=>10, 2=>20])
missing

julia> [1, 2] .∈ [2, 3]
2-element BitVector:
 0
 0

julia> [1, 2] .∈ ([2, 3],)
2-element BitVector:
 0
 1

```

[source](#)

Base.∉ – Function.

```

∉(item, collection) -> Bool
∋(collection, item) -> Bool

```

Negation of \in and \ni , i.e. checks that item is not in collection.

When broadcasting with items \notin collection, both item and collection are broadcasted over, which is often not what is intended. For example, if both arguments are vectors (and the dimensions match), the result is a vector indicating whether each value in collection items is not in the value at the corresponding position in collection. To get a vector indicating whether each value in items is not in collection, wrap collection in a tuple or a Ref like this: items \notin Ref(collection).

Examples

```

julia> 1 ∉ 2:4
true

julia> 1 ∉ 1:3
false

julia> [1, 2] .∉ [2, 3]
2-element BitVector:
 1
 1

julia> [1, 2] .∉ ([2, 3],)
2-element BitVector:
 1
 0

```

[source](#)

Base.etype – Function.

```
| etype(type)
```

Determine the type of the elements generated by iterating a collection of the given type. For dictionary types, this will be a `Pair{KeyType,ValType}`. The definition `etype(x) = etype(typeof(x))` is provided for convenience so that instances can be passed instead of types. However the form that accepts a type argument should be defined for new types.

See also: [keytype](#), [typeof](#).

Examples

```
julia> etype(fill(1f0, (2,2)))  
Float32  
  
julia> etype(fill(0x1, (2,2)))  
UInt8
```

[source](#)

Base.indexin – Function.

```
| indexin(a, b)
```

Return an array containing the first index in `b` for each value in `a` that is a member of `b`. The output array contains nothing wherever `a` is not a member of `b`.

See also: [sortperm](#), [findfirst](#).

Examples

```
julia> a = ['a', 'b', 'c', 'b', 'd', 'a'];  
  
julia> b = ['a', 'b', 'c'];  
  
julia> indexin(a, b)  
6-element Vector{Union{Nothing, Int64}}:  
 1  
 2  
 3  
 2  
 nothing  
 1  
  
julia> indexin(b, a)  
3-element Vector{Union{Nothing, Int64}}:  
 1  
 2  
 3
```

[source](#)

Base.unique – Function.

```
| unique(itr)
```

Return an array containing only the unique elements of collection `itr`, as determined by `isequal`, in the order that the first of each set of equivalent elements originally appears. The element type of the input is preserved.

See also: `unique!`, `allunique`, `allequal`.

Examples

```
julia> unique([1, 2, 6, 2])
3-element Vector{Int64}:
 1
 2
 6

julia> unique(Real[1, 1.0, 2])
2-element Vector{Real}:
 1
 2
```

source

```
| unique(f, itr)
```

Return an array containing one value from `itr` for each unique value produced by `f` applied to elements of `itr`.

Examples

```
julia> unique(x -> x^2, [1, -1, 3, -3, 4])
3-element Vector{Int64}:
 1
 3
 4
```

This functionality can also be used to extract the indices of the first occurrences of unique elements in an array:

```
julia> a = [3.1, 4.2, 5.3, 3.1, 3.1, 3.1, 4.2, 1.7];

julia> i = unique(i -> a[i], eachindex(a))
4-element Vector{Int64}:
 1
 2
 3
 8

julia> a[i]
4-element Vector{Float64}:
 3.1
 4.2
```

```

5.3
1.7

julia> a[i] == unique(a)
true

```

[source](#)

```
unique(A::AbstractArray; dims::Int)
```

Return unique regions of A along dimension dims.

Examples

```

julia> A = map(isodd, reshape(Vector{Bool}(1:8), (2,2,2)))
2×2×2 Array{Bool, 3}:
[:, :, 1] =
 1  1
 0  0

[:, :, 2] =
 1  1
 0  0

julia> unique(A)
2-element Vector{Bool}:
 1
 0

julia> unique(A, dims=2)
2×1×2 Array{Bool, 3}:
[:, :, 1] =
 1
 0

[:, :, 2] =
 1
 0

julia> unique(A, dims=3)
2×2×1 Array{Bool, 3}:
[:, :, 1] =
 1  1
 0  0

```

[source](#)

Base.unique! – Function.

```
unique!(f, A::AbstractVector)
```

Selects one value from A for each unique value produced by f applied to elements of A, then return the modified A.

Julia 1.1

This method is available as of Julia 1.1.

Examples

```
julia> unique!(x -> x^2, [1, -1, 3, -3, 4])
3-element Vector{Int64}:
 1
 3
 4

julia> unique!(n -> n%3, [5, 1, 8, 9, 3, 4, 10, 7, 2, 6])
3-element Vector{Int64}:
 5
 1
 9

julia> unique!(iseven, [2, 3, 5, 7, 9])
2-element Vector{Int64}:
 2
 3
```

source

```
unique!(A::AbstractVector)
```

Remove duplicate items as determined by `isequal`, then return the modified A. `unique!` will return the elements of A in the order that they occur. If you do not care about the order of the returned data, then calling `(sort!(A); unique!(A))` will be much more efficient as long as the elements of A can be sorted.

Examples

```
julia> unique!([1, 1, 1])
1-element Vector{Int64}:
 1

julia> A = [7, 3, 2, 3, 7, 5];

julia> unique!(A)
4-element Vector{Int64}:
 7
 3
 2
 5

julia> B = [7, 6, 42, 6, 7, 42];

julia> sort!(B); # unique! is able to process sorted data much more efficiently.

julia> unique!(B)
3-element Vector{Int64}:
 6
```

```
| 7  
| 42
```

[source](#)

Base.allunique – Function.

```
| allunique(itr) -> Bool
```

Return true if all values from itr are distinct when compared with [isequal](#).

See also: [unique](#), [issorted](#), [allequal](#).

Examples

```
| julia> allunique([1, 2, 3])  
true  
  
| julia> allunique([1, 2, 1, 2])  
false  
  
| julia> allunique(Real[1, 1.0, 2])  
false  
  
| julia> allunique([NaN, 2.0, NaN, 4.0])  
false
```

[source](#)

Base.allequal – Function.

```
| allequal(itr) -> Bool
```

Return true if all values from itr are equal when compared with [isequal](#).

See also: [unique](#), [allunique](#).

Julia 1.8

The allequal function requires at least Julia 1.8.

Examples

```
| julia> allequal([])  
true  
  
| julia> allequal([1])  
true  
  
| julia> allequal([1, 1])  
true  
  
| julia> allequal([1, 2])  
false  
  
| julia> allequal(Dict{:a => 1, :b => 1})  
false
```

[source](#)**Base.reduce** – Method.

```
| reduce(op, itr; [init])
```

Reduce the given collection `itr` with the given binary operator `op`. If provided, the initial value `init` must be a neutral element for `op` that will be returned for empty collections. It is unspecified whether `init` is used for non-empty collections.

For empty collections, providing `init` will be necessary, except for some special cases (e.g. when `op` is one of `+`, `*`, `max`, `min`, `&`, `|`) when Julia can determine the neutral element of `op`.

Reductions for certain commonly-used operators may have special implementations, and should be used instead: `maximum(itr)`, `minimum(itr)`, `sum(itr)`, `prod(itr)`, `any(itr)`, `all(itr)`. There are efficient methods for concatenating certain arrays of arrays by calling `reduce(vcat, arr)` or `reduce(hcat, arr)`.

The associativity of the reduction is implementation dependent. This means that you can't use non-associative operations like `-` because it is undefined whether `reduce(-, [1,2,3])` should be evaluated as `(1-2)-3` or `1-(2-3)`. Use `foldl` or `foldr` instead for guaranteed left or right associativity.

Some operations accumulate error. Parallelism will be easier if the reduction can be executed in groups. Future versions of Julia might change the algorithm. Note that the elements are not reordered if you use an ordered collection.

Examples

```
| julia> reduce(*, [2; 3; 4])
24
julia> reduce(*, [2; 3; 4]; init=-1)
-24
```

[source](#)**Base.reduce** – Method.

```
| reduce(f, A::AbstractArray; dims=:, [init])
```

Reduce 2-argument function `f` along dimensions of `A`. `dims` is a vector specifying the dimensions to reduce, and the keyword argument `init` is the initial value to use in the reductions. For `+`, `*`, `max` and `min` the `init` argument is optional.

The associativity of the reduction is implementation-dependent; if you need a particular associativity, e.g. left-to-right, you should write your own loop or consider using `foldl` or `foldr`. See documentation for [reduce](#).

Examples

```
| julia> a = reshape(Vector{Int64}(1:16), (4,4))
4×4 Matrix{Int64}:
 1  5  9 13
 2  6 10 14
 3  7 11 15
```

```

4  8 12 16

julia> reduce(max, a, dims=2)
4×1 Matrix{Int64}:
13
14
15
16

julia> reduce(max, a, dims=1)
1×4 Matrix{Int64}:
4  8 12 16

```

[source](#)

Base.foldl – Method.

```
| foldl(op, itr; [init])
```

Like [reduce](#), but with guaranteed left associativity. If provided, the keyword argument `init` will be used exactly once. In general, it will be necessary to provide `init` to work with empty collections.

See also [mapfoldl](#), [foldr](#), [accumulate](#).

Examples

```

julia> foldl(=>, 1:4)
((1 => 2) => 3) => 4

julia> foldl(=>, 1:4; init=0)
(((0 => 1) => 2) => 3) => 4

julia> accumulate(=>, (1,2,3,4))
(1, 1 => 2, (1 => 2) => 3, ((1 => 2) => 3) => 4)

```

[source](#)

Base.foldr – Method.

```
| foldr(op, itr; [init])
```

Like [reduce](#), but with guaranteed right associativity. If provided, the keyword argument `init` will be used exactly once. In general, it will be necessary to provide `init` to work with empty collections.

Examples

```

julia> foldr(=>, 1:4)
1 => (2 => (3 => 4))

julia> foldr(=>, 1:4; init=0)
1 => (2 => (3 => (4 => 0)))

```

[source](#)

Base.maximum – Function.

```
| maximum(f, itr; [init])
```

Return the largest result of calling function `f` on each element of `itr`.

The value returned for empty `itr` can be specified by `init`. It must be a neutral element for `max` (i.e. which is less than or equal to any other element) as it is unspecified whether `init` is used for non-empty collections.

Julia 1.6

Keyword argument `init` requires Julia 1.6 or later.

Examples

```
julia> maximum(length, ["Julion", "Julia", "Jule"])
6

julia> maximum(length, []; init=-1)
-1

julia> maximum(sin, Real[]; init=-1.0) # good, since output of sin is >= -1
-1.0
```

[source](#)

```
| maximum(itr; [init])
```

Return the largest element in a collection.

The value returned for empty `itr` can be specified by `init`. It must be a neutral element for `max` (i.e. which is less than or equal to any other element) as it is unspecified whether `init` is used for non-empty collections.

Julia 1.6

Keyword argument `init` requires Julia 1.6 or later.

Examples

```
julia> maximum(-20.5:10)
9.5

julia> maximum([1,2,3])
3

julia> maximum()
ERROR: MethodError: reducing over an empty collection is not allowed; consider supplying
↪ `init` to the reducer
Stacktrace:
[...]

julia> maximum(); init=-Inf
-Inf
```

[source](#)

```
| maximum(A::AbstractArray; dims)
```

Compute the maximum value of an array over the given dimensions. See also the [max\(a,b\)](#) function to take the maximum of two or more arguments, which can be applied elementwise to arrays via `max.(a,b)`.

See also: [maximum!](#), [extrema](#), [findmax](#), [argmax](#).

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> maximum(A, dims=1)
1×2 Matrix{Int64}:
 3  4

julia> maximum(A, dims=2)
2×1 Matrix{Int64}:
 2
 4
```

source

```
| maximum(f, A::AbstractArray; dims)
```

Compute the maximum value by calling the function `f` on each element of an array over the given dimensions.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> maximum(abs2, A, dims=1)
1×2 Matrix{Int64}:
 9 16

julia> maximum(abs2, A, dims=2)
2×1 Matrix{Int64}:
 4
16
```

source

`Base.maximum!` – Function.

```
| maximum!(r, A)
```

Compute the maximum value of `A` over the singleton dimensions of `r`, and write results to `r`.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> maximum!([1; 1], A)
2-element Vector{Int64}:
 2
 4

julia> maximum!([1 1], A)
1×2 Matrix{Int64}:
 3  4
```

[source](#)

`Base.minimum` - Function.

```
minimum(f, itr; [init])
```

Return the smallest result of calling function `f` on each element of `itr`.

The value returned for empty `itr` can be specified by `init`. It must be a neutral element for `min` (i.e. which is greater than or equal to any other element) as it is unspecified whether `init` is used for non-empty collections.

Julia 1.6

Keyword argument `init` requires Julia 1.6 or later.

Examples

```
julia> minimum(length, ["Julion", "Julia", "Jule"])
4

julia> minimum(length, []; init=typemax{Int64}())
9223372036854775807

julia> minimum(sin, Real[]; init=1.0) # good, since output of sin is <= 1
1.0
```

[source](#)

```
minimum(itr; [init])
```

Return the smallest element in a collection.

The value returned for empty `itr` can be specified by `init`. It must be a neutral element for `min` (i.e. which is greater than or equal to any other element) as it is unspecified whether `init` is used for non-empty collections.

Julia 1.6

Keyword argument `init` requires Julia 1.6 or later.

Examples

```
julia> minimum(-20.5:10)
-20.5

julia> minimum([1,2,3])
1

julia> minimum([])
ERROR: MethodError: reducing over an empty collection is not allowed; consider supplying
↪ `init` to the reducer
Stacktrace:
[...]

julia> minimum([], init=Inf)
Inf
```

source

```
minimum(A::AbstractArray; dims)
```

Compute the minimum value of an array over the given dimensions. See also the [min\(a,b\)](#) function to take the minimum of two or more arguments, which can be applied elementwise to arrays via `min.(a,b)`.

See also: [minimum!](#), [extrema](#), [findmin](#), [argmin](#).

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> minimum(A, dims=1)
1×2 Matrix{Int64}:
 1  2

julia> minimum(A, dims=2)
2×1 Matrix{Int64}:
 1
 3
```

source

```
minimum(f, A::AbstractArray; dims)
```

Compute the minimum value by calling the function `f` on each element of an array over the given dimensions.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> minimum(abs2, A, dims=1)
1×2 Matrix{Int64}:
 1  4

julia> minimum(abs2, A, dims=2)
2×1 Matrix{Int64}:
 1
 9
```

[source](#)

Base.minimum! - Function.

```
minimum!(r, A)
```

Compute the minimum value of A over the singleton dimensions of r, and write results to r.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> minimum!([1; 1], A)
2-element Vector{Int64}:
 1
 3

julia> minimum!([1 1], A)
1×2 Matrix{Int64}:
 1  2
```

[source](#)

Base.extrema - Function.

```
extrema(itr; [init]) -> (mn, mx)
```

Compute both the minimum mn and maximum mx element in a single pass, and return them as a 2-tuple.

The value returned for empty itr can be specified by init. It must be a 2-tuple whose first and second elements are neutral elements for min and max respectively (i.e. which are greater/less than or equal to any other element). As a consequence, when itr is empty the returned (mn, mx) tuple will satisfy $mn \geq mx$. When init is specified it may be used even for non-empty itr.

Julia 1.8

Keyword argument `init` requires Julia 1.8 or later.

Examples

```
julia> extrema(2:10)
(2, 10)

julia> extrema([9,pi,4.5])
(3.141592653589793, 9.0)

julia> extrema([]; init = (Inf, -Inf))
(Inf, -Inf)
```

source

```
extrema(f, itr; [init]) -> (mn, mx)
```

Compute both the minimum `mn` and maximum `mx` of `f` applied to each element in `itr` and return them as a 2-tuple. Only one pass is made over `itr`.

The value returned for empty `itr` can be specified by `init`. It must be a 2-tuple whose first and second elements are neutral elements for `min` and `max` respectively (i.e. which are greater/less than or equal to any other element). It is used for non-empty collections. Note: it implies that, for empty `itr`, the returned value `(mn, mx)` satisfies `mn ≥ mx` even though for non-empty `itr` it satisfies `mn ≤ mx`. This is a "paradoxical" but yet expected result.

Julia 1.2

This method requires Julia 1.2 or later.

Julia 1.8

Keyword argument `init` requires Julia 1.8 or later.

Examples

```
julia> extrema(sin, 0:π)
(0.0, 0.9092974268256817)

julia> extrema(sin, Real[]; init = (1.0, -1.0)) # good, since -1 ≤ sin(::Real) ≤ 1
(1.0, -1.0)
```

source

```
extrema(A::AbstractArray; dims) -> Array{Tuple}
```

Compute the minimum and maximum elements of an array over the given dimensions.

See also: [minimum](#), [maximum](#), [extrema!](#).

Examples

```
julia> A = reshape(Vector{Int64}(1:2:16), (2,2,2))
2×2×2 Array{Int64, 3}:
[:, :, 1] =
 1  5
 3  7

[:, :, 2] =
 9 13
11 15

julia> extrema(A, dims = (1,2))
1×1×2 Array{Tuple{Int64, Int64}, 3}:
[:, :, 1] =
 (1, 7)

[:, :, 2] =
 (9, 15)
```

source

```
extrema(f, A::AbstractArray; dims) -> Array{Tuple}
```

Compute the minimum and maximum of f applied to each element in the given dimensions of A .

Julia 1.2

This method requires Julia 1.2 or later.

source

Base.extrema! - Function.

```
extrema!(r, A)
```

Compute the minimum and maximum value of A over the singleton dimensions of r , and write results to r .

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Julia 1.8

This method requires Julia 1.8 or later.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> extrema!([(1, 1); (1, 1)], A)
2-element Vector{Tuple{Int64, Int64}}:
```

```

(1, 2)
(3, 4)

julia> extrema!([(1, 1); (1, 1)], A)
1×2 Matrix{Tuple{Int64, Int64}}:
(1, 3) (2, 4)

```

[source](#)

Base.argmax – Function.

```
| argmax(r::AbstractRange)
```

Ranges can have multiple maximal elements. In that case `argmax` will return a maximal index, but not necessarily the first one.

[source](#)

```
| argmax(f, domain)
```

Return a value `x` from `domain` for which `f(x)` is maximised. If there are multiple maximal values for `f(x)` then the first one will be found.

`domain` must be a non-empty iterable.

Values are compared with `isless`.

Julia 1.7

This method requires Julia 1.7 or later.

See also [argmin](#), [findmax](#).

Examples

```

julia> argmax(abs, -10:5)
-10

julia> argmax(cos, 0:π/2:2π)
0.0

```

[source](#)

```
| argmax(itr)
```

Return the index or key of the maximal element in a collection. If there are multiple maximal elements, then the first one will be returned.

The collection must not be empty.

Values are compared with `isless`.

See also: [argmin](#), [findmax](#).

Examples

```
julia> argmax([8, 0.1, -9, pi])
1

julia> argmax([1, 7, 7, 6])
2

julia> argmax([1, 7, 7, NaN])
4
```

[source](#)

```
| argmax(A; dims) -> indices
```

For an array input, return the indices of the maximum elements over the given dimensions. NaN is treated as greater than all other values except missing.

Examples

```
julia> A = [1.0 2; 3 4]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> argmax(A, dims=1)
1×2 Matrix{CartesianIndex{2}}:
 CartesianIndex(2, 1) CartesianIndex(2, 2)

julia> argmax(A, dims=2)
2×1 Matrix{CartesianIndex{2}}:
 CartesianIndex(1, 2)
 CartesianIndex(2, 2)
```

[source](#)

Base.argmin – Function.

```
| argmin(r::AbstractRange)
```

Ranges can have multiple minimal elements. In that case `argmin` will return a minimal index, but not necessarily the first one.

[source](#)

```
| argmin(f, domain)
```

Return a value `x` from `domain` for which `f(x)` is minimised. If there are multiple minimal values for `f(x)` then the first one will be found.

`domain` must be a non-empty iterable.

NaN is treated as less than all other values except missing.

Julia 1.7

This method requires Julia 1.7 or later.

See also [argmax](#), [findmin](#).

Examples

```
julia> argmin(sign, -10:5)
-10

julia> argmin(x -> -x^3 + x^2 - 10, -5:5)
5

julia> argmin(acos, 0:0.1:1)
1.0
```

[source](#)

```
argmin(itr)
```

Return the index or key of the minimal element in a collection. If there are multiple minimal elements, then the first one will be returned.

The collection must not be empty.

NaN is treated as less than all other values except missing.

See also: [argmax](#), [findmin](#).

Examples

```
julia> argmin([8, 0.1, -9, pi])
3

julia> argmin([7, 1, 1, 6])
2

julia> argmin([7, 1, 1, NaN])
4
```

[source](#)

```
argmin(A; dims) -> indices
```

For an array input, return the indices of the minimum elements over the given dimensions. NaN is treated as less than all other values except missing.

Examples

```
julia> A = [1.0 2; 3 4]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> argmin(A, dims=1)
1×2 Matrix{CartesianIndex{2}}:
 CartesianIndex(1, 1) CartesianIndex(1, 2)

julia> argmin(A, dims=2)
```

```
2×1 Matrix{CartesianIndex{2}}:
 CartesianIndex{1, 1}
 CartesianIndex{2, 1}
```

[source](#)

Base.findmax – Function.

```
findmax(f, domain) -> (f(x), index)
```

Return a pair of a value in the codomain (outputs of `f`) and the index of the corresponding value in the domain (inputs to `f`) such that `f(x)` is maximised. If there are multiple maximal points, then the first one will be returned.

domain must be a non-empty iterable.

Values are compared with `isless`.

Julia 1.7

This method requires Julia 1.7 or later.

Examples

```
julia> findmax(identity, 5:9)
(9, 5)

julia> findmax(-, 1:10)
(-1, 1)

julia> findmax(first, [(1, :a), (3, :b), (3, :c)])
(3, 2)

julia> findmax(cos, 0:π/2:2π)
(1.0, 1)
```

[source](#)

```
findmax(itr) -> (x, index)
```

Return the maximal element of the collection `itr` and its index or key. If there are multiple maximal elements, then the first one will be returned. Values are compared with `isless`.

See also: [findmin](#), [argmax](#), [maximum](#).

Examples

```
julia> findmax([8, 0.1, -9, π])
(8.0, 1)

julia> findmax([1, 7, 7, 6])
(7, 2)

julia> findmax([1, 7, 7, NaN])
(NaN, 4)
```

[source](#)

```
| findmax(A; dims) -> (maxval, index)
```

For an array input, returns the value and index of the maximum over the given dimensions. NaN is treated as greater than all other values except missing.

Examples

```
julia> A = [1.0 2; 3 4]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> findmax(A, dims=1)
([3.0 4.0], CartesianIndex{2}[CartesianIndex(2, 1) CartesianIndex(2, 2)])

julia> findmax(A, dims=2)
([2.0; 4.0;;], CartesianIndex{2}[CartesianIndex(1, 2); CartesianIndex(2, 2);;])
```

[source](#)

```
| findmax(f, A; dims) -> (f(x), index)
```

For an array input, returns the value in the codomain and index of the corresponding value which maximize f over the given dimensions.

Examples

```
julia> A = [-1.0 1; -0.5 2]
2×2 Matrix{Float64}:
-1.0  1.0
-0.5  2.0

julia> findmax(abs2, A, dims=1)
([1.0 4.0], CartesianIndex{2}[CartesianIndex(1, 1) CartesianIndex(2, 2)])

julia> findmax(abs2, A, dims=2)
([1.0; 4.0;;], CartesianIndex{2}[CartesianIndex(1, 1); CartesianIndex(2, 2);;])
```

[source](#)

Base.findmin – Function.

```
| findmin(f, domain) -> (f(x), index)
```

Return a pair of a value in the codomain (outputs of f) and the index of the corresponding value in the domain (inputs to f) such that f(x) is minimised. If there are multiple minimal points, then the first one will be returned.

domain must be a non-empty iterable.

NaN is treated as less than all other values except missing.

Julia 1.7

This method requires Julia 1.7 or later.

Examples

```
julia> findmin(identity, 5:9)
(5, 1)

julia> findmin(-, 1:10)
(-10, 10)

julia> findmin(first, [(2, :a), (2, :b), (3, :c)])
(2, 1)

julia> findmin(cos, 0:π/2:2π)
(-1.0, 3)
```

source

```
findmin(itr) -> (x, index)
```

Return the minimal element of the collection `itr` and its index or key. If there are multiple minimal elements, then the first one will be returned. NaN is treated as less than all other values except missing.

See also: [findmax](#), [argmin](#), [minimum](#).

Examples

```
julia> findmin([8, 0.1, -9, π])
(-9.0, 3)

julia> findmin([1, 7, 7, 6])
(1, 1)

julia> findmin([1, 7, 7, NaN])
(NaN, 4)
```

source

```
findmin(A; dims) -> (minval, index)
```

For an array input, returns the value and index of the minimum over the given dimensions. NaN is treated as less than all other values except missing.

Examples

```
julia> A = [1.0 2; 3 4]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> findmin(A, dims=1)
([1.0 2.0], CartesianIndex{2}[CartesianIndex{1, 1} CartesianIndex{1, 2}])

julia> findmin(A, dims=2)
([1.0; 3.0; ;], CartesianIndex{2}[CartesianIndex{1, 1}; CartesianIndex{2, 1}; ;])
```

source

```
| findmin(f, A; dims) -> (f(x), index)
```

For an array input, returns the value in the codomain and index of the corresponding value which minimize f over the given dimensions.

Examples

```
julia> A = [-1.0 1; -0.5 2]
2×2 Matrix{Float64}:
-1.0  1.0
-0.5  2.0

julia> findmin(abs2, A, dims=1)
([0.25 1.0], CartesianIndex{2}[CartesianIndex(2, 1) CartesianIndex(1, 2)])

julia> findmin(abs2, A, dims=2)
([1.0; 0.25;;], CartesianIndex{2}[CartesianIndex(1, 1); CartesianIndex(2, 1);;])
```

[source](#)

`Base.findmax!` – Function.

```
| findmax!(rval, rind, A) -> (maxval, index)
```

Find the maximum of A and the corresponding linear index along singleton dimensions of $rval$ and $rind$, and store the results in $rval$ and $rind$. NaN is treated as greater than all other values except missing.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

`Base.findmin!` – Function.

```
| findmin!(rval, rind, A) -> (minval, index)
```

Find the minimum of A and the corresponding linear index along singleton dimensions of $rval$ and $rind$, and store the results in $rval$ and $rind$. NaN is treated as less than all other values except missing.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

`Base.sum` – Function.

```
| sum(f, itr; [init])
```

Sum the results of calling function `f` on each element of `itr`.

The return type is `Int` for signed integers of less than system word size, and `UInt` for unsigned integers of less than system word size. For all other arguments, a common return type is found to which all arguments are promoted.

The value returned for empty `itr` can be specified by `init`. It must be the additive identity (i.e. zero) as it is unspecified whether `init` is used for non-empty collections.

Julia 1.6

Keyword argument `init` requires Julia 1.6 or later.

Examples

```
julia> sum(abs2, [2; 3; 4])
29
```

Note the important difference between `sum(A)` and `reduce(+, A)` for arrays with small integer eltype:

```
julia> sum{Int8}[100, 28]
128

julia> reduce(+, Int8[100, 28])
-128
```

In the former case, the integers are widened to system word size and therefore the result is 128. In the latter case, no such widening happens and integer overflow results in -128.

source

```
sum(itr; [init])
```

Return the sum of all elements in a collection.

The return type is `Int` for signed integers of less than system word size, and `UInt` for unsigned integers of less than system word size. For all other arguments, a common return type is found to which all arguments are promoted.

The value returned for empty `itr` can be specified by `init`. It must be the additive identity (i.e. zero) as it is unspecified whether `init` is used for non-empty collections.

Julia 1.6

Keyword argument `init` requires Julia 1.6 or later.

See also: [reduce](#), [mapreduce](#), [count](#), [union](#).

Examples

```
julia> sum{1:20}
210

julia> sum{1:20; init = 0.0}
210.0
```

[source](#)

```
| sum(A::AbstractArray; dims)
```

Sum elements of an array over the given dimensions.

Examples

```
| julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> sum(A, dims=1)
1×2 Matrix{Int64}:
 4  6

julia> sum(A, dims=2)
2×1 Matrix{Int64}:
 3
 7
```

[source](#)

```
| sum(f, A::AbstractArray; dims)
```

Sum the results of calling function `f` on each element of an array over the given dimensions.

Examples

```
| julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> sum(abs2, A, dims=1)
1×2 Matrix{Int64}:
10 20

julia> sum(abs2, A, dims=2)
2×1 Matrix{Int64}:
 5
25
```

[source](#)

Base.sum! – Function.

```
| sum!(r, A)
```

Sum elements of `A` over the singleton dimensions of `r`, and write results to `r`.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> sum!([1; 1], A)
2-element Vector{Int64}:
 3
 7

julia> sum!([1 1], A)
1×2 Matrix{Int64}:
 4  6
```

[source](#)**Base.prod** – Function.

```
| prod(f, itr; [init])
```

Return the product of `f` applied to each element of `itr`.

The return type is `Int` for signed integers of less than system word size, and `UInt` for unsigned integers of less than system word size. For all other arguments, a common return type is found to which all arguments are promoted.

The value returned for empty `itr` can be specified by `init`. It must be the multiplicative identity (i.e. one) as it is unspecified whether `init` is used for non-empty collections.

Julia 1.6

Keyword argument `init` requires Julia 1.6 or later.

Examples

```
julia> prod(abs2, [2; 3; 4])
576
```

[source](#)

```
| prod(itr; [init])
```

Return the product of all elements of a collection.

The return type is `Int` for signed integers of less than system word size, and `UInt` for unsigned integers of less than system word size. For all other arguments, a common return type is found to which all arguments are promoted.

The value returned for empty `itr` can be specified by `init`. It must be the multiplicative identity (i.e. one) as it is unspecified whether `init` is used for non-empty collections.

Julia 1.6

Keyword argument `init` requires Julia 1.6 or later.

See also: [reduce](#), [cumprod](#), [any](#).

Examples

```
julia> prod(1:5)
120

julia> prod(1:5; init = 1.0)
120.0
```

[source](#)

```
prod(A::AbstractArray; dims)
```

Multiply elements of an array over the given dimensions.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> prod(A, dims=1)
1×2 Matrix{Int64}:
 3  8

julia> prod(A, dims=2)
2×1 Matrix{Int64}:
 2
12
```

[source](#)

```
prod(f, A::AbstractArray; dims)
```

Multiply the results of calling the function `f` on each element of an array over the given dimensions.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> prod(abs2, A, dims=1)
1×2 Matrix{Int64}:
 9 64

julia> prod(abs2, A, dims=2)
2×1 Matrix{Int64}:
 4
144
```

[source](#)

Base.prod! – Function.

```
| prod!(r, A)
```

Multiply elements of A over the singleton dimensions of r, and write results to r.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> prod!([1; 1], A)
2-element Vector{Int64}:
 2
12

julia> prod!([1 1], A)
1×2 Matrix{Int64}:
 3  8
```

[source](#)

Base.any – Method.

```
| any(itr) -> Bool
```

Test whether any elements of a boolean collection are true, returning true as soon as the first true value in itr is encountered (short-circuiting). To short-circuit on false, use [all](#).

If the input contains [missing](#) values, return missing if all non-missing values are false (or equivalently, if the input contains no true value), following [three-valued logic](#).

See also: [all](#), [count](#), [sum](#), [|](#), [||](#).

Examples

```
julia> a = [true, false, false, true]
4-element Vector{Bool}:
 1
 0
 0
 1

julia> any(a)
true

julia> any((println(i); v) for (i, v) in enumerate(a))
1
```

```

true

julia> any([missing, true])
true

julia> any([false, missing])
missing

```

[source](#)

Base.any – Method.

```
| any(p, itr) -> Bool
```

Determine whether predicate `p` returns true for any elements of `itr`, returning true as soon as the first item in `itr` for which `p` returns true is encountered (short-circuiting). To short-circuit on false, use [all](#).

If the input contains [missing](#) values, return missing if all non-missing values are false (or equivalently, if the input contains no true value), following [three-valued logic](#).

Examples

```

julia> any(i->(4<=i<=6), [3,5,7])
true

julia> any(i -> (println(i); i > 3), 1:10)
1
2
3
4
true

julia> any(i -> i > 0, [1, missing])
true

julia> any(i -> i > 0, [-1, missing])
missing

julia> any(i -> i > 0, [-1, 0])
false

```

[source](#)

Base.any! – Function.

```
| any!(r, A)
```

Test whether any values in `A` along the singleton dimensions of `r` are true, and write results to `r`.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
julia> A = [true false; true false]
2×2 Matrix{Bool}:
 1  0
 1  0

julia> any!([1; 1], A)
2-element Vector{Int64}:
 1
 1

julia> any!([1 1], A)
1×2 Matrix{Int64}:
 1  0
```

[source](#)

Base.all – Method.

```
| all(itr) -> Bool
```

Test whether all elements of a boolean collection are true, returning false as soon as the first false value in itr is encountered (short-circuiting). To short-circuit on true, use [any](#).

If the input contains [missing](#) values, return missing if all non-missing values are true (or equivalently, if the input contains no false value), following [three-valued logic](#).

See also: [all!](#), [any](#), [count](#), [&](#), [&&](#), [allunique](#).

Examples

```
julia> a = [true, false, false, true]
4-element Vector{Bool}:
 1
 0
 0
 1

julia> all(a)
false

julia> all((println(i); v) for (i, v) in enumerate(a))
1
2
false

julia> all([missing, false])
false

julia> all([true, missing])
missing
```

[source](#)

Base.all – Method.

```
| all(p, itr) -> Bool
```

Determine whether predicate `p` returns true for all elements of `itr`, returning false as soon as the first item in `itr` for which `p` returns false is encountered (short-circuiting). To short-circuit on true, use [any](#).

If the input contains [missing](#) values, return missing if all non-missing values are true (or equivalently, if the input contains no false value), following [three-valued logic](#).

Examples

```
julia> all(i->(4<=i<=6), [4,5,6])
true

julia> all(i -> (println(i); i < 3), 1:10)
1
2
3
false

julia> all(i -> i > 0, [1, missing])
missing

julia> all(i -> i > 0, [-1, missing])
false

julia> all(i -> i > 0, [1, 2])
true
```

[source](#)

Base.all! – Function.

```
| all!(r, A)
```

Test whether all values in `A` along the singleton dimensions of `r` are true, and write results to `r`.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
julia> A = [true false; true false]
2×2 Matrix{Bool}:
 1  0
 1  0

julia> all!([1; 1], A)
2-element Vector{Int64}:
 0
```

```

0

julia> all!([1 1], A)
1×2 Matrix{Int64}:
 1  0

```

[source](#)

`Base.count` – Function.

```
count([f=identity,] itr; init=0) -> Integer
```

Count the number of elements in `itr` for which the function `f` returns `true`. If `f` is omitted, count the number of `true` elements in `itr` (which should be a collection of boolean values). `init` optionally specifies the value to start counting from and therefore also determines the output type.

Julia 1.6

`init` keyword was added in Julia 1.6.

See also: [any](#), [sum](#).

Examples

```

julia> count(i->(4<=i<=6), [2,3,4,5,6])
3

julia> count([true, false, true, true])
3

julia> count(>(3), 1:7, init=0x03)
0x07

```

[source](#)

```

count(
    pattern::Union{AbstractChar,AbstractString,AbstractPattern},
    string::AbstractString;
    overlap::Bool = false,
)

```

Return the number of matches for `pattern` in `string`. This is equivalent to calling `length(findall(pattern, string))` but more efficient.

If `overlap=true`, the matching sequences are allowed to overlap indices in the original string, otherwise they must be from disjoint character ranges.

Julia 1.3

This method requires at least Julia 1.3.

Julia 1.7

Using a character as the pattern requires at least Julia 1.7.

Examples

```
julia> count('a', "JuliaLang")
2

julia> count(r"a(.)a", "cabacabac", overlap=true)
3

julia> count(r"a(.)a", "cabacabac")
2
```

[source](#)

```
count([f=identity,] A::AbstractArray; dims=:)
```

Count the number of elements in A for which f returns true over the given dimensions.

Julia 1.5

dims keyword was added in Julia 1.5.

Julia 1.6

init keyword was added in Julia 1.6.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> count(<=(2), A, dims=1)
1×2 Matrix{Int64}:
 1  1

julia> count(<=(2), A, dims=2)
2×1 Matrix{Int64}:
 2
 0
```

[source](#)

Base.foreach - Function.

```
foreach(f, c...) -> Nothing
```

Call function f on each element of iterable c. For multiple iterable arguments, f is called elementwise, and iteration stops when any iterator is finished.

foreach should be used instead of [map](#) when the results of f are not needed, for example in `foreach println, array)`.

Examples

```
julia> tri = 1:3:7; res = Int[];

julia> foreach(x -> push!(res, x^2), tri)

julia> res
3-element Vector{Int64}:
 1
16
49

julia> foreach((x, y) -> println(x, " with ", y), tri, 'a':'z')
1 with a
4 with b
7 with c
```

[source](#)

Base.map – Function.

```
map(f, c...) -> collection
```

Transform collection *c* by applying *f* to each element. For multiple collection arguments, apply *f* elementwise, and stop when any of them is exhausted.

See also [map!](#), [foreach](#), [mapreduce](#), [mapslices](#), [zip](#), [Iterators.map](#).

Examples

```
julia> map(x -> x * 2, [1, 2, 3])
3-element Vector{Int64}:
 2
 4
 6

julia> map(+, [1, 2, 3], [10, 20, 30, 400, 5000])
3-element Vector{Int64}:
11
22
33
```

[source](#)

```
map(f, A::AbstractArray...) -> N-array
```

When acting on multi-dimensional arrays of the same [ndims](#), they must all have the same [axes](#), and the answer will too.

See also [broadcast](#), which allows mismatched sizes.

Examples

```
julia> map(/, [1 2; 3 4], [4 3; 2 1])
2×2 Matrix{Rational{Int64}}:
 1//4  2//3
 3//2  4//1
```

```
julia> map(+, [1 2; 3 4], zeros(2,1))
ERROR: DimensionMismatch

julia> map(+, [1 2; 3 4], [1,10,100,1000], zeros(3,1)) # iterates until 3rd is exhausted
3-element Vector{Float64}:
 2.0
13.0
102.0
```

[source](#)

Base.map! – Function.

```
map!(function, destination, collection...)
```

Like [map](#), but stores the result in destination rather than a new collection. destination must be at least as large as the smallest collection.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

See also: [map](#), [foreach](#), [zip](#), [copyto!](#).

Examples

```
julia> a = zeros(3);

julia> map!(x -> x * 2, a, [1, 2, 3]);

julia> a
3-element Vector{Float64}:
 2.0
 4.0
 6.0

julia> map!(+, zeros(Int, 5), 100:999, 1:3)
5-element Vector{Int64}:
101
103
105
 0
 0
```

[source](#)

```
map!(f, values(dict::AbstractDict))
```

Modifies dict by transforming each value from val to f(val). Note that the type of dict cannot be changed: if f(val) is not an instance of the value type of dict then it will be converted to the value type if possible and otherwise raise an error.

Julia 1.2

`map!(f, values(dict::AbstractDict))` requires Julia 1.2 or later.

Examples

```
julia> d = Dict{:a => 1, :b => 2}
Dict{Symbol, Int64} with 2 entries:
 :a => 1
 :b => 2

julia> map!(v -> v-1, values(d))
ValueIterator for a Dict{Symbol, Int64} with 2 entries. Values:
 0
 1
```

[source](#)

`Base.mapreduce` – Method.

```
| mapreduce(f, op, itr...; [init])
```

Apply function `f` to each element(s) in `itr`s, and then reduce the result using the binary function `op`. If provided, `init` must be a neutral element for `op` that will be returned for empty collections. It is unspecified whether `init` is used for non-empty collections. In general, it will be necessary to provide `init` to work with empty collections.

`mapreduce` is functionally equivalent to calling `reduce(op, map(f, itr); init=init)`, but will in general execute faster since no intermediate collection needs to be created. See documentation for [reduce](#) and [map](#).

Julia 1.2

`mapreduce` with multiple iterators requires Julia 1.2 or later.

Examples

```
julia> mapreduce(x->x^2, +, [1:3;]) # == 1 + 4 + 9
14
```

The associativity of the reduction is implementation-dependent. Additionally, some implementations may reuse the return value of `f` for elements that appear multiple times in `itr`. Use [mapfoldl](#) or [mapfoldr](#) instead for guaranteed left or right associativity and invocation of `f` for every value.

[source](#)

`Base.mapfoldl` – Method.

```
| mapfoldl(f, op, itr; [init])
```

Like [mapreduce](#), but with guaranteed left associativity, as in [foldl](#). If provided, the keyword argument `init` will be used exactly once. In general, it will be necessary to provide `init` to work with empty collections.

[source](#)

`Base.mapfoldr` – Method.

```
| mapfoldr(f, op, itr; [init])
```

Like `mapreduce`, but with guaranteed right associativity, as in `foldr`. If provided, the keyword argument `init` will be used exactly once. In general, it will be necessary to provide `init` to work with empty collections.

[source](#)

`Base.first` – Function.

```
| first(coll)
```

Get the first element of an iterable collection. Return the start point of an `AbstractRange` even if it is empty.

See also: [only](#), [firstindex](#), [last](#).

Examples

```
| julia> first(2:2:10)
2
| julia> first([1; 2; 3; 4])
1
```

[source](#)

```
| first(itr, n::Integer)
```

Get the first `n` elements of the iterable collection `itr`, or fewer elements if `itr` is not long enough.

See also: [startswith](#), [Iterators.take](#).

Julia 1.6

This method requires at least Julia 1.6.

Examples

```
| julia> first(["foo", "bar", "qux"], 2)
2-element Vector{String}:
 "foo"
 "bar"
| julia> first(1:6, 10)
1:6
| julia> first{Bool[], 1)
Bool[]
```

[source](#)

```
| first(s::AbstractString, n::Integer)
```

Get a string consisting of the first n characters of s .

Examples

```
julia> first("∀ε≠0: ε²>0", 0)
""

julia> first("∀ε≠0: ε²>0", 1)
"∀"

julia> first("∀ε≠0: ε²>0", 3)
"∀ε≠"
```

[source](#)

Base.last – Function.

```
| last(coll)
```

Get the last element of an ordered collection, if it can be computed in $O(1)$ time. This is accomplished by calling [lastindex](#) to get the last index. Return the end point of an [AbstractRange](#) even if it is empty.

See also [first](#), [endswith](#).

Examples

```
julia> last(1:2:10)
9

julia> last([1; 2; 3; 4])
4
```

[source](#)

```
| last(itr, n::Integer)
```

Get the last n elements of the iterable collection itr , or fewer elements if itr is not long enough.

Julia 1.6

This method requires at least Julia 1.6.

Examples

```
julia> last(["foo", "bar", "qux"], 2)
2-element Vector{String}:
 "bar"
 "qux"

julia> last(1:6, 10)
1:6

julia> last(Float64[], 1)
Float64[]
```

source

```
| last(s::AbstractString, n::Integer)
```

Get a string consisting of the last n characters of s.

Examples

```
| julia> last("∀ε≠0: ε²>0", 0)
| ""
|
| julia> last("∀ε≠0: ε²>0", 1)
| "0"
|
| julia> last("∀ε≠0: ε²>0", 3)
| "²>0"
```

source

Base.front – Function.

```
| front(x::Tuple)::Tuple
```

Return a Tuple consisting of all but the last component of x.

See also: [first](#), [tail](#).

Examples

```
| julia> Base.front((1,2,3))
| (1, 2)
|
| julia> Base.front(())
| ERROR: ArgumentError: Cannot call front on an empty tuple.
```

source

Base.tail – Function.

```
| tail(x::Tuple)::Tuple
```

Return a Tuple consisting of all but the first component of x.

See also: [front](#), [rest](#), [first](#), [Iterators.peel](#).

Examples

```
| julia> Base.tail((1,2,3))
| (2, 3)
|
| julia> Base.tail(())
| ERROR: ArgumentError: Cannot call tail on an empty tuple.
```

source

Base.step – Function.

```
| step(r)
```

Get the step size of an [AbstractRange](#) object.

Examples

```
julia> step(1:10)
1

julia> step(1:2:10)
2

julia> step(2.5:0.3:10.9)
0.3

julia> step(range(2.5, stop=10.9, length=85))
0.1
```

[source](#)

Base.collect – Method.

```
| collect(collection)
```

Return an Array of all items in a collection or iterator. For dictionaries, returns `Vector{Pair{KeyType, ValType}}`. If the argument is array-like or is an iterator with the [HasShape](#) trait, the result will have the same shape and number of dimensions as the argument.

Used by comprehensions to turn a generator into an Array.

Examples

```
julia> collect(1:2:13)
7-element Vector{Int64}:
 1
 3
 5
 7
 9
11
13

julia> [x^2 for x in 1:8 if isodd(x)]
4-element Vector{Int64}:
 1
 9
25
49
```

[source](#)

Base.collect – Method.

```
| collect(element_type, collection)
```

Return an Array with the given element type of all items in a collection or iterable. The result has the same shape and number of dimensions as collection.

Examples

```
| julia> collect{Float64, 1:2:5}
3-element Vector{Float64}:
 1.0
 3.0
 5.0
```

[source](#)

Base.filter – Function.

```
| filter(f, a)
```

Return a copy of collection a, removing elements for which f is false. The function f is passed one argument.

Julia 1.4

Support for a as a tuple requires at least Julia 1.4.

See also: [filter!](#), [Iterators.filter](#).

Examples

```
| julia> a = 1:10
1:10

julia> filter(isodd, a)
5-element Vector{Int64}:
 1
 3
 5
 7
 9
```

[source](#)

```
| filter(f)
```

Create a function that filters its arguments with function f using [filter](#), i.e. a function equivalent to `x -> filter(f, x)`.

The returned function is of type `Base.Fix1{typeof(filter)}`, which can be used to implement specialized methods.

Examples

```
julia> (1, 2, Inf, 4, NaN, 6) |> filter(isfinite)
(1, 2, 4, 6)

julia> map(filter(iseven), [1:3, 2:4, 3:5])
3-element Vector{Vector{Int64}}:
 [2]
 [2, 4]
 [4]
```

Julia 1.9

This method requires at least Julia 1.9.

source

```
filter(f, d::AbstractDict)
```

Return a copy of `d`, removing elements for which `f` is false. The function `f` is passed `key=>value` pairs.

Examples

```
julia> d = Dict{1=>"a", 2=>"b"}
Dict{Int64, String} with 2 entries:
 2 => "b"
 1 => "a"

julia> filter(p->isodd(p.first), d)
Dict{Int64, String} with 1 entry:
 1 => "a"
```

source

```
filter(f, itr::SkipMissing{<:AbstractArray})
```

Return a vector similar to the array wrapped by the given `SkipMissing` iterator but with all missing elements and those for which `f` returns false removed.

Julia 1.2

This method requires Julia 1.2 or later.

Examples

```
julia> x = [1 2; missing 4]
2×2 Matrix{Union{Missing, Int64}}:
 1      2
 missing 4

julia> filter(isodd, skipmissing(x))
1-element Vector{Int64}:
 1
```

source

`Base.filter!` – Function.

```
| filter!(f, a)
```

Update collection `a`, removing elements for which `f` is false. The function `f` is passed one argument.

Examples

```
| julia> filter!(isodd, Vector{Int64}(1:10))
5-element Vector{Int64}:
 1
 3
 5
 7
 9
```

[source](#)

```
| filter!(f, d::AbstractDict)
```

Update `d`, removing elements for which `f` is false. The function `f` is passed key=>value pairs.

Example

```
| julia> d = Dict{Int64, String}(1=>"a", 2=>"b", 3=>"c")
Dict{Int64, String} with 3 entries:
 2 => "b"
 3 => "c"
 1 => "a"

| julia> filter!(p->isodd(p.first), d)
Dict{Int64, String} with 2 entries:
 3 => "c"
 1 => "a"
```

[source](#)

`Base.replace` – Method.

```
| replace(A, old_new::Pair...; [count::Integer])
```

Return a copy of collection `A` where, for each pair `old=>new` in `old_new`, all occurrences of `old` are replaced by `new`. Equality is determined using [isequal](#). If `count` is specified, then replace at most `count` occurrences in total.

The element type of the result is chosen using promotion (see [promote_type](#)) based on the element type of `A` and on the types of the new values in pairs. If `count` is omitted and the element type of `A` is a `Union`, the element type of the result will not include singleton types which are replaced with values of a different type: for example, `Union{T,Missing}` will become `T` if `missing` is replaced.

See also [replace!](#), [splice!](#), [delete!](#), [insert!](#).

Julia 1.7

Version 1.7 is required to replace elements of a `Tuple`.

Examples

```
julia> replace([1, 2, 1, 3], 1=>0, 2=>4, count=2)
4-element Vector{Int64}:
 0
 4
 1
 3

julia> replace([1, missing], missing=>0)
2-element Vector{Int64}:
 1
 0
```

[source](#)

Base.replace – Method.

```
replace(new::Union{Function, Type}, A; [count::Integer])
```

Return a copy of A where each value x in A is replaced by new(x). If count is specified, then replace at most count values in total (replacements being defined as new(x) != x).

Julia 1.7

Version 1.7 is required to replace elements of a Tuple.

Examples

```
julia> replace(x -> isodd(x) ? 2x : x, [1, 2, 3, 4])
4-element Vector{Int64}:
 2
 2
 6
 4

julia> replace(Dict{Int64, Int64}(1=>2, 3=>4)) do kv
    first(kv) < 3 ? first(kv)==>3 : kv
end
Dict{Int64, Int64} with 2 entries:
 3 => 4
 1 => 3
```

[source](#)

Base.replace! – Function.

```
replace!(A, old_new::Pair...; [count::Integer])
```

For each pair old=>new in old_new, replace all occurrences of old in collection A by new. Equality is determined using [isequal](#). If count is specified, then replace at most count occurrences in total. See also [replace](#).

Examples

```
julia> replace!([1, 2, 1, 3], 1=>0, 2=>4, count=2)
4-element Vector{Int64}:
 0
 4
 1
 3

julia> replace!(Set{Int64}([1, 2, 3]), 1=>0)
Set{Int64} with 3 elements:
 0
 2
 3
```

[source](#)

```
replace!(new::Union{Function, Type}, A; [count::Integer])
```

Replace each element x in collection A by $\text{new}(x)$. If count is specified, then replace at most count values in total (replacements being defined as $\text{new}(x) \neq x$).

Examples

```
julia> replace!(x -> isodd(x) ? 2x : x, [1, 2, 3, 4])
4-element Vector{Int64}:
 2
 2
 6
 4

julia> replace!(Dict{Int64, Int64}(), 1=>2, 3=>4) do kv
    first(kv) < 3 ? first(kv)>3 : kv
end
Dict{Int64, Int64} with 2 entries:
 3 => 4
 1 => 3

julia> replace!(x->2x, Set{Int64}([3, 6]))
Set{Int64} with 2 elements:
 6
12
```

[source](#)

Base.rest – Function.

```
Base.rest(collection[, itr_state])
```

Generic function for taking the tail of `collection`, starting from a specific iteration state `itr_state`. Return a `Tuple`, if `collection` itself is a `Tuple`, a subtype of `AbstractVector`, if `collection` is an `AbstractArray`, a subtype of `AbstractString` if `collection` is an `AbstractString`, and an arbitrary iterator, falling back to `Iterators.rest(collection[, itr_state])`, otherwise.

Can be overloaded for user-defined collection types to customize the behavior of [slurping in assignments](#) in final position, like `a, b... = collection`.

Julia 1.6

`Base.rest` requires at least Julia 1.6.

See also: [first](#), [Iterators.rest](#), [Base.split_rest](#).

Examples

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> first, state = iterate(a)
(1, 2)

julia> first, Base.rest(a, state)
(1, [3, 2, 4])
```

[source](#)

`Base.split_rest` - Function.

```
| Base.split_rest(collection, n::Int[, itr_state]) -> (rest_but_n, last_n)
```

Generic function for splitting the tail of `collection`, starting from a specific iteration state `itr_state`. Returns a tuple of two new collections. The first one contains all elements of the tail but the `n` last ones, which make up the second collection.

The type of the first collection generally follows that of [Base.rest](#), except that the fallback case is not lazy, but is collected eagerly into a vector.

Can be overloaded for user-defined collection types to customize the behavior of [slurping in assignments](#) in non-final position, like `a, b..., c = collection`.

Julia 1.9

`Base.split_rest` requires at least Julia 1.9.

See also: [Base.rest](#).

Examples

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> first, state = iterate(a)
(1, 2)

julia> first, Base.split_rest(a, 1, state)
(1, ([3, 2], [4]))
```

[source](#)

42.5 Indexable Collections

`Base.getindex` – Function.

```
| getindex(collection, key...)
```

Retrieve the value(s) stored at the given key or index within a collection. The syntax `a[i,j,...]` is converted by the compiler to `getindex(a, i, j, ...)`.

See also [get](#), [keys](#), [eachindex](#).

Examples

```
julia> A = Dict{"a" => 1, "b" => 2}
Dict{String, Int64} with 2 entries:
  "b" => 2
  "a" => 1

julia> getindex(A, "a")
1
```

[source](#)

`Base.setindex!` – Function.

```
| setindex!(collection, value, key...)
```

Store the given value at the given key or index within a collection. The syntax `a[i,j,...] = x` is converted by the compiler to `(setindex!(a, x, i, j, ...); x)`.

Examples

```
julia> a = Dict{"a"=>1}
Dict{String, Int64} with 1 entry:
  "a" => 1

julia> setindex!(a, 2, "b")
Dict{String, Int64} with 2 entries:
  "b" => 2
  "a" => 1
```

[source](#)

`Base.firstindex` – Function.

```
| firstindex(collection) -> Integer
| firstindex(collection, d) -> Integer
```

Return the first index of collection. If `d` is given, return the first index of collection along dimension `d`.

The syntaxes `A[begin]` and `A[1, begin]` lower to `A[firstindex(A)]` and `A[1, firstindex(A, 2)]`, respectively.

See also: [first](#), [axes](#), [lastindex](#), [nextind](#).

Examples

```
julia> firstindex([1,2,4])
1

julia> firstindex(rand(3,4,5), 2)
1
```

[source](#)

`Base.lastindex` – Function.

```
lastindex(collection) -> Integer
lastindex(collection, d) -> Integer
```

Return the last index of collection. If `d` is given, return the last index of collection along dimension `d`.

The syntaxes `A[end]` and `A[end, end]` lower to `A[lastindex(A)]` and `A[lastindex(A, 1), lastindex(A, 2)]`, respectively.

See also: [axes](#), [firstindex](#), [eachindex](#), [prevind](#).

Examples

```
julia> lastindex([1,2,4])
3

julia> lastindex(rand(3,4,5), 2)
4
```

[source](#)

Fully implemented by:

- [Array](#)
- [BitArray](#)
- [AbstractArray](#)
- [SubArray](#)

Partially implemented by:

- [AbstractRange](#)
- [UnitRange](#)
- [Tuple](#)
- [AbstractString](#)
- [Dict](#)
- [IdDict](#)
- [WeakKeyDict](#)
- [NamedTuple](#)

42.6 Dictionaries

`Dict` is the standard dictionary. Its implementation uses `hash` as the hashing function for the key, and `isequal` to determine equality. Define these two functions for custom types to override how they are stored in a hash table.

`IdDict` is a special hash table where the keys are always object identities.

`WeakKeyDict` is a hash table implementation where the keys are weak references to objects, and thus may be garbage collected even when referenced in a hash table. Like `Dict` it uses `hash` for hashing and `isequal` for equality, unlike `Dict` it does not convert keys on insertion.

`Dicts` can be created by passing pair objects constructed with `=>` to a `Dict` constructor: `Dict("A"=>1, "B"=>2)`. This call will attempt to infer type information from the keys and values (i.e. this example creates a `Dict{String, Int64}`). To explicitly specify types use the syntax `Dict{KeyType,ValueType}(...)`. For example, `Dict{String,Int32}("A"=>1, "B"=>2)`.

Dictionaries may also be created with generators. For example, `Dict(i => f(i) for i = 1:10)`.

Given a dictionary `D`, the syntax `D[x]` returns the value of key `x` (if it exists) or throws an error, and `D[x] = y` stores the key-value pair `x => y` in `D` (replacing any existing value for the key `x`). Multiple arguments to `D[...]` are converted to tuples; for example, the syntax `D[x,y]` is equivalent to `D[(x,y)]`, i.e. it refers to the value keyed by the tuple `(x,y)`.

`Base.AbstractDict` - Type.

```
| AbstractDict{K, V}
```

Supertype for dictionary-like types with keys of type `K` and values of type `V`. `Dict`, `IdDict` and other types are subtypes of this. An `AbstractDict{K, V}` should be an iterator of `Pair{K, V}`.

source

`Base.Dict` - Type.

```
| Dict{itr}
```

`Dict{K,V}()` constructs a hash table with keys of type `K` and values of type `V`. Keys are compared with `isequal` and hashed with `hash`.

Given a single iterable argument, constructs a `Dict` whose key-value pairs are taken from 2-tuples `(key,value)` generated by the argument.

Examples

```
| julia> Dict{String, Int64}([("A", 1), ("B", 2)])
Dict{String, Int64} with 2 entries:
  "B" => 2
  "A" => 1
```

Alternatively, a sequence of pair arguments may be passed.

```
| julia> Dict{String, Int64}("A"=>1, "B"=>2)
Dict{String, Int64} with 2 entries:
  "B" => 2
  "A" => 1
```

[source](#)

Base.IdDict - Type.

```
| IdDict([itr])
```

IdDict{K,V}() constructs a hash table using [objectid](#) as hash and == as equality with keys of type K and values of type V.

See [Dict](#) for further help. In the example below, The Dict keys are all isequal and therefore get hashed the same, so they get overwritten. The IdDict hashes by object-id, and thus preserves the 3 different keys.

Examples

```
julia> Dict{true => "yes", 1 => "no", 1.0 => "maybe"}
Dict{Real, String} with 1 entry:
  1.0 => "maybe"

julia> IdDict{true => "yes", 1 => "no", 1.0 => "maybe"}
IdDict{Any, String} with 3 entries:
  true => "yes"
  1.0  => "maybe"
  1    => "no"
```

[source](#)

Base.WeakKeyDict - Type.

```
| WeakKeyDict([itr])
```

WeakKeyDict() constructs a hash table where the keys are weak references to objects which may be garbage collected even when referenced in a hash table.

See [Dict](#) for further help. Note, unlike [Dict](#), WeakKeyDict does not convert keys on insertion, as this would imply the key object was unreferenced anywhere before insertion.

See also [WeakRef](#).

[source](#)

Base.ImmutableDict - Type.

```
| ImmutableDict
```

ImmutableDict is a dictionary implemented as an immutable linked list, which is optimal for small dictionaries that are constructed over many individual insertions. Note that it is not possible to remove a value, although it can be partially overridden and hidden by inserting a new value with the same key.

```
| ImmutableDict(KV::Pair)
```

Create a new entry in the ImmutableDict for a key => value pair

- use (key => value) in dict to see if this particular combination is in the properties set
- use get(dict, key, default) to retrieve the most recent value for a particular key

[source](#)

Base.haskey – Function.

```
| haskey(collection, key) -> Bool
```

Determine whether a collection has a mapping for a given key.

Examples

```
julia> D = Dict{'a'=>2, 'b'=>3}
Dict{Char, Int64} with 2 entries:
  'a' => 2
  'b' => 3

julia> haskey(D, 'a')
true

julia> haskey(D, 'c')
false
```

[source](#)

Base.get – Function.

```
| get(collection, key, default)
```

Return the value stored for the given key, or the given default value if no mapping for the key is present.

Julia 1.7

For tuples and numbers, this function requires at least Julia 1.7.

Examples

```
julia> d = Dict{"a"=>1, "b"=>2};

julia> get(d, "a", 3)
1

julia> get(d, "c", 3)
3
```

[source](#)

```
| get(f::Union{Function, Type}, collection, key)
```

Return the value stored for the given key, or if no mapping for the key is present, return `f()`. Use [get!](#) to also store the default value in the dictionary.

This is intended to be called using do block syntax

```
| get(dict, key) do
    # default value calculated here
    time()
end
```

[source](#)

Base.get! – Function.

```
| get!(collection, key, default)
```

Return the value stored for the given key, or if no mapping for the key is present, store key => default, and return default.

Examples

```
julia> d = Dict{"a"=>1, "b"=>2, "c"=>3};

julia> get!(d, "a", 5)
1

julia> get!(d, "d", 4)
4

julia> d
Dict{String, Int64} with 4 entries:
  "c" => 3
  "b" => 2
  "a" => 1
  "d" => 4
```

[source](#)

```
| get!(f::Union{Function, Type}, collection, key)
```

Return the value stored for the given key, or if no mapping for the key is present, store key => f(), and return f().

This is intended to be called using do block syntax.

Examples

```
julia> squares = Dict{Int, Int}();

julia> function get_square!(d, i)
    get!(d, i) do
        i^2
    end
end

get_square! (generic function with 1 method)

julia> get_square!(squares, 2)
4

julia> squares
Dict{Int64, Int64} with 1 entry:
  2 => 4
```

[source](#)

Base.getkey – Function.

```
| getkey(collection, key, default)
```

Return the key matching argument key if one exists in collection, otherwise return default.

Examples

```
julia> D = Dict{'a'=>2, 'b'=>3}
Dict{Char, Int64} with 2 entries:
  'a' => 2
  'b' => 3

julia> getkey(D, 'a', 1)
'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)

julia> getkey(D, 'd', 'a')
'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)
```

[source](#)

Base.delete! – Function.

```
| delete!(collection, key)
```

Delete the mapping for the given key in a collection, if any, and return the collection.

Examples

```
julia> d = Dict{"a"=>1, "b"=>2}
Dict{String, Int64} with 2 entries:
  "b" => 2
  "a" => 1

julia> delete!(d, "b")
Dict{String, Int64} with 1 entry:
  "a" => 1

julia> delete!(d, "b") # d is left unchanged
Dict{String, Int64} with 1 entry:
  "a" => 1
```

[source](#)

Base.pop! – Method.

```
| pop!(collection, key[, default])
```

Delete and return the mapping for key if it exists in collection, otherwise return default, or throw an error if default is not specified.

Examples

```
julia> d = Dict{"a"=>1, "b"=>2, "c"=>3};

julia> pop!(d, "a")
1

julia> pop!(d, "d")
ERROR: KeyError: key "d" not found
Stacktrace:
[...]

julia> pop!(d, "e", 4)
4
```

[source](#)

Base.keys – Function.

```
| keys(iterator)
```

For an iterator or collection that has keys and values (e.g. arrays and dictionaries), return an iterator over the keys.

[source](#)

Base.values – Function.

```
| values(iterator)
```

For an iterator or collection that has keys and values, return an iterator over the values. This function simply returns its argument by default, since the elements of a general iterator are normally considered its "values".

Examples

```
julia> d = Dict{"a"=>1, "b"=>2};

julia> values(d)
ValueIterator for a Dict{String, Int64} with 2 entries. Values:
 2
 1

julia> values([2])
1-element Vector{Int64}:
 2
```

[source](#)

```
| values(a::AbstractDict)
```

Return an iterator over all values in a collection. `collect(values(a))` returns an array of values. When the values are stored internally in a hash table, as is the case for `Dict`, the order in which they are returned may vary. But `keys(a)` and `values(a)` both iterate `a` and return the elements in the same order.

Examples

```
julia> D = Dict{'a'=>2, 'b'=>3}
Dict{Char, Int64} with 2 entries:
  'a' => 2
  'b' => 3

julia> collect(values(D))
2-element Vector{Int64}:
 2
 3
```

[source](#)

Base.pairs – Function.

```
pairs(IndexLinear(), A)
pairs(IndexCartesian(), A)
pairs(IndexStyle(A), A)
```

An iterator that accesses each element of the array *A*, returning *i* => *x*, where *i* is the index for the element and *x* = *A*[*i*]. Identical to *pairs*(*A*), except that the style of index can be selected. Also similar to *enumerate*(*A*), except *i* will be a valid index for *A*, while *enumerate* always counts from 1 regardless of the indices of *A*.

Specifying *IndexLinear*() ensures that *i* will be an integer; specifying *IndexCartesian*() ensures that *i* will be a *Base.CartesianIndex*; specifying *IndexStyle*(*A*) chooses whichever has been defined as the native indexing style for array *A*.

Mutation of the bounds of the underlying array will invalidate this iterator.

Examples

```
julia> A = ["a" "d"; "b" "e"; "c" "f"];

julia> for (index, value) in pairs(IndexStyle(A), A)
    println("$index $value")
end
1 a
2 b
3 c
4 d
5 e
6 f

julia> S = view(A, 1:2, :);

julia> for (index, value) in pairs(IndexStyle(S), S)
    println("$index $value")
end
CartesianIndex{1, 1} a
CartesianIndex{2, 1} b
CartesianIndex{1, 2} d
CartesianIndex{2, 2} e
```

See also *IndexStyle*, *axes*.

[source](#)

```
| pairs(collection)
```

Return an iterator over key => value pairs for any collection that maps a set of keys to a set of values. This includes arrays, where the keys are the array indices.

Examples

```
julia> a = Dict{String, Int64}(zip(["a", "b", "c"], [1, 2, 3]))
Dict{String, Int64} with 3 entries:
  "c" => 3
  "b" => 2
  "a" => 1

julia> pairs(a)
Dict{String, Int64} with 3 entries:
  "c" => 3
  "b" => 2
  "a" => 1

julia> foreach(println, pairs(["a", "b", "c"]))
1 => "a"
2 => "b"
3 => "c"

julia> (;a=1, b=2, c=3) |> pairs |> collect
3-element Vector{Pair{Symbol, Int64}}:
 :a => 1
 :b => 2
 :c => 3

julia> (;a=1, b=2, c=3) |> collect
3-element Vector{Int64}:
 1
 2
 3
```

[source](#)

Base.merge - Function.

```
| merge(d::AbstractDict, others::AbstractDict...)
```

Construct a merged collection from the given collections. If necessary, the types of the resulting collection will be promoted to accommodate the types of the merged collections. If the same key is present in another collection, the value for that key will be the value it has in the last collection listed. See also [mergewith](#) for custom handling of values with the same key.

Examples

```
julia> a = Dict{String, Float64}("foo" => 0.0, "bar" => 42.0)
Dict{String, Float64} with 2 entries:
  "bar" => 42.0
  "foo" => 0.0
```

```
julia> b = Dict{"baz" => 17, "bar" => 4711}
Dict{String, Int64} with 2 entries:
  "bar" => 4711
  "baz" => 17

julia> merge(a, b)
Dict{String, Float64} with 3 entries:
  "bar" => 4711.0
  "baz" => 17.0
  "foo" => 0.0

julia> merge(b, a)
Dict{String, Float64} with 3 entries:
  "bar" => 42.0
  "baz" => 17.0
  "foo" => 0.0
```

source

```
merge(a::NamedTuple, bs::NamedTuple...)
```

Construct a new named tuple by merging two or more existing ones, in a left-associative manner. Merging proceeds left-to-right, between pairs of named tuples, and so the order of fields present in both the leftmost and rightmost named tuples take the same position as they are found in the leftmost named tuple. However, values are taken from matching fields in the rightmost named tuple that contains that field. Fields present in only the rightmost named tuple of a pair are appended at the end. A fallback is implemented for when only a single named tuple is supplied, with signature `merge(a::NamedTuple)`.

Julia 1.1

Merging 3 or more `NamedTuple` requires at least Julia 1.1.

Examples

```
julia> merge((a=1, b=2, c=3), (b=4, d=5))
(a = 1, b = 4, c = 3, d = 5)

julia> merge((a=1, b=2), (b=3, c=(d=1,)), (c=(d=2,)))
(a = 1, b = 3, c = (d = 2,))
```

source

```
merge(a::NamedTuple, iterable)
```

Interpret an iterable of key-value pairs as a named tuple, and perform a merge.

```
julia> merge((a=1, b=2, c=3), [:b=>4, :d=>5])
(a = 1, b = 4, c = 3, d = 5)
```

source

`Base.mergewith` – Function.

```
mergewith(combine, d::AbstractDict, others::AbstractDict...)
mergewith(combine)
merge(combine, d::AbstractDict, others::AbstractDict...)
```

Construct a merged collection from the given collections. If necessary, the types of the resulting collection will be promoted to accommodate the types of the merged collections. Values with the same key will be combined using the combiner function. The curried form `mergewith(combine)` returns the function `(args...) -> mergewith(combine, args...)`.

Method `merge(combine::Union{Function,Type}, args...)` as an alias of `mergewith(combine, args...)` is still available for backward compatibility.

Julia 1.5

`mergewith` requires Julia 1.5 or later.

Examples

```
julia> a = Dict{"foo" => 0.0, "bar" => 42.0}
Dict{String, Float64} with 2 entries:
  "bar" => 42.0
  "foo" => 0.0

julia> b = Dict{"baz" => 17, "bar" => 4711}
Dict{String, Int64} with 2 entries:
  "bar" => 4711
  "baz" => 17

julia> mergewith(+, a, b)
Dict{String, Float64} with 3 entries:
  "bar" => 4753.0
  "baz" => 17.0
  "foo" => 0.0

julia> ans == mergewith(+)(a, b)
true
```

[source](#)

`Base.merge!` – Function.

```
merge!(d::AbstractDict, others::AbstractDict...)
```

Update collection with pairs from the other collections. See also [merge](#).

Examples

```
julia> d1 = Dict{1 => 2, 3 => 4};

julia> d2 = Dict{1 => 4, 4 => 5};

julia> merge!(d1, d2);

julia> d1
```

```
Dict{Int64, Int64} with 3 entries:
 4 => 5
 3 => 4
 1 => 4
```

[source](#)

Base.mergewith! – Function.

```
mergewith!(combine, d::AbstractDict, others::AbstractDict...) -> d
mergewith!(combine)
merge!(combine, d::AbstractDict, others::AbstractDict...) -> d
```

Update collection with pairs from the other collections. Values with the same key will be combined using the combiner function. The curried form `mergewith!(combine)` returns the function `(args...) -> mergewith!(combine, args...)`.

Method `merge!(combine::Union{Function,Type}, args...)` as an alias of `mergewith!(combine, args...)` is still available for backward compatibility.

Julia 1.5

`mergewith!` requires Julia 1.5 or later.

Examples

```
julia> d1 = Dict{1 => 2, 3 => 4};

julia> d2 = Dict{1 => 4, 4 => 5};

julia> mergewith!(+, d1, d2);

julia> d1
Dict{Int64, Int64} with 3 entries:
 4 => 5
 3 => 4
 1 => 6

julia> mergewith!(-, d1, d1);

julia> d1
Dict{Int64, Int64} with 3 entries:
 4 => 0
 3 => 0
 1 => 0

julia> foldl(mergewith!(+), [d1, d2]; init=Dict{Int64, Int64}())
Dict{Int64, Int64} with 3 entries:
 4 => 5
 3 => 0
 1 => 4
```

[source](#)

`Base.sizehint!` – Function.

```
| sizehint!(s, n) -> s
```

Suggest that collection `s` reserve capacity for at least `n` elements. That is, if you expect that you're going to have to push a lot of values onto `s`, you can avoid the cost of incremental reallocation by doing it once up front; this can improve performance.

See also [resize!](#).

Notes on the performance model

For types that support `sizehint!`,

1. `push!` and `append!` methods generally may (but are not required to) preallocate extra storage. For types implemented in `Base`, they typically do, using a heuristic optimized for a general use case.
2. `sizehint!` may control this preallocation. Again, it typically does this for types in `Base`.
3. `empty!` is nearly costless (and $O(1)$) for types that support this kind of preallocation.

[source](#)

`Base.keytype` – Function.

```
| keytype(T::Type{<:AbstractArray})
| keytype(A::AbstractArray)
```

Return the key type of an array. This is equal to the `eltype` of the result of `keys(...)`, and is provided mainly for compatibility with the dictionary interface.

Examples

```
| julia> keytype([1, 2, 3]) == Int
true
| julia> keytype([1 2; 3 4])
CartesianIndex{2}
```

Julia 1.2

For arrays, this function requires at least Julia 1.2.

[source](#)

```
| keytype(type)
```

Get the key type of a dictionary type. Behaves similarly to `eltype`.

Examples

```
| julia> keytype(Dict{Int32}(1 => "foo"))
Int32
```

[source](#)

Base.valtype – Function.

```
valtype(T::Type{<:AbstractArray})
valtype(A::AbstractArray)
```

Return the value type of an array. This is identical to [eltype](#) and is provided mainly for compatibility with the dictionary interface.

Examples

```
julia> valtype(["one", "two", "three"])
String
```

Julia 1.2

For arrays, this function requires at least Julia 1.2.

[source](#)

```
valtype(type)
```

Get the value type of a dictionary type. Behaves similarly to [eltype](#).

Examples

```
julia> valtype(Dict{Int32, String}())
String
```

[source](#)

Fully implemented by:

- [IdDict](#)
- [Dict](#)
- [WeakKeyDict](#)

Partially implemented by:

- [BitSet](#)
- [Set](#)
- [EnvDict](#)
- [Array](#)
- [BitArray](#)
- [ImmutableDict](#)
- [Iterators.Pairs](#)

42.7 Set-Like Collections

Base.AbstractSet – Type.

```
| AbstractSet{T}
```

Supertype for set-like types whose elements are of type T. [Set](#), [BitSet](#) and other types are subtypes of this.

[source](#)

Base.Set – Type.

```
| Set{T} <: AbstractSet{T}
```

Sets are mutable containers that provide fast membership testing.

Sets have efficient implementations of set operations such as `in`, `union` and `intersect`. Elements in a `Set` are unique, as determined by the elements' definition of `isequal`. The order of elements in a `Set` is an implementation detail and cannot be relied on.

See also: [AbstractSet](#), [BitSet](#), [Dict](#), [push!](#), [empty!](#), [union!](#), [in](#), [isequal](#)

Examples

```
julia> s = Set("aaBca")
Set{Char} with 3 elements:
 'a'
 'c'
 'B'

julia> push!(s, 'b')
Set{Char} with 4 elements:
 'a'
 'b'
 'B'
 'c'

julia> s = Set([NaN, 0.0, 1.0, 2.0]);

julia> -0.0 in s # isequal(0.0, -0.0) is false
false

julia> NaN in s # isequal(NaN, NaN) is true
true
```

[source](#)

Base.BitSet – Type.

```
| BitSet{Itr}
```

Construct a sorted set of Ints generated by the given iterable object, or an empty set. Implemented as a bit string, and therefore designed for dense integer sets. If the set will be sparse (for example, holding a few very large integers), use [Set](#) instead.

[source](#)

Base.union – Function.

```
union(s, itr...)
u(s, itr...)
```

Construct an object containing all distinct elements from all of the arguments.

The first argument controls what kind of container is returned. If this is an array, it maintains the order in which elements first appear.

Unicode `u` can be typed by writing `\cup` then pressing tab in the Julia REPL, and in many editors. This is an infix operator, allowing `s u itr`.

See also [unique](#), [intersect](#), [isdisjoint](#), [vcat](#), [Iterators.flatten](#).

Examples

```
julia> union([1, 2], [3])
3-element Vector{Int64}:
 1
 2
 3

julia> union([4 2 3 4 4], 1:3, 3.0)
4-element Vector{Float64}:
 4.0
 2.0
 3.0
 1.0

julia> (0, 0.0) u (-0.0, NaN)
3-element Vector{Real}:
 0
 -0.0
 NaN

julia> union(Set{Int64}([1, 2]), 2:3)
Set{Int64} with 3 elements:
 2
 3
 1
```

[source](#)

Base.union! – Function.

```
union!(s::Union{AbstractSet, AbstractVector}, itr...)
```

Construct the [union](#) of passed in sets and overwrite `s` with the result. Maintain order with arrays.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
julia> a = Set{Int64}([3, 4, 5]);

julia> union!(a, 1:2:7);

julia> a
Set{Int64} with 5 elements:
 5
 4
 7
 3
 1
```

[source](#)

`Base.intersect` – Function.

```
intersect(s, itr...)
n(s, itr...)
```

Construct the set containing those elements which appear in all of the arguments.

The first argument controls what kind of container is returned. If this is an array, it maintains the order in which elements first appear.

Unicode `n` can be typed by writing `\cap` then pressing tab in the Julia REPL, and in many editors. This is an infix operator, allowing `s n itr`.

See also [setdiff](#), [isdisjoint](#), [issubset](#), [issetequal](#).

Julia 1.8

As of Julia 1.8 `intersect` returns a result with the eltype of the type-promoted eltypes of the two inputs

Examples

```
julia> intersect([1, 2, 3], [3, 4, 5])
1-element Vector{Int64}:
 3

julia> intersect([1, 4, 4, 5, 6], [6, 4, 6, 7, 8])
2-element Vector{Int64}:
 4
 6

julia> intersect(1:16, 7:99)
7:16

julia> (0, 0.0) n (-0.0, 0)
1-element Vector{Real}:
 0

julia> intersect(Set{Float64}([1, 2]), BitSet{Int64}([2, 3]), 1.0:10.0)
Set{Float64} with 1 element:
 2.0
```

[source](#)

Base.setdiff – Function.

```
| setdiff(s, itrs...)
```

Construct the set of elements in *s* but not in any of the iterables in *itrs*. Maintain order with arrays.

See also [setdiff!](#), [union](#) and [intersect](#).

Examples

```
| julia> setdiff([1,2,3], [3,4,5])  
2-element Vector{Int64}:  
 1  
 2
```

[source](#)

Base.setdiff! – Function.

```
| setdiff!(s, itrs...)
```

Remove from set *s* (in-place) each element of each iterable from *itrs*. Maintain order with arrays.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
| julia> a = Set{Int64}([1, 3, 4, 5]);  
  
| julia> setdiff!(a, 1:2:6);  
  
| julia> a  
Set{Int64} with 1 element:  
 4
```

[source](#)

Base.symdiff – Function.

```
| symdiff(s, itrs...)
```

Construct the symmetric difference of elements in the passed in sets. When *s* is not an `AbstractSet`, the order is maintained.

See also [symdiff!](#), [setdiff](#), [union](#) and [intersect](#).

Examples

```
julia> symdiff([1,2,3], [3,4,5], [4,5,6])
3-element Vector{Int64}:
 1
 2
 6

julia> symdiff([1,2,1], [2, 1, 2])
Int64[]
```

[source](#)

Base.symdiff! – Function.

```
| symdiff!(s::Union{AbstractSet, AbstractVector}, itrs...)
```

Construct the symmetric difference of the passed in sets, and overwrite `s` with the result. When `s` is an array, the order is maintained. Note that in this case the multiplicity of elements matters.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

Base.intersect! – Function.

```
| intersect!(s::Union{AbstractSet, AbstractVector}, itrs...)
```

Intersect all passed in sets and overwrite `s` with the result. Maintain order with arrays.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

Base.issubset – Function.

```
| issubset(a, b) -> Bool
| ⊆(a, b) -> Bool
| ⊇(b, a) -> Bool
```

Determine whether every element of `a` is also in `b`, using `in`.

See also `⊄`, `⊈`, `n`, `u`, `contains`.

Examples

```
julia> issubset([1, 2], [1, 2, 3])
true

julia> [1, 2, 3] ⊆ [1, 2]
false

julia> [1, 2, 3] ⊇ [1, 2]
true
```

[source](#)

Base. $\not\subseteq$ - Function.

```
 $\not\subseteq$ (a, b) -> Bool
 $\not\supseteq$ (b, a) -> Bool
```

Negation of \subseteq and \supseteq , i.e. checks that a is not a subset of b.

See also [issubset](#) (\subseteq), [\$\not\subseteq\$](#) .

Examples

```
julia> (1, 2)  $\not\subseteq$  (2, 3)
true

julia> (1, 2)  $\not\subseteq$  (1, 2, 3)
false
```

[source](#)

Base. \subsetneq - Function.

```
 $\subsetneq$ (a, b) -> Bool
 $\supsetneq$ (b, a) -> Bool
```

Determines if a is a subset of, but not equal to, b.

See also [issubset](#) (\subseteq), [\$\not\subseteq\$](#) .

Examples

```
julia> (1, 2)  $\subsetneq$  (1, 2, 3)
true

julia> (1, 2)  $\subsetneq$  (1, 2)
false
```

[source](#)

Base.issetequal - Function.

```
issetequal(a, b) -> Bool
```

Determine whether a and b have the same elements. Equivalent to $a \subseteq b \ \&\& \ b \subseteq a$ but more efficient when possible.

See also: [isdisjoint](#), [union](#).

Examples

```
julia> issetequal([1, 2], [1, 2, 3])
false

julia> issetequal([1, 2], [2, 1])
true
```

[source](#)

`Base.isdisjoint` – Function.

```
| isdisjoint(a, b) -> Bool
```

Determine whether the collections `a` and `b` are disjoint. Equivalent to `isempty(a ∩ b)` but more efficient when possible.

See also: [intersect](#), [isempty](#), [issetequal](#).

Julia 1.5

This function requires at least Julia 1.5.

Examples

```
| julia> isdisjoint([1, 2], [2, 3, 4])
false

julia> isdisjoint([3, 1], [2, 4])
true
```

[source](#)

Fully implemented by:

- [BitSet](#)
- [Set](#)

Partially implemented by:

- [Array](#)

42.8 Dequeues

`Base.push!` – Function.

```
| push!(collection, items...) -> collection
```

Insert one or more `items` in `collection`. If `collection` is an ordered container, the items are inserted at the end (in the given order).

Examples

```
| julia> push!([1, 2, 3], 4, 5, 6)
6-element Vector{Int64}:
 1
 2
 3
 4
 5
 6
```

If collection is ordered, use `append!` to add all the elements of another collection to it. The result of the preceding example is equivalent to `append!([1, 2, 3], [4, 5, 6])`. For `AbstractSet` objects, `union!` can be used instead.

See `sizehint!` for notes about the performance model.

See also `pushfirst!`.

[source](#)

`Base.pop!` – Function.

```
| pop!(collection) -> item
```

Remove an item in collection and return it. If collection is an ordered container, the last item is returned; for unordered containers, an arbitrary element is returned.

See also: `popfirst!`, `popat!`, `delete!`, `deleteat!`, `splice!`, and `push!`.

Examples

```
julia> A=[1, 2, 3]
3-element Vector{Int64}:
 1
 2
 3

julia> pop!(A)
3

julia> A
2-element Vector{Int64}:
 1
 2

julia> S = Set{Int64}([1, 2])
Set{Int64} with 2 elements:
 2
 1

julia> pop!(S)
2

julia> S
Set{Int64} with 1 element:
 1

julia> pop!(Dict{Int64, Int64}())
1 => 2
```

[source](#)

```
| pop!(collection, key[, default])
```

Delete and return the mapping for key if it exists in collection, otherwise return default, or throw an error if default is not specified.

Examples

```
julia> d = Dict{"a"=>1, "b"=>2, "c"=>3};

julia> pop!(d, "a")
1

julia> pop!(d, "d")
ERROR: KeyError: key "d" not found
Stacktrace:
[...]

julia> pop!(d, "e", 4)
4
```

[source](#)

Base.popat! – Function.

```
popat!(a::Vector, i::Integer, [default])
```

Remove the item at the given *i* and return it. Subsequent items are shifted to fill the resulting gap. When *i* is not a valid index for *a*, return default, or throw an error if default is not specified.

See also: [pop!](#), [popfirst!](#), [deleteat!](#), [splice!](#).

Julia 1.5

This function is available as of Julia 1.5.

Examples

```
julia> a = [4, 3, 2, 1]; popat!(a, 2)
3

julia> a
3-element Vector{Int64}:
 4
 2
 1

julia> popat!(a, 4, missing)
missing

julia> popat!(a, 4)
ERROR: BoundsError: attempt to access 3-element Vector{Int64} at index [4]
[...]
```

[source](#)

Base.pushfirst! – Function.

```
| pushfirst!(collection, items...) -> collection
```

Insert one or more items at the beginning of collection.

This function is called unshift in many other programming languages.

Examples

```
| julia> pushfirst!([1, 2, 3, 4], 5, 6)
6-element Vector{Int64}:
 5
 6
 1
 2
 3
 4
```

[source](#)

Base.popfirst! – Function.

```
| popfirst!(collection) -> item
```

Remove the first item from collection.

This function is called shift in many other programming languages.

See also: [pop!](#), [popat!](#), [delete!](#).

Examples

```
| julia> A = [1, 2, 3, 4, 5, 6]
6-element Vector{Int64}:
 1
 2
 3
 4
 5
 6

julia> popfirst!(A)
1

julia> A
5-element Vector{Int64}:
 2
 3
 4
 5
 6
```

[source](#)

Base.insert! – Function.

```
| insert!(a::Vector, index::Integer, item)
```

Insert an item into `a` at the given index. `index` is the index of item in the resulting `a`.

See also: [push!](#), [replace](#), [popat!](#), [splice!](#).

Examples

```
julia> insert!(Any[1:6;], 3, "here")
7-element Vector{Any}:
 1
 2
 "here"
 3
 4
 5
 6
```

[source](#)

`Base.deleteat!` – Function.

```
deleteat!(a::Vector, i::Integer)
```

Remove the item at the given `i` and return the modified `a`. Subsequent items are shifted to fill the resulting gap.

See also: [keepat!](#), [delete!](#), [popat!](#), [splice!](#).

Examples

```
julia> deleteat!([6, 5, 4, 3, 2, 1], 2)
5-element Vector{Int64}:
 6
 4
 3
 2
 1
```

[source](#)

```
deleteat!(a::Vector, inds)
```

Remove the items at the indices given by `inds`, and return the modified `a`. Subsequent items are shifted to fill the resulting gap.

`inds` can be either an iterator or a collection of sorted and unique integer indices, or a boolean vector of the same length as `a` with `true` indicating entries to delete.

Examples

```
julia> deleteat!([6, 5, 4, 3, 2, 1], 1:2:5)
3-element Vector{Int64}:
 5
 3
 1
```

```
julia> deleteat!([6, 5, 4, 3, 2, 1], [true, false, true, false, true, false])
3-element Vector{Int64}:
 5
 3
 1

julia> deleteat!([6, 5, 4, 3, 2, 1], (2, 2))
ERROR: ArgumentError: indices must be unique and sorted
Stacktrace:
[...]

```

[source](#)

Base.keepat! – Function.

```
keepat!(a::Vector, inds)
keepat!(a::BitVector, inds)
```

Remove the items at all the indices which are not given by `inds`, and return the modified `a`. Items which are kept are shifted to fill the resulting gaps.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

`inds` must be an iterator of sorted and unique integer indices. See also [deleteat!](#).

Julia 1.7

This function is available as of Julia 1.7.

Examples

```
julia> keepat!([6, 5, 4, 3, 2, 1], 1:2:5)
3-element Vector{Int64}:
 6
 4
 2

```

[source](#)

```
keepat!(a::Vector, m::AbstractVector{Bool})
keepat!(a::BitVector, m::AbstractVector{Bool})
```

The in-place version of logical indexing `a = a[m]`. That is, `keepat!(a, m)` on vectors of equal length `a` and `m` will remove all elements from `a` for which `m` at the corresponding index is `false`.

Examples

```
julia> a = [:a, :b, :c];

julia> keepat!(a, [true, false, true])
2-element Vector{Symbol}:
 :a
 :c

```

```

:a
:c

julia> a
2-element Vector{Symbol}:
:a
:c

```

[source](#)

Base.splice! – Function.

```
splice!(a::Vector, index::Integer, [replacement]) -> item
```

Remove the item at the given index, and return the removed item. Subsequent items are shifted left to fill the resulting gap. If specified, replacement values from an ordered collection will be spliced in place of the removed item.

See also: [replace](#), [delete!](#), [deleteat!](#), [pop!](#), [popat!](#).

Examples

```

julia> A = [6, 5, 4, 3, 2, 1]; splice!(A, 5)
2

julia> A
5-element Vector{Int64}:
 6
 5
 4
 3
 1

julia> splice!(A, 5, -1)
1

julia> A
5-element Vector{Int64}:
 6
 5
 4
 3
-1

julia> splice!(A, 1, [-1, -2, -3])
6

julia> A
7-element Vector{Int64}:
-1
-2
-3
 5
 4

```

```
| 3
| -1
```

To insert replacement before an index *n* without removing any items, use `splice!(collection, n:n-1, replacement)`.

source

```
| splice!(a::Vector, indices, [replacement]) -> items
```

Remove items at specified indices, and return a collection containing the removed items. Subsequent items are shifted left to fill the resulting gaps. If specified, replacement values from an ordered collection will be spliced in place of the removed items; in this case, `indices` must be a `AbstractUnitRange`.

To insert replacement before an index *n* without removing any items, use `splice!(collection, n:n-1, replacement)`.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Julia 1.5

Prior to Julia 1.5, `indices` must always be a `UnitRange`.

Julia 1.8

Prior to Julia 1.8, `indices` must be a `UnitRange` if splicing in replacement values.

Examples

```
julia> A = [-1, -2, -3, 5, 4, 3, -1]; splice!(A, 4:3, 2)
Int64[]

julia> A
8-element Vector{Int64}:
-1
-2
-3
 2
 5
 4
 3
-1
```

source

`Base.resize!` – Function.

```
| resize!(a::Vector, n::Integer) -> Vector
```

Resize *a* to contain *n* elements. If *n* is smaller than the current collection length, the first *n* elements will be retained. If *n* is larger, the new elements are not guaranteed to be initialized.

Examples

```

julia> resize!([6, 5, 4, 3, 2, 1], 3)
3-element Vector{Int64}:
 6
 5
 4

julia> a = resize!([6, 5, 4, 3, 2, 1], 8);

julia> length(a)
8

julia> a[1:6]
6-element Vector{Int64}:
 6
 5
 4
 3
 2
 1

```

[source](#)

`Base.append!` – Function.

```
| append!(collection, collections...) -> collection.
```

For an ordered container collection, add the elements of each collections to the end of it.

Julia 1.6

Specifying multiple collections to be appended requires at least Julia 1.6.

Examples

```

julia> append!([1], [2, 3])
3-element Vector{Int64}:
 1
 2
 3

julia> append!([1, 2, 3], [4, 5], [6])
6-element Vector{Int64}:
 1
 2
 3
 4
 5
 6

```

Use `push!` to add individual items to collection which are not already themselves in another collection. The result of the preceding example is equivalent to `push!([1, 2, 3], 4, 5, 6)`.

See `sizehint!` for notes about the performance model.

See also `vcats` for vectors, `union!` for sets, and `prepend!` and `pushfirst!` for the opposite order.

[source](#)

`Base.prepend!` – Function.

```
| prepend!(a::Vector, collections...) -> collection
```

Insert the elements of each collections to the beginning of a.

When collections specifies multiple collections, order is maintained: elements of collections[1] will appear leftmost in a, and so on.

Julia 1.6

Specifying multiple collections to be prepended requires at least Julia 1.6.

Examples

```
julia> prepend!([3], [1, 2])
3-element Vector{Int64}:
 1
 2
 3

julia> prepend!([6], [1, 2], [3, 4, 5])
6-element Vector{Int64}:
 1
 2
 3
 4
 5
 6
```

[source](#)

Fully implemented by:

- `Vector` (a.k.a. 1-dimensional [Array](#))
- `BitVector` (a.k.a. 1-dimensional [BitArray](#))

42.9 Utility Collections

`Core.Pair` – Type.

```
| Pair(x, y)
x => y
```

Construct a `Pair` object with type `Pair{typeof(x), typeof(y)}`. The elements are stored in the fields `first` and `second`. They can also be accessed via iteration (but a `Pair` is treated as a single "scalar" for broadcasting operations).

See also [Dict](#).

Examples

```
julia> p = "foo" => 7
"foo" => 7

julia> typeof(p)
Pair{String, Int64}

julia> p.first
"foo"

julia> for x in p
    println(x)
end
foo
7

julia> replace(["xops", "oxps"], "x" => "o")
2-element Vector{String}:
"oops"
"oops"
```

[source](#)

Base.Pairs – Type.

```
| Iterators.Pairs(values, keys) <: AbstractDict{eltype(keys), eltype(values)}
```

Transforms an indexable container into a Dictionary-view of the same data. Modifying the key-space of the underlying data may invalidate this object.

[source](#)

Chapter 43

Mathematics

43.1 Mathematical Operators

Base.: - - Method.

```
| -(x)
```

Unary minus operator.

See also: [abs](#), [flipsign](#).

Examples

```
julia> -1
-1

julia> -(2)
-2

julia> -[1 2; 3 4]
2×2 Matrix{Int64}:
-1  -2
-3  -4
```

[source](#)

Base.:+ - Function.

```
| dt::Date + t::Time -> DateTime
```

The addition of a Date with a Time produces a DateTime. The hour, minute, second, and millisecond parts of the Time are used along with the year, month, and day of the Date to create the new DateTime. Non-zero microseconds or nanoseconds in the Time type will result in an InexactError being thrown.

```
| +(x, y...)
```

Addition operator. `x+y+z+...` calls this function with all arguments, i.e. `+(x, y, z, ...)`.

Examples

```
julia> 1 + 20 + 4
25

julia> +(1, 20, 4)
25
```

[source](#)

Base.: - Method.

```
| -(x, y)
```

Subtraction operator.

Examples

```
julia> 2 - 3
-1

julia> -(2, 4.5)
-2.5
```

[source](#)

Base.:* - Method.

```
| *(x, y...)
```

Multiplication operator. `x*y*z*...` calls this function with all arguments, i.e. `*(x, y, z, ...)`.

Examples

```
julia> 2 * 7 * 8
112

julia> *(2, 7, 8)
112
```

[source](#)

Base.:/ - Function.

```
| /(x, y)
```

Right division operator: multiplication of `x` by the inverse of `y` on the right. Gives floating-point results for integer arguments.

Examples

```
julia> 1/2
0.5

julia> 4/2
2.0

julia> 4.5/2
2.25
```

[source](#)

| A / B

Matrix right-division: A / B is equivalent to $(B' \setminus A')$ where \setminus is the left-division operator. For square matrices, the result X is such that $A == X*B$.

See also: [rdiv!](#).

Examples

```
julia> A = Float64[1 4 5; 3 9 2]; B = Float64[1 4 2; 3 4 2; 8 7 1];

julia> X = A / B
2×3 Matrix{Float64}:
-0.65  3.75 -1.2
 3.25 -2.75  1.0

julia> isapprox(A, X*B)
true

julia> isapprox(X, A*pinv(B))
true
```

Base.: \setminus – Method.

| $\setminus(x, y)$

Left division operator: multiplication of y by the inverse of x on the left. Gives floating-point results for integer arguments.

Examples

```
julia> 3 \ 6
2.0

julia> inv(3) * 6
2.0

julia> A = [4 3; 2 1]; x = [5, 6];

julia> A \ x
2-element Vector{Float64}:
 6.5
-7.0

julia> inv(A) * x
2-element Vector{Float64}:
 6.5
-7.0
```

[source](#)

Base.: $^{\wedge}$ – Method.

```
| ^{x, y}
```

Exponentiation operator. If x is a matrix, computes matrix exponentiation.

If y is an Int literal (e.g. 2 in x^2 or -3 in x^{-3}), the Julia code x^y is transformed by the compiler to `Base.literal_pow(^, x, Val(y))`, to enable compile-time specialization on the value of the exponent. (As a default fallback we have `Base.literal_pow(^, x, Val(y)) = ^{x,y}`, where usually $^ == Base.^$ unless $^$ has been defined in the calling namespace.) If y is a negative integer literal, then `Base.literal_pow` transforms the operation to $\text{inv}(x)^{-y}$ by default, where $-y$ is positive.

Examples

```
julia> 3^5
243

julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> A^3
2×2 Matrix{Int64}:
 37  54
 81 118
```

[source](#)

Base.fma – Function.

```
| fma(x, y, z)
```

Computes $x*y+z$ without rounding the intermediate result $x*y$. On some systems this is significantly more expensive than $x*y+z$. `fma` is used to improve accuracy in certain algorithms. See [muladd](#).

[source](#)

Base.muladd – Function.

```
| muladd(x, y, z)
```

Combined multiply-add: computes $x*y+z$, but allowing the add and multiply to be merged with each other or with surrounding operations for performance. For example, this may be implemented as an [fma](#) if the hardware supports it efficiently. The result can be different on different machines and can also be different on the same machine due to constant propagation or other optimizations. See [fma](#).

Examples

```
julia> muladd(3, 2, 1)
7

julia> 3 * 2 + 1
7
```

[source](#)

```
| muladd(A, y, z)
```

Combined multiply-add, $A*y \ .+ \ z$, for matrix-matrix or matrix-vector multiplication. The result is always the same size as $A*y$, but z may be smaller, or a scalar.

Julia 1.6

These methods require Julia 1.6 or later.

Examples

```
julia> A=[1.0 2.0; 3.0 4.0]; B=[1.0 1.0; 1.0 1.0]; z=[0, 100];

julia> muladd(A, B, z)
2×2 Matrix{Float64}:
 3.0   3.0
107.0 107.0
```

Base.inv - Method.

```
| inv(x)
```

Return the multiplicative inverse of x , such that $x*\text{inv}(x)$ or $\text{inv}(x)*x$ yields [one\(x\)](#) (the multiplicative identity) up to roundoff errors.

If x is a number, this is essentially the same as $\text{one}(x)/x$, but for some types $\text{inv}(x)$ may be slightly more efficient.

Examples

```
julia> inv(2)
0.5

julia> inv(1 + 2im)
0.2 - 0.4im

julia> inv(1 + 2im) * (1 + 2im)
1.0 + 0.0im

julia> inv(2//3)
3//2
```

Julia 1.2

`inv(::Missing)` requires at least Julia 1.2.

[source](#)

Base.div - Function.

```
| div(x, y)
| ÷(x, y)
```

The quotient from Euclidean (integer) division. Generally equivalent to a mathematical operation x/y without a fractional part.

See also: [cld](#), [fld](#), [rem](#), [divrem](#).

Examples

```
julia> 9 ÷ 4
2

julia> -5 ÷ 3
-1

julia> 5.0 ÷ 2
2.0

julia> div.(-5:5, 3)'
1×11 adjoint(::Vector{Int64}) with eltype Int64:
-1 -1 -1 0 0 0 0 0 1 1 1
```

[source](#)

Base.fld – Function.

```
| fld(x, y)
```

Largest integer less than or equal to x / y . Equivalent to `div(x, y, RoundDown)`.

See also [div](#), [cld](#), [fld1](#).

Examples

```
julia> fld(7.3, 5.5)
1.0

julia> fld.(-5:5, 3)'
1×11 adjoint(::Vector{Int64}) with eltype Int64:
-2 -2 -1 -1 -1 0 0 0 1 1 1
```

Because `fld(x, y)` implements strictly correct floored rounding based on the true value of floating-point numbers, unintuitive situations can arise. For example:

```
julia> fld(6.0, 0.1)
59.0
julia> 6.0 / 0.1
60.0
julia> 6.0 / big(0.1)
59.99999999999999666933092612453056361837965690217069245739573412231113406246995
```

What is happening here is that the true value of the floating-point number written as `0.1` is slightly larger than the numerical value $1/10$ while `6.0` represents the number 6 precisely. Therefore the true value of $6.0 / 0.1$ is slightly less than 60. When doing division, this is rounded to precisely `60.0`, but `fld(6.0, 0.1)` always takes the floor of the true value, so the result is `59.0`.

[source](#)

Base.cld – Function.

```
| cld(x, y)
```

Smallest integer larger than or equal to x / y . Equivalent to `div(x, y, RoundUp)`.

See also [div](#), [fld](#).

Examples

```
julia> cld(5.5, 2.2)
3.0

julia> cld.(-5:5, 3)'
1×11 adjoint(::Vector{Int64}) with eltype Int64:
-1 -1 -1 0 0 0 1 1 1 2 2
```

[source](#)

Base.mod – Function.

```
| mod(x::Integer, r::AbstractUnitRange)
```

Find y in the range r such that $xy(modn)$, where $n = \text{length}(r)$, i.e. $y = \text{mod}(x - \text{first}(r), n) + \text{first}(r)$.

See also [mod1](#).

Examples

```
julia> mod(0, Base.OneTo(3)) # mod1(0, 3)
3

julia> mod(3, 0:2) # mod(3, 3)
0
```

Julia 1.3

This method requires at least Julia 1.3.

[source](#)

```
| mod(x, y)
| rem(x, y, RoundDown)
```

The reduction of x modulo y , or equivalently, the remainder of x after floored division by y , i.e. $x - y*\text{fld}(x, y)$ if computed without intermediate rounding.

The result will have the same sign as y , and magnitude less than $\text{abs}(y)$ (with some exceptions, see note below).

Note

When used with floating point values, the exact result may not be representable by the type, and so rounding error may occur. In particular, if the exact result is very close to y , then it may be rounded to y .

See also: [rem](#), [div](#), [fld](#), [mod1](#), [invmod](#).

```
julia> mod(8, 3)
2

julia> mod(9, 3)
0

julia> mod(8.9, 3)
2.9000000000000004

julia> mod(eps(), 3)
2.220446049250313e-16

julia> mod(-eps(), 3)
3.0

julia> mod.(-5:5, 3)'
1×11 adjoint(::Vector{Int64}) with eltype Int64:
 1  2  0  1  2  0  1  2  0  1  2
```

[source](#)

```
rem(x::Integer, T::Type{<:Integer}) -> T
mod(x::Integer, T::Type{<:Integer}) -> T
%(x::Integer, T::Type{<:Integer}) -> T
```

Find $y::T$ such that $x \equiv y \pmod{n}$, where n is the number of integers representable in T , and y is an integer in $[\text{typemin}(T), \text{typemax}(T)]$. If T can represent any integer (e.g. $T == \text{BigInt}$), then this operation corresponds to a conversion to T .

Examples

```
julia> x = 129 % Int8
-127

julia> typeof(x)
Int8

julia> x = 129 % BigInt
129

julia> typeof(x)
BigInt
```

[source](#)

Base.rem - Function.

```
rem(x, y)
%(x, y)
```

Remainder from Euclidean division, returning a value of the same sign as x , and smaller in magnitude than y . This value is always exact.

See also: [div](#), [mod](#), [mod1](#), [divrem](#).

Examples

```
julia> x = 15; y = 4;

julia> x % y
3

julia> x == div(x, y) * y + rem(x, y)
true

julia> rem.(-5:5, 3)'
1×11 adjoint(::Vector{Int64}) with eltype Int64:
-2 -1 0 -2 -1 0 1 2 0 1 2
```

[source](#)

`Base.Math.rem2pi` – Function.

```
| rem2pi(x, r::RoundingMode)
```

Compute the remainder of x after integer division by 2π , with the quotient rounded according to the rounding mode r . In other words, the quantity

```
|  $x - \pi 2 * \text{round}(x\pi / (2), r)$ 
```

without any intermediate rounding. This internally uses a high precision approximation of 2π , and so will give a more accurate result than `rem(x, 2 π , r)`

- if $r == \text{RoundNearest}$, then the result is in the interval $[-,]$. This will generally be the most accurate result. See also [RoundNearest](#).
- if $r == \text{RoundToZero}$, then the result is in the interval $[0, 2]$ if x is positive, or $[-2, 0]$ otherwise. See also [RoundToZero](#).
- if $r == \text{RoundDown}$, then the result is in the interval $[0, 2]$. See also [RoundDown](#).
- if $r == \text{RoundUp}$, then the result is in the interval $[-2, 0]$. See also [RoundUp](#).

Examples

```
julia> rem2pi(7pi/4, RoundNearest)
-0.7853981633974485

julia> rem2pi(7pi/4, RoundDown)
5.497787143782138
```

[source](#)

`Base.Math.mod2pi` – Function.

```
| mod2pi(x)
```

Modulus after division by 2π , returning in the range $[0, 2)$.

This function computes a floating point representation of the modulus after division by numerically exact 2π , and is therefore not exactly the same as $\text{mod}(x, 2\pi)$, which would compute the modulus of x relative to division by the floating-point number 2π .

Note

Depending on the format of the input value, the closest representable value to 2π may be less than 2π . For example, the expression $\text{mod2pi}(2\pi)$ will not return 0, because the intermediate value of $2*\pi$ is a `Float64` and $2*\text{Float64}(\pi) < 2*\text{big}(\pi)$. See [rem2pi](#) for more refined control of this behavior.

Examples

```
julia> mod2pi(9*pi/4)
0.7853981633974481
```

[source](#)

`Base.divrem` – Function.

```
divrem(x, y, r::RoundingMode=RoundToZero)
```

The quotient and remainder from Euclidean division. Equivalent to $(\text{div}(x, y, r), \text{rem}(x, y, r))$. Equivalently, with the default value of r , this call is equivalent to $(x \div y, x \% y)$.

See also: [fldmod](#), [cld](#).

Examples

```
julia> divrem(3, 7)
(0, 3)

julia> divrem(7, 3)
(2, 1)
```

[source](#)

`Base.fldmod` – Function.

```
fldmod(x, y)
```

The floored quotient and modulus after division. A convenience wrapper for $\text{divrem}(x, y, \text{RoundDown})$. Equivalent to $(\text{fld}(x, y), \text{mod}(x, y))$.

See also: [fld](#), [cld](#), [fldmod1](#).

[source](#)

`Base.fld1` – Function.

```
fld1(x, y)
```

Flooring division, returning a value consistent with `mod1(x, y)`

See also [mod1](#), [fldmod1](#).

Examples

```
julia> x = 15; y = 4;

julia> fld1(x, y)
4

julia> x == fld(x, y) * y + mod(x, y)
true

julia> x == (fld1(x, y) - 1) * y + mod1(x, y)
true
```

[source](#)

`Base.mod1` – Function.

```
| mod1(x, y)
```

Modulus after flooring division, returning a value `r` such that `mod(r, y) == mod(x, y)` in the range $(0, y]$ for positive `y` and in the range $[y, 0)$ for negative `y`.

With integer arguments and positive `y`, this is equal to `mod(x, 1:y)`, and hence natural for 1-based indexing. By comparison, `mod(x, y) == mod(x, 0:y-1)` is natural for computations with offsets or strides.

See also [mod](#), [fld1](#), [fldmod1](#).

Examples

```
julia> mod1(4, 2)
2

julia> mod1.(-5:5, 3)'
1×11 adjoint(::Vector{Int64}) with eltype Int64:
 1  2  3  1  2  3  1  2  3  1  2

julia> mod1.([-0.1, 0, 0.1, 1, 2, 2.9, 3, 3.1]', 3)
1×8 Matrix{Float64}:
 2.9  3.0  0.1  1.0  2.0  2.9  3.0  0.1
```

[source](#)

`Base.fldmod1` – Function.

```
| fldmod1(x, y)
```

Return `(fld1(x, y), mod1(x, y))`.

See also [fld1](#), [mod1](#).

[source](#)

Base.:// – Function.

```
| //(num, den)
```

Divide two integers or rational numbers, giving a [Rational](#) result.

Examples

```
| julia> 3 // 5
3//5

julia> (3 // 5) // (2 // 1)
3//10
```

[source](#)

Base.rationalize – Function.

```
| rationalize([T<:Integer=Int,] x; tol::Real=eps(x))
```

Approximate floating point number x as a [Rational](#) number with components of the given integer type. The result will differ from x by no more than tol.

Examples

```
| julia> rationalize(5.6)
28//5

julia> a = rationalize(BigInt, 10.3)
103//10

julia> typeof(numerator(a))
BigInt
```

[source](#)

Base.numerator – Function.

```
| numerator(x)
```

Numerator of the rational representation of x.

Examples

```
| julia> numerator(2//3)
2

julia> numerator(4)
4
```

[source](#)

Base.denominator – Function.

```
| denominator(x)
```

Denominator of the rational representation of x .

Examples

```
julia> denominator(2//3)
3

julia> denominator(4)
1
```

[source](#)

Base.:<< - Function.

```
<<(x, n)
```

Left bit shift operator, $x \ll n$. For $n \geq 0$, the result is x shifted left by n bits, filling with 0s. This is equivalent to $x * 2^n$. For $n < 0$, this is equivalent to $x \gg -n$.

Examples

```
julia> Int8(3) << 2
12

julia> bitstring(Int8(3))
"00000011"

julia> bitstring(Int8(12))
"00001100"
```

See also [>>](#), [>>>](#), [exp2](#), [ldexp](#).

[source](#)

```
<<(B::BitVector, n) -> BitVector
```

Left bit shift operator, $B \ll n$. For $n \geq 0$, the result is B with elements shifted n positions backwards, filling with false values. If $n < 0$, elements are shifted forwards. Equivalent to $B \gg -n$.

Examples

```
julia> B = BitVector([true, false, true, false, false])
5-element BitVector:
 1
 0
 1
 0
 0

julia> B << 1
5-element BitVector:
 0
 1
 0
 0
 0
```

```

0

julia> B << -1
5-element BitVector:
 0
 1
 0
 1
 0

```

[source](#)

Base.:>> - Function.

```
|>>(x, n)
```

Right bit shift operator, $x \gg n$. For $n \geq 0$, the result is x shifted right by n bits, filling with 0s if $x \geq 0$, 1s if $x < 0$, preserving the sign of x . This is equivalent to $\text{fld}(x, 2^n)$. For $n < 0$, this is equivalent to $x \ll -n$.

Examples

```

julia> Int8(13) >> 2
3

julia> bitstring(Int8(13))
"00001101"

julia> bitstring(Int8(3))
"00000011"

julia> Int8(-14) >> 2
-4

julia> bitstring(Int8(-14))
"11110010"

julia> bitstring(Int8(-4))
"11111100"

```

See also >>>, <<.

[source](#)

```
|>>(B::BitVector, n) -> BitVector
```

Right bit shift operator, $B \gg n$. For $n \geq 0$, the result is B with elements shifted n positions forward, filling with false values. If $n < 0$, elements are shifted backwards. Equivalent to $B \ll -n$.

Examples

```

julia> B = BitVector([true, false, true, false, false])
5-element BitVector:
 1

```

```

0
1
0
0

julia> B >> 1
5-element BitVector:
 0
 1
 0
 1
 0

julia> B >> -1
5-element BitVector:
 0
 1
 0
 0
 0

```

[source](#)

Base.:>>> - Function.

```
>>>(x, n)
```

Unsigned right bit shift operator, $x \ggg n$. For $n \geq 0$, the result is x shifted right by n bits, filling with 0s. For $n < 0$, this is equivalent to $x \ll -n$.

For [Unsigned](#) integer types, this is equivalent to `>>`. For [Signed](#) integer types, this is equivalent to `signed(unsigned(x) >> n)`.

Examples

```

julia> Int8(-14) >>> 2
60

julia> bitstring(Int8(-14))
"11110010"

julia> bitstring(Int8(60))
"00111100"

```

[BigInts](#) are treated as if having infinite size, so no filling is required and this is equivalent to `>>`.

See also `>>`, `<<`.

[source](#)

```
>>>(B::BitVector, n) -> BitVector
```

Unsigned right bitshift operator, $B \ggg n$. Equivalent to $B \gg n$. See `>>` for details and examples.

[source](#)

`Base.bitrotate` – Function.

```
| bitrotate(x::Base.BitInteger, k::Integer)
```

`bitrotate(x, k)` implements bitwise rotation. It returns the value of `x` with its bits rotated left `k` times. A negative value of `k` will rotate to the right instead.

Julia 1.5

This function requires Julia 1.5 or later.

See also: [<<](#), [circshift](#), [BitArray](#).

```
julia> bitrotate(UInt8(114), 2)
0xc9

julia> bitstring(bitrotate(0b01110010, 2))
"11001001"

julia> bitstring(bitrotate(0b01110010, -2))
"10011100"

julia> bitstring(bitrotate(0b01110010, 8))
"01110010"
```

[source](#)

`Base.::` – Function.

```
| :expr
```

Quote an expression `expr`, returning the abstract syntax tree (AST) of `expr`. The AST may be of type `Expr`, `Symbol`, or a literal value. The syntax `:identifier` evaluates to a `Symbol`.

See also: [Expr](#), [Symbol](#), [Meta.parse](#)

Examples

```
julia> expr = :(a = b + 2*x)
:(a = b + 2x)

julia> sym = :some_identifier
:some_identifier

julia> value = :0xff
0xff

julia> typeof((expr, sym, value))
Tuple{Expr, Symbol, UInt8}
```

[source](#)

`Base.range` – Function.

```
range(start, stop, length)
range(start, stop; length, step)
range(start; length, stop, step)
range(;start, length, stop, step)
```

Construct a specialized array with evenly spaced elements and optimized storage (an [AbstractRange](#)) from the arguments. Mathematically a range is uniquely determined by any three of start, step, stop and length. Valid invocations of range are:

- Call range with any three of start, step, stop, length.
- Call range with two of start, stop, length. In this case step will be assumed to be one. If both arguments are Integers, a [UnitRange](#) will be returned.
- Call range with one of stop or length. start and step will be assumed to be one.

See Extended Help for additional details on the returned type.

Examples

```
julia> range(1, length=100)
1:100

julia> range(1, stop=100)
1:100

julia> range(1, step=5, length=100)
1:5:496

julia> range(1, step=5, stop=100)
1:5:96

julia> range(1, 10, length=101)
1.0:0.09:10.0

julia> range(1, 100, step=5)
1:5:96

julia> range(stop=10, length=5)
6:10

julia> range(stop=10, step=1, length=5)
6:1:10

julia> range(start=1, step=1, stop=10)
1:1:10

julia> range(; length = 10)
Base.OneTo(10)

julia> range(; stop = 6)
Base.OneTo(6)

julia> range(; stop = 6.5)
1.0:1.0:6.0
```

If length is not specified and $\text{stop} - \text{start}$ is not an integer multiple of step, a range that ends before stop will be produced.

```
julia> range(1, 3.5, step=2)
1.0:2.0:3.0
```

Special care is taken to ensure intermediate values are computed rationally. To avoid this induced overhead, see the [LinRange](#) constructor.

Julia 1.1

stop as a positional argument requires at least Julia 1.1.

Julia 1.7

The versions without keyword arguments and start as a keyword argument require at least Julia 1.7.

Julia 1.8

The versions with stop as a sole keyword argument, or length as a sole keyword argument require at least Julia 1.8.

Extended Help

range will produce a `Base.OneTo` when the arguments are Integers and

- Only length is provided
- Only stop is provided

range will produce a `UnitRange` when the arguments are Integers and

- Only start and stop are provided
- Only length and stop are provided

A `UnitRange` is not produced if step is provided even if specified as one.

[source](#)

`Base.OneTo` – Type.

```
Base.OneTo(n)
```

Define an `AbstractUnitRange` that behaves like `1:n`, with the added distinction that the lower limit is guaranteed (by the type system) to be 1.

[source](#)

`Base.StepRangeLen` – Type.

```
StepRangeLen(ref::R, step::S, len, [offset=1]) where { R,S}
StepRangeLen{T,R,S}(ref::R, step::S, len, [offset=1]) where {T,R,S}
StepRangeLen{T,R,S,L}(ref::R, step::S, len, [offset=1]) where {T,R,S,L}
```

A range `r` where `r[i]` produces values of type `T` (in the first form, `T` is deduced automatically), parameterized by a reference value, a step, and the length. By default `ref` is the starting value `r[1]`, but alternatively you can supply it as the value of `r[offset]` for some other index $1 \leq \text{offset} \leq \text{len}$. The syntax `a:b` or `a:b:c`, where any of `a`, `b`, or `c` are floating-point numbers, creates a `StepRangeLen`.

Julia 1.7

The 4th type parameter `L` requires at least Julia 1.7.

source

Base.::== – Function.

```
==(x, y)
```

Generic equality operator. Falls back to `===`. Should be implemented for all types with a notion of equality, based on the abstract value that an instance represents. For example, all numeric types are compared by numeric value, ignoring type. Strings are compared as sequences of characters, ignoring encoding. For collections, `==` is generally called recursively on all contents, though other properties (like the shape for arrays) may also be taken into account.

This operator follows IEEE semantics for floating-point numbers: `0.0 == -0.0` and `NaN != NaN`.

The result is of type `Bool`, except when one of the operands is `missing`, in which case `missing` is returned ([three-valued logic](#)). For collections, `missing` is returned if at least one of the operands contains a missing value and all non-missing values are equal. Use `isequal` or `===` to always get a `Bool` result.

Implementation

New numeric types should implement this function for two arguments of the new type, and handle comparison to other types via promotion rules where possible.

`isequal` falls back to `==`, so new methods of `==` will be used by the `Dict` type to compare keys. If your type will be used as a dictionary key, it should therefore also implement `hash`.

If some type defines `==`, `isequal`, and `isless` then it should also implement `<` to ensure consistency of comparisons.

source

Base.::!= – Function.

```
!=(x, y)
≠(x,y)
```

Not-equals comparison operator. Always gives the opposite answer as `==`.

Implementation

New types should generally not implement this, and rely on the fallback definition `!=(x,y) = !(x==y)` instead.

Examples

```
julia> 3 != 2
true

julia> "foo" ≠ "foo"
false
```

source

```
!=(x)
```

Create a function that compares its argument to `x` using `!=`, i.e. a function equivalent to `y -> y != x`. The returned function is of type `Base.Fix2{typeof(!=)}`, which can be used to implement specialized methods.

Julia 1.2

This functionality requires at least Julia 1.2.

source

Base. :`!=` – Function.

```
!=(x, y)
≠(x, y)
```

Always gives the opposite answer as `==`.

Examples

```
julia> a = [1, 2]; b = [1, 2];

julia> a ≠ b
true

julia> a ≠ a
false
```

source

Base. :`<` – Function.

```
<(x, y)
```

Less-than comparison operator. Falls back to `isless`. Because of the behavior of floating-point NaN values, this operator implements a partial order.

Implementation

New types with a canonical partial order should implement this function for two arguments of the new type. Types with a canonical total order should implement `isless` instead.

See also `isunordered`.

Examples

```
julia> 'a' < 'b'
true

julia> "abc" < "abd"
true

julia> 5 < 3
false
```

source

```
| <(x)
```

Create a function that compares its argument to x using `<`, i.e. a function equivalent to $y \rightarrow y < x$. The returned function is of type `Base.Fix2{typeof(<)}`, which can be used to implement specialized methods.

Julia 1.2

This functionality requires at least Julia 1.2.

source

Base.:<= - Function.

```
| <=(x, y)
| ≤(x,y)
```

Less-than-or-equals comparison operator. Falls back to $(x < y) \mid (x == y)$.

Examples

```
julia> 'a' <= 'b'
true

julia> 7 ≤ 7 ≤ 9
true

julia> "abc" ≤ "abc"
true

julia> 5 <= 3
false
```

source

```
| <=(x)
```

Create a function that compares its argument to x using `<=`, i.e. a function equivalent to $y \rightarrow y \leq x$. The returned function is of type `Base.Fix2{typeof(<=)}`, which can be used to implement specialized methods.

Julia 1.2

This functionality requires at least Julia 1.2.

source

Base.:> - Function.

```
| >(x, y)
```

Greater-than comparison operator. Falls back to $y < x$.

Implementation

Generally, new types should implement `<` instead of this function, and rely on the fallback definition `>(x, y) = y < x`.

Examples

```
julia> 'a' > 'b'
false

julia> 7 > 3 > 1
true

julia> "abc" > "abd"
false

julia> 5 > 3
true
```

source

```
>(x)
```

Create a function that compares its argument to x using `>`, i.e. a function equivalent to `y -> y > x`. The returned function is of type `Base.Fix2{typeof(>)}`, which can be used to implement specialized methods.

Julia 1.2

This functionality requires at least Julia 1.2.

source

`Base. :>=` – Function.

```
>=(x, y)
≥(x,y)
```

Greater-than-or-equals comparison operator. Falls back to $y <= x$.

Examples

```
julia> 'a' >= 'b'
false

julia> 7 ≥ 7 ≥ 3
true

julia> "abc" ≥ "abc"
true

julia> 5 >= 3
true
```

source

```
| >=(x)
```

Create a function that compares its argument to `x` using `>=`, i.e. a function equivalent to `y -> y >= x`. The returned function is of type `Base.Fix2{typeof(>=)}`, which can be used to implement specialized methods.

Julia 1.2

This functionality requires at least Julia 1.2.

source

`Base.cmp` – Function.

```
| cmp(x,y)
```

Return -1, 0, or 1 depending on whether `x` is less than, equal to, or greater than `y`, respectively. Uses the total order implemented by `isless`.

Examples

```
julia> cmp(1, 2)
-1

julia> cmp(2, 1)
1

julia> cmp(2+im, 3-im)
ERROR: MethodError: no method matching isless(::Complex{Int64}, ::Complex{Int64})
[...]
```

source

```
| cmp(<, x, y)
```

Return -1, 0, or 1 depending on whether `x` is less than, equal to, or greater than `y`, respectively. The first argument specifies a less-than comparison function to use.

source

```
| cmp(a::AbstractString, b::AbstractString) -> Int
```

Compare two strings. Return 0 if both strings have the same length and the character at each index is the same in both strings. Return -1 if `a` is a prefix of `b`, or if `a` comes before `b` in alphabetical order. Return 1 if `b` is a prefix of `a`, or if `b` comes before `a` in alphabetical order (technically, lexicographical order by Unicode code points).

Examples

```
julia> cmp("abc", "abc")
0

julia> cmp("ab", "abc")
```

```

-1

julia> cmp("abc", "ab")
1

julia> cmp("ab", "ac")
-1

julia> cmp("ac", "ab")
1

julia> cmp("α", "a")
1

julia> cmp("b", "β")
-1

```

[source](#)

Base.:~ – Function.

```
| ~(x)
```

Bitwise not.

See also: [!](#), [&](#), [|](#).

Examples

```

julia> ~4
-5

julia> ~10
-11

julia> ~true
false

```

[source](#)

Base.:& – Function.

```
| x & y
```

Bitwise and. Implements [three-valued logic](#), returning [missing](#) if one operand is missing and the other is true. Add parentheses for function application form: `(&)(x, y)`.

See also: [|](#), [xor](#), [&&](#).

Examples

```

julia> 4 & 10
0

julia> 4 & 12
4

```

```

4
julia> true & missing
missing
julia> false & missing
false

```

[source](#)

Base.:| – Function.

```
| x | y
```

Bitwise or. Implements [three-valued logic](#), returning [missing](#) if one operand is missing and the other is false.

See also: [&](#), [xor](#), [||](#).

Examples

```

julia> 4 | 10
14
julia> 4 | 1
5
julia> true | missing
true
julia> false | missing
missing

```

[source](#)

Base.xor – Function.

```

xor(x, y)
⊞(x, y)

```

Bitwise exclusive or of x and y. Implements [three-valued logic](#), returning [missing](#) if one of the arguments is missing.

The infix operation $a \ \underline{\vee} \ b$ is a synonym for `xor(a,b)`, and $\underline{\vee}$ can be typed by tab-completing `\xor` or `\veebar` in the Julia REPL.

Examples

```

julia> xor(true, false)
true
julia> xor(true, true)
false
julia> xor(true, missing)

```

```

missing

julia> false ∨ false
false

julia> [true; true; false] .∨ [true; false; false]
3-element BitVector:
 0
 1
 0

```

[source](#)

Base.nand – Function.

```

nand(x, y)
(x, y)

```

Bitwise nand (not and) of x and y . Implements [three-valued logic](#), returning [missing](#) if one of the arguments is missing.

The infix operation $a \ \bar{\wedge} \ b$ is a synonym for `nand(a,b)`, and can be typed by tab-completing `\nand` or `\barwedge` in the Julia REPL.

Examples

```

julia> nand(true, false)
true

julia> nand(true, true)
false

julia> nand(true, missing)
missing

julia> false false
true

julia> [true; true; false] . [true; false; false]
3-element BitVector:
 0
 1
 1

```

[source](#)

Base.nor – Function.

```

nor(x, y)
(x, y)

```

Bitwise nor (not or) of x and y . Implements [three-valued logic](#), returning [missing](#) if one of the arguments is missing and the other is not true.

The infix operation `a ~ b` is a synonym for `nor(a,b)`, and `~` can be typed by tab-completing `\nor` or `\barvee` in the Julia REPL.

Examples

```
julia> nor(true, false)
false

julia> nor(true, true)
false

julia> nor(true, missing)
false

julia> false ~ false
true

julia> false ~ missing
missing

julia> [true; true; false] ~ [true; false; false]
3-element BitVector:
 0
 0
 1
```

[source](#)

Base.`!` – Function.

```
!(x)
```

Boolean not. Implements [three-valued logic](#), returning `missing` if `x` is missing.

See also `~` for bitwise not.

Examples

```
julia> !true
false

julia> !false
true

julia> !missing
missing

julia> ![true false true]
1×3 BitMatrix:
 0  1  0
```

[source](#)

```
!f::Function
```

Predicate function negation: when the argument of `!` is a function, it returns a composed function which computes the boolean negation of `f`.

See also [◦](#).

Examples

```
julia> str = "∀ ε > 0, ∃ δ > 0: |x-y| < δ ⇒ |f(x)-f(y)| < ε"
"∀ ε > 0, ∃ δ > 0: |x-y| < δ ⇒ |f(x)-f(y)| < ε"

julia> filter(isletter, str)
"εδxyδfxfyε"

julia> filter(!isletter, str)
"∀ > 0, ∃ > 0: |-| < ⇒ |()-()| < "
```

Julia 1.9

Starting with Julia 1.9, `!f` returns a [ComposedFunction](#) instead of an anonymous function.

[source](#)

`&&` – Keyword.

```
| x && y
```

Short-circuiting boolean AND.

See also [&](#), the ternary operator `? :`, and the manual section on [control flow](#).

Examples

```
julia> x = 3;

julia> x > 1 && x < 10 && x isa Int
true

julia> x < 0 && error("expected positive x")
false
```

[source](#)

`||` – Keyword.

```
| x || y
```

Short-circuiting boolean OR.

See also: [|](#), [xor](#), [&&](#).

Examples

```
julia> pi < 3 || < 3
true

julia> false || true || println("neither is true!")
true
```

[source](#)

43.2 Mathematical Functions

Base.isapprox – Function.

```
isapprox(x, y; atol::Real=0, rtol::Real=atol>0 ? 0 : √eps, nans::Bool=false[,
↪ norm::Function])
```

Inexact equality comparison. Two numbers compare equal if their relative distance or their absolute distance is within tolerance bounds: `isapprox` returns true if $\text{norm}(x-y) \leq \max(\text{atol}, \text{rtol} \cdot \max(\text{norm}(x), \text{norm}(y)))$. The default `atol` (absolute tolerance) is zero and the default `rtol` (relative tolerance) depends on the types of `x` and `y`. The keyword argument `nans` determines whether or not NaN values are considered equal (defaults to false).

For real or complex floating-point values, if an `atol > 0` is not specified, `rtol` defaults to the square root of `eps` of the type of `x` or `y`, whichever is bigger (least precise). This corresponds to requiring equality of about half of the significant digits. Otherwise, e.g. for integer arguments or if an `atol > 0` is supplied, `rtol` defaults to zero.

The `norm` keyword defaults to `abs` for numeric `(x, y)` and to `LinearAlgebra.norm` for arrays (where an alternative norm choice is sometimes useful). When `x` and `y` are arrays, if $\text{norm}(x-y)$ is not finite (i.e. $\pm\text{Inf}$ or NaN), the comparison falls back to checking whether all elements of `x` and `y` are approximately equal component-wise.

The binary operator `≈` is equivalent to `isapprox` with the default arguments, and `x ≠ y` is equivalent to `!isapprox(x, y)`.

Note that `x ≈ 0` (i.e., comparing to zero with the default tolerances) is equivalent to `x == 0` since the default `atol` is 0. In such cases, you should either supply an appropriate `atol` (or use `norm(x) ≤ atol`) or rearrange your code (e.g. use `x ≈ y` rather than `x - y ≈ 0`). It is not possible to pick a nonzero `atol` automatically because it depends on the overall scaling (the "units") of your problem: for example, in `x - y ≈ 0`, `atol=1e-9` is an absurdly small tolerance if `x` is the [radius of the Earth](#) in meters, but an absurdly large tolerance if `x` is the [radius of a Hydrogen atom](#) in meters.

Julia 1.6

Passing the `norm` keyword argument when comparing numeric (non-array) arguments requires Julia 1.6 or later.

Examples

```
julia> isapprox(0.1, 0.15; atol=0.05)
true

julia> isapprox(0.1, 0.15; rtol=0.34)
true

julia> isapprox(0.1, 0.15; rtol=0.33)
false

julia> 0.1 + 1e-10 ≈ 0.1
true

julia> 1e-10 ≈ 0
false
```

```
julia> isapprox(1e-10, 0, atol=1e-8)
true

julia> isapprox([10.0^9, 1.0], [10.0^9, 2.0]) # using `norm`
true
```

source

```
isapprox(x; kwargs...) / ≈(x; kwargs...)
```

Create a function that compares its argument to x using \approx , i.e. a function equivalent to $y \rightarrow y \approx x$.

The keyword arguments supported here are the same as those in the 2-argument `isapprox`.

Julia 1.5

This method requires Julia 1.5 or later.

source

`Base.sin` – Method.

```
sin(x)
```

Compute sine of x , where x is in radians.

See also [sind](#), [sinpi](#), [sincos](#), [cis](#), [asin](#).

Examples

```
julia> round.(sin.(range(0, 2pi, length=9)'), digits=3)
1×9 Matrix{Float64}:
 0.0  0.707  1.0  0.707  0.0 -0.707 -1.0 -0.707 -0.0

julia> sind(45)
0.7071067811865476

julia> sinpi(1/4)
0.7071067811865475

julia> round.(sincos(pi/6), digits=3)
(0.5, 0.866)

julia> round(cis(pi/6), digits=3)
0.866 + 0.5im

julia> round(exp(im*pi/6), digits=3)
0.866 + 0.5im
```

source

`Base.cos` – Method.

```
cos(x)
```

Compute cosine of x , where x is in radians.

See also [cosd](#), [cospi](#), [sincos](#), [cis](#).

[source](#)

`Base.Math.sincos` – Method.

| `sincos(x)`

Simultaneously compute the sine and cosine of x , where x is in radians, returning a tuple (sine, cosine).

See also [cis](#), [sincospi](#), [sincosd](#).

[source](#)

`Base.tan` – Method.

| `tan(x)`

Compute tangent of x , where x is in radians.

[source](#)

`Base.Math.sind` – Function.

| `sind(x)`

Compute sine of x , where x is in degrees. If x is a matrix, x needs to be a square matrix.

Julia 1.7

Matrix arguments require Julia 1.7 or later.

[source](#)

`Base.Math.cosd` – Function.

| `cosd(x)`

Compute cosine of x , where x is in degrees. If x is a matrix, x needs to be a square matrix.

Julia 1.7

Matrix arguments require Julia 1.7 or later.

[source](#)

`Base.Math.tand` – Function.

| `tand(x)`

Compute tangent of x , where x is in degrees. If x is a matrix, x needs to be a square matrix.

Julia 1.7

Matrix arguments require Julia 1.7 or later.

[source](#)

`Base.Math.sincosd` – Function.

| `sincosd(x)`

Simultaneously compute the sine and cosine of x , where x is in degrees.

Julia 1.3

This function requires at least Julia 1.3.

[source](#)

`Base.Math.sinpi` – Function.

| `sinpi(x)`

Compute $\sin(\pi x)$ more accurately than $\sin(\pi * x)$, especially for large x .

See also [sind](#), [cospi](#), [sincospi](#).

[source](#)

`Base.Math.cospi` – Function.

| `cospi(x)`

Compute $\cos(\pi x)$ more accurately than $\cos(\pi * x)$, especially for large x .

[source](#)

`Base.Math.sincospi` – Function.

| `sincospi(x)`

Simultaneously compute [sinpi\(x\)](#) and [cospi\(x\)](#) (the sine and cosine of $\pi * x$, where x is in radians), returning a tuple (sine, cosine).

Julia 1.6

This function requires Julia 1.6 or later.

See also: [cispi](#), [sincosd](#), [sinpi](#).

[source](#)

`Base.sinh` – Method.

| `sinh(x)`

Compute hyperbolic sine of x .

[source](#)

`Base.cosh` – Method.

| `cosh(x)`

Compute hyperbolic cosine of x.

[source](#)

Base.tanh – Method.

| tanh(x)

Compute hyperbolic tangent of x.

See also [tan](#), [atanh](#).

Examples

```
julia> tanh.(-3:3f0) # Here 3f0 isa Float32
7-element Vector{Float32}:
-0.9950548
-0.9640276
-0.7615942
 0.0
 0.7615942
 0.9640276
 0.9950548

julia> tan.(im .* (1:3))
3-element Vector{ComplexF64}:
0.0 + 0.7615941559557649im
0.0 + 0.9640275800758169im
0.0 + 0.9950547536867306im
```

[source](#)

Base.asin – Method.

| asin(x)

Compute the inverse sine of x, where the output is in radians.

See also [asind](#) for output in degrees.

Examples

```
julia> asin.((0, 1/2, 1))
(0.0, 0.5235987755982989, 1.5707963267948966)

julia> asind.((0, 1/2, 1))
(0.0, 30.000000000000004, 90.0)
```

[source](#)

Base.acos – Method.

| acos(x)

Compute the inverse cosine of x, where the output is in radians

[source](#)

Base.atan – Method.

```
atan(y)
atan(y, x)
```

Compute the inverse tangent of y or y/x , respectively.

For one argument, this is the angle in radians between the positive x-axis and the point $(1, y)$, returning a value in the interval $[-\pi/2, \pi/2]$.

For two arguments, this is the angle in radians between the positive x-axis and the point (x, y) , returning a value in the interval $[-\pi, \pi]$. This corresponds to a standard `atan2` function. Note that by convention `atan(0.0, x)` is defined as π and `atan(-0.0, x)` is defined as $-\pi$ when $x < 0$.

See also `atand` for degrees.

Examples

```
julia> rad2deg(atan(-1/√3))
-30.000000000000004

julia> rad2deg(atan(-1, √3))
-30.000000000000004

julia> rad2deg(atan(1, -√3))
150.0
```

[source](#)

Base.Math.asind – Function.

```
asind(x)
```

Compute the inverse sine of x , where the output is in degrees. If x is a matrix, x needs to be a square matrix.

Julia 1.7

Matrix arguments require Julia 1.7 or later.

[source](#)

Base.Math.acosd – Function.

```
acosd(x)
```

Compute the inverse cosine of x , where the output is in degrees. If x is a matrix, x needs to be a square matrix.

Julia 1.7

Matrix arguments require Julia 1.7 or later.

[source](#)

Base.Math.atand – Function.

```
| atand(y)
| atand(y,x)
```

Compute the inverse tangent of y or y/x , respectively, where the output is in degrees.

Julia 1.7

The one-argument method supports square matrix arguments as of Julia 1.7.

[source](#)

`Base.Math.sec` – Method.

```
| sec(x)
```

Compute the secant of x , where x is in radians.

[source](#)

`Base.Math.csc` – Method.

```
| csc(x)
```

Compute the cosecant of x , where x is in radians.

[source](#)

`Base.Math.cot` – Method.

```
| cot(x)
```

Compute the cotangent of x , where x is in radians.

[source](#)

`Base.Math.secd` – Function.

```
| secd(x)
```

Compute the secant of x , where x is in degrees.

[source](#)

`Base.Math.cscd` – Function.

```
| cscd(x)
```

Compute the cosecant of x , where x is in degrees.

[source](#)

`Base.Math.cotd` – Function.

```
| cotd(x)
```

Compute the cotangent of x , where x is in degrees.

[source](#)

`Base.Math.asec` – Method.

| `asec(x)`

Compute the inverse secant of x , where the output is in radians.

[source](#)

`Base.Math.acsc` – Method.

| `acsc(x)`

Compute the inverse cosecant of x , where the output is in radians.

[source](#)

`Base.Math.acot` – Method.

| `acot(x)`

Compute the inverse cotangent of x , where the output is in radians.

[source](#)

`Base.Math.asecd` – Function.

| `asecd(x)`

Compute the inverse secant of x , where the output is in degrees. If x is a matrix, x needs to be a square matrix.

Julia 1.7

Matrix arguments require Julia 1.7 or later.

[source](#)

`Base.Math.acscd` – Function.

| `acscd(x)`

Compute the inverse cosecant of x , where the output is in degrees. If x is a matrix, x needs to be a square matrix.

Julia 1.7

Matrix arguments require Julia 1.7 or later.

[source](#)

`Base.Math.acotd` – Function.

| `acotd(x)`

Compute the inverse cotangent of x , where the output is in degrees. If x is a matrix, x needs to be a square matrix.

Julia 1.7

Matrix arguments require Julia 1.7 or later.

[source](#)

`Base.Math.sech` – Method.

| `sech(x)`

Compute the hyperbolic secant of x .

[source](#)

`Base.Math.csch` – Method.

| `csch(x)`

Compute the hyperbolic cosecant of x .

[source](#)

`Base.Math.coth` – Method.

| `coth(x)`

Compute the hyperbolic cotangent of x .

[source](#)

`Base.asinh` – Method.

| `asinh(x)`

Compute the inverse hyperbolic sine of x .

[source](#)

`Base.acosh` – Method.

| `acosh(x)`

Compute the inverse hyperbolic cosine of x .

[source](#)

`Base.atanh` – Method.

| `atanh(x)`

Compute the inverse hyperbolic tangent of x .

[source](#)

`Base.Math.asech` – Method.

| `asech(x)`

Compute the inverse hyperbolic secant of x .

[source](#)

`Base.Math.acsch` – Method.

```
| acsch(x)
```

Compute the inverse hyperbolic cosecant of x .

[source](#)

`Base.Math.acoth` – Method.

```
| acoth(x)
```

Compute the inverse hyperbolic cotangent of x .

[source](#)

`Base.Math.sinc` – Function.

```
| sinc(x)
```

Compute $\sin(\pi x)/(\pi x)$ if $x \neq 0$, and 1 if $x = 0$.

See also [cosc](#), its derivative.

[source](#)

`Base.Math.cosc` – Function.

```
| cosc(x)
```

Compute $\cos(\pi x)/x - \sin(\pi x)/(\pi x^2)$ if $x \neq 0$, and 0 if $x = 0$. This is the derivative of `sinc(x)`.

[source](#)

`Base.Math.deg2rad` – Function.

```
| deg2rad(x)
```

Convert x from degrees to radians.

See also [rad2deg](#), [sind](#), [pi](#).

Examples

```
| julia> deg2rad(90)
1.5707963267948966
```

[source](#)

`Base.Math.rad2deg` – Function.

```
| rad2deg(x)
```

Convert x from radians to degrees.

See also [deg2rad](#).

Examples

```
julia> rad2deg(pi)
180.0
```

[source](#)

`Base.Math.hypot` – Function.

```
| hypot(x, y)
```

Compute the hypotenuse $\sqrt{|x|^2 + |y|^2}$ avoiding overflow and underflow.

This code is an implementation of the algorithm described in: An Improved Algorithm for `hypot(a,b)` by Carlos F. Borges The article is available online at arXiv at the link <https://arxiv.org/abs/1904.09481>

```
| hypot(x...)
```

Compute the hypotenuse $\sqrt{\sum |x_i|^2}$ avoiding overflow and underflow.

See also `norm` in the [LinearAlgebra](#) standard library.

Examples

```
julia> a = Int64(10)^10;

julia> hypot(a, a)
1.4142135623730951e10

julia> √(a^2 + a^2) # a^2 overflows
ERROR: DomainError with -2.914184810805068e18:

julia> norm([a, a, a, a]) == hypot(a, a, a, a)
true
```

[source](#)

Base.log – Method.

```
| log(x)
```

Compute the natural logarithm of x. Throws `DomainError` for negative `Real` arguments. Use complex negative arguments to obtain complex results.

See also , `log1p`, `log2`, `log10`.

Examples

```
julia> log(2)
0.6931471805599453

julia> log(-3)
ERROR: DomainError with -3.0:
log was called with a negative real argument but will only return a complex result if called
↳ with a complex argument. Try log(Complex(x)).
Stacktrace:
 [1] throw_complex_domainerror(::Symbol, ::Float64) at ./math.jl:31

  0.0
  1.0
```

[source](#)

Base.log – Method.

```
| log(b,x)
```

Compute the base b logarithm of x. Throws `DomainError` for negative `Real` arguments.

Examples

```
julia> log(4,8)
1.5

julia> log(4,2)
0.5

julia> log(-2, 3)
ERROR: DomainError with -2.0:
log was called with a negative real argument but will only return a complex result if called
↳ with a complex argument. Try log(Complex(x)).
Stacktrace:
 [1] throw_complex_domainerror(::Symbol, ::Float64) at ./math.jl:31
 [...]

julia> log(2, -3)
ERROR: DomainError with -3.0:
```

```
log was called with a negative real argument but will only return a complex result if called
↪ with a complex argument. Try log(Complex(x)).
Stacktrace:
 [1] throw_complex_domainerror(::Symbol, ::Float64) at ./math.jl:31
[...]
```

Note

If b is a power of 2 or 10, `log2` or `log10` should be used, as these will typically be faster and more accurate. For example,

```
julia> log(100, 1000000)
2.9999999999999996

julia> log10(1000000)/2
3.0
```

[source](#)

`Base.log2` – Function.

```
| log2(x)
```

Compute the logarithm of x to base 2. Throws `DomainError` for negative `Real` arguments.

See also: `exp2`, `ldexp`, `ispow2`.

Examples

```
julia> log2(4)
2.0

julia> log2(10)
3.321928094887362

julia> log2(-2)
ERROR: DomainError with -2.0:
log2 was called with a negative real argument but will only return a complex result if called
↪ with a complex argument. Try log2(Complex(x)).

```

```
julia> log2.(2.0.^(-1:1))
3-element Vector{Float64}:
-1.0
 0.0
 1.0
```

[source](#)

`Base.log10` – Function.

```
| log10(x)
```

Compute the logarithm of x to base 10. Throws `DomainError` for negative `Real` arguments.

Examples

```
julia> log10(100)
2.0

julia> log10(2)
0.3010299956639812

julia> log10(-2)
ERROR: DomainError with -2.0:

 [...]
```

[source](#)

`Base.log1p` – Function.

```
| log1p(x)
```

Accurate natural logarithm of $1+x$. Throws `DomainError` for `Real` arguments less than -1.

Examples

```
julia> log1p(-0.5)
-0.6931471805599453

julia> log1p(0)
0.0

julia> log1p(-2)
ERROR: DomainError with -2.0:

↪ with a complex argument. Try log1p(Complex(x)).
Stacktrace:
 [1] throw_complex_domainerror(::Symbol, ::Float64) at ./math.jl:31
 [...]
```

[source](#)

`Base.Math.frexp` – Function.

```
| frexp(val)
```

Return (x, exp) such that x has a magnitude in the interval $[1/2, 1)$ or 0, and val is equal to $x \times 2^{\text{exp}}$.

Examples

```
julia> frexp(12.8)
(0.8, 4)
```

[source](#)

Base.exp – Method.

`| exp(x)`

Compute the natural base exponential of x , in other words e^x .

See also [exp2](#), [exp10](#) and [cis](#).

Examples

```
julia> exp(1.0)
2.718281828459045

julia> exp(im * pi) ≈ cis(pi)
true
```

[source](#)

Base.exp2 – Function.

`| exp2(x)`

Compute the base 2 exponential of x , in other words 2^x .

See also [ldexp](#), [<<](#).

Examples

```
julia> exp2(5)
32.0

julia> 2^5
32

julia> exp2(63) > typemax{Int}
true
```

[source](#)

Base.exp10 – Function.

`| exp10(x)`

Compute the base 10 exponential of x , in other words 10^x .

Examples

```
julia> exp10(2)
100.0

julia> 10^2
100
```

[source](#)

Base.Math.ldexp – Function.

```
| ldexp(x, n)
```

Compute $x \times 2^n$.

Examples

```
| julia> ldexp(5., 2)
| 20.0
```

[source](#)

Base.Math.modf – Function.

```
| modf(x)
```

Return a tuple (fpart, ipart) of the fractional and integral parts of a number. Both parts have the same sign as the argument.

Examples

```
| julia> modf(3.5)
| (0.5, 3.0)
|
| julia> modf(-3.5)
| (-0.5, -3.0)
```

[source](#)

Base.expm1 – Function.

```
| expm1(x)
```

Accurately compute $e^x - 1$. It avoids the loss of precision involved in the direct evaluation of $\exp(x) - 1$ for small values of x .

Examples

```
| julia> expm1(1e-16)
| 1.0e-16
|
| julia> exp(1e-16) - 1
| 0.0
```

[source](#)

Base.round – Method.

```
| round([T,] x, [r::RoundingMode])
| round(x, [r::RoundingMode]; digits::Integer=0, base = 10)
| round(x, [r::RoundingMode]; sigdigits::Integer, base = 10)
```

Rounds the number `x`.

Without keyword arguments, `x` is rounded to an integer value, returning a value of type `T`, or of the same type of `x` if no `T` is provided. An `InexactError` will be thrown if the value is not representable by `T`, similar to `convert`.

If the `digits` keyword argument is provided, it rounds to the specified number of digits after the decimal place (or before if negative), in base `base`.

If the `sigdigits` keyword argument is provided, it rounds to the specified number of significant digits, in base `base`.

The `RoundingMode` `r` controls the direction of the rounding; the default is `RoundNearest`, which rounds to the nearest integer, with ties (fractional values of 0.5) being rounded to the nearest even integer. Note that `round` may give incorrect results if the global rounding mode is changed (see `rounding`).

Examples

```
julia> round(1.7)
2.0

julia> round{Int, 1.7}
2

julia> round(1.5)
2.0

julia> round(2.5)
2.0

julia> round(pi; digits=2)
3.14

julia> round(pi; digits=3, base=2)
3.125

julia> round(123.456; sigdigits=2)
120.0

julia> round(357.913; sigdigits=4, base=2)
352.0
```

Note

Rounding to specified digits in bases other than 2 can be inexact when operating on binary floating point numbers. For example, the `Float64` value represented by 1.15 is actually less than 1.15, yet will be rounded to 1.2. For example:

```
julia> x = 1.15
1.15

julia> big(1.15)
1.14999999999999991182158029987476766109466552734375

julia> x < 115//100
true
```

```
julia> round(x, digits=1)
1.2
```

Extensions

To extend `round` to new numeric types, it is typically sufficient to define `Base.round(x::NewType, r::RoundingMode)`.

[source](#)

`Base.Rounding.RoundingMode` – Type.

`RoundingMode`

A type used for controlling the rounding mode of floating point operations (via [rounding/setrounding](#) functions), or as optional arguments for rounding to the nearest integer (via the [round](#) function).

Currently supported rounding modes are:

- [RoundNearest](#) (default)
- [RoundNearestTiesAway](#)
- [RoundNearestTiesUp](#)
- [RoundToZero](#)
- [RoundFromZero](#)
- [RoundUp](#)
- [RoundDown](#)

Julia 1.9

`RoundFromZero` requires at least Julia 1.9. Prior versions support `RoundFromZero` for `BigFloats` only.

[source](#)

`Base.Rounding.RoundNearest` – Constant.

`RoundNearest`

The default rounding mode. Rounds to the nearest integer, with ties (fractional values of 0.5) being rounded to the nearest even integer.

[source](#)

`Base.Rounding.RoundNearestTiesAway` – Constant.

`RoundNearestTiesAway`

Rounds to nearest integer, with ties rounded away from zero (C/C++ [round](#) behaviour).

[source](#)

`Base.Rounding.RoundNearestTiesUp` – Constant.

```
| RoundNearestTiesUp
```

Rounds to nearest integer, with ties rounded toward positive infinity (Java/JavaScript [round](#) behaviour).

[source](#)

Base.Rounding.RoundToZero – Constant.

```
| RoundToZero
```

[round](#) using this rounding mode is an alias for [trunc](#).

[source](#)

Base.Rounding.RoundFromZero – Constant.

```
| RoundFromZero
```

Rounds away from zero.

Julia 1.9

RoundFromZero requires at least Julia 1.9. Prior versions support RoundFromZero for BigFloats only.

Examples

```
| julia> BigFloat("1.0000000000000001", 5, RoundFromZero)
1.06
```

[source](#)

Base.Rounding.RoundUp – Constant.

```
| RoundUp
```

[round](#) using this rounding mode is an alias for [ceil](#).

[source](#)

Base.Rounding.RoundDown – Constant.

```
| RoundDown
```

[round](#) using this rounding mode is an alias for [floor](#).

[source](#)

Base.round – Method.

```
| round(z::Complex{<T>, RoundingModeReal}, [RoundingModeImaginary])
| round(z::Complex{<T>, RoundingModeReal}, [RoundingModeImaginary]; digits=0, base=10)
| round(z::Complex{<T>, RoundingModeReal}, [RoundingModeImaginary]; sigdigits, base=10)
```

Return the nearest integral value of the same type as the complex-valued z to z , breaking ties using the specified [RoundingModes](#). The first [RoundingMode](#) is used for rounding the real components while the second is used for rounding the imaginary components.

`RoundingModeReal` and `RoundingModeImaginary` default to [RoundNearest](#), which rounds to the nearest integer, with ties (fractional values of 0.5) being rounded to the nearest even integer.

Example

```
julia> round(3.14 + 4.5im)
3.0 + 4.0im

julia> round(3.14 + 4.5im, RoundUp, RoundNearestTiesUp)
4.0 + 5.0im

julia> round(3.14159 + 4.512im; digits = 1)
3.1 + 4.5im

julia> round(3.14159 + 4.512im; sigdigits = 3)
3.14 + 4.51im
```

[source](#)

`Base.ceil` – Function.

```
ceil([T,] x)
ceil(x; digits::Integer= [], base = 10)
ceil(x; sigdigits::Integer= [], base = 10)
```

`ceil(x)` returns the nearest integral value of the same type as x that is greater than or equal to x .

`ceil(T, x)` converts the result to type T , throwing an `InexactError` if the value is not representable.

Keywords `digits`, `sigdigits` and `base` work as for [round](#).

[source](#)

`Base.floor` – Function.

```
floor([T,] x)
floor(x; digits::Integer= [], base = 10)
floor(x; sigdigits::Integer= [], base = 10)
```

`floor(x)` returns the nearest integral value of the same type as x that is less than or equal to x .

`floor(T, x)` converts the result to type T , throwing an `InexactError` if the value is not representable.

Keywords `digits`, `sigdigits` and `base` work as for [round](#).

[source](#)

`Base.trunc` – Function.

```
trunc([T,] x)
trunc(x; digits::Integer= [], base = 10)
trunc(x; sigdigits::Integer= [], base = 10)
```

`trunc(x)` returns the nearest integral value of the same type as `x` whose absolute value is less than or equal to the absolute value of `x`.

`trunc(T, x)` converts the result to type `T`, throwing an `InexactError` if the value is not representable.

Keywords `digits`, `sigdigits` and `base` work as for [round](#).

See also: [%](#), [floor](#), [unsigned](#), [unsafe_trunc](#).

Examples

```
julia> trunc(2.22)
2.0

julia> trunc(-2.22, digits=1)
-2.2

julia> trunc{Int}(-2.22)
-2
```

[source](#)

`Base.unsigned_trunc` – Function.

```
unsigned_trunc{T}(x)
```

Return the nearest integral value of type `T` whose absolute value is less than or equal to the absolute value of `x`. If the value is not representable by `T`, an arbitrary value will be returned. See also [trunc](#).

Examples

```
julia> unsigned_trunc{Int}(-2.2)
-2

julia> unsigned_trunc{Int}(NaN)
-9223372036854775808
```

[source](#)

`Base.min` – Function.

```
min(x, y, ...)
```

Return the minimum of the arguments (with respect to [isless](#)). See also the [minimum](#) function to take the minimum element from a collection.

Examples

```
julia> min(2, 5, 1)
1
```

[source](#)

`Base.max` – Function.

```
max(x, y, ...)
```

Return the maximum of the arguments (with respect to [isless](#)). See also the [maximum](#) function to take the maximum element from a collection.

Examples

```
julia> max(2, 5, 1)
5
```

[source](#)

Base.minmax – Function.

```
minmax(x, y)
```

Return $(\min(x, y), \max(x, y))$.

See also [extrema](#) that returns $(\min(x), \max(x))$.

Examples

```
julia> minmax('c', 'b')
('b', 'c')
```

[source](#)

Base.Math.clamp – Function.

```
clamp(x, lo, hi)
```

Return x if $lo \leq x \leq hi$. If $x > hi$, return hi . If $x < lo$, return lo . Arguments are promoted to a common type.

See also [clamp!](#), [min](#), [max](#).

Julia 1.3

missing as the first argument requires at least Julia 1.3.

Examples

```
julia> clamp([pi, 1.0, big(10)], 2.0, 9.0)
3-element Vector{BigFloat}:
 3.141592653589793238462643383279502884197169399375105820974944592307816406286198
 2.0
 9.0

julia> clamp([11, 8, 5], 10, 6) # an example where lo > hi
3-element Vector{Int64}:
 6
 6
10
```

[source](#)

```
clamp(x, T)::T
```

Clamp x between $\text{typemin}(T)$ and $\text{typemax}(T)$ and convert the result to type T .

See also [trunc](#).

Examples

```
julia> clamp(200, Int8)
127

julia> clamp(-200, Int8)
-128

julia> trunc(Int, 4pi^2)
39
```

[source](#)

```
clamp(x::Integer, r::AbstractUnitRange)
```

Clamp x to lie within range r .

Julia 1.6

This method requires at least Julia 1.6.

[source](#)

`Base.Math.clamp!` – Function.

```
clamp!(array::AbstractArray, lo, hi)
```

Restrict values in array to the specified range, in-place. See also [clamp](#).

Julia 1.3

missing entries in array require at least Julia 1.3.

Examples

```
julia> row = collect(-4:4)';

julia> clamp!(row, 0, Inf)
1×9 adjoint(::Vector{Int64}) with eltype Int64:
 0  0  0  0  0  1  2  3  4

julia> clamp((-4:4)', 0, Inf)
1×9 Matrix{Float64}:
 0.0  0.0  0.0  0.0  0.0  1.0  2.0  3.0  4.0
```

[source](#)

`Base.abs` – Function.

```
abs(x)
```

The absolute value of x .

When `abs` is applied to signed integers, overflow may occur, resulting in the return of a negative value. This overflow occurs only when `abs` is applied to the minimum representable value of a signed integer. That is, when `x == typemin(typeof(x))`, `abs(x) == x < 0`, not `-x` as might be expected.

See also: [abs2](#), [unsigned](#), [sign](#).

Examples

```
julia> abs(-3)
3

julia> abs(1 + im)
1.4142135623730951

julia> abs.(Int8[-128 -127 -126 0 126 127]) # overflow at typemin(Int8)
1×6 Matrix{Int8}:
 -128  127  126  0  126  127

julia> maximum(abs, [1, -2, 3, -4])
4
```

[source](#)

`Base.Checked.checked_abs` – Function.

```
| Base.checked_abs(x)
```

Calculates `abs(x)`, checking for overflow errors where applicable. For example, standard two's complement signed integers (e.g. `Int`) cannot represent `abs(typemin(Int))`, thus leading to an overflow.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_neg` – Function.

```
| Base.checked_neg(x)
```

Calculates `-x`, checking for overflow errors where applicable. For example, standard two's complement signed integers (e.g. `Int`) cannot represent `-typemin(Int)`, thus leading to an overflow.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_add` – Function.

```
| Base.checked_add(x, y)
```

Calculates `x+y`, checking for overflow errors where applicable.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_sub` – Function.

| `Base.checked_sub(x, y)`

Calculates $x - y$, checking for overflow errors where applicable.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_mul` – Function.

| `Base.checked_mul(x, y)`

Calculates $x * y$, checking for overflow errors where applicable.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_div` – Function.

| `Base.checked_div(x, y)`

Calculates $\text{div}(x, y)$, checking for overflow errors where applicable.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_rem` – Function.

| `Base.checked_rem(x, y)`

Calculates $x \% y$, checking for overflow errors where applicable.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_fld` – Function.

| `Base.checked_fld(x, y)`

Calculates $\text{fld}(x, y)$, checking for overflow errors where applicable.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_mod` – Function.

| `Base.checked_mod(x, y)`

Calculates $\text{mod}(x, y)$, checking for overflow errors where applicable.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.checked_cld` – Function.

```
| Base.checked_cld(x, y)
```

Calculates `cld(x, y)`, checking for overflow errors where applicable.

The overflow protection may impose a perceptible performance penalty.

[source](#)

`Base.Checked.add_with_overflow` – Function.

```
| Base.add_with_overflow(x, y) -> (r, f)
```

Calculates $r = x + y$, with the flag `f` indicating whether overflow has occurred.

[source](#)

`Base.Checked.sub_with_overflow` – Function.

```
| Base.sub_with_overflow(x, y) -> (r, f)
```

Calculates $r = x - y$, with the flag `f` indicating whether overflow has occurred.

[source](#)

`Base.Checked.mul_with_overflow` – Function.

```
| Base.mul_with_overflow(x, y) -> (r, f)
```

Calculates $r = x * y$, with the flag `f` indicating whether overflow has occurred.

[source](#)

`Base.abs2` – Function.

```
| abs2(x)
```

Squared absolute value of `x`.

This can be faster than `abs(x)^2`, especially for complex numbers where `abs(x)` requires a square root via [hypot](#).

See also [abs](#), [conj](#), [real](#).

Examples

```
julia> abs2(-3)
9

julia> abs2(3.0 + 4.0im)
25.0

julia> sum(abs2, [1+2im, 3+4im]) # LinearAlgebra.norm(x)^2
30
```

[source](#)

`Base.copysign` – Function.

```
| copysign(x, y) -> z
```

Return z which has the magnitude of x and the same sign as y.

Examples

```
| julia> copysign(1, -2)
-1
| julia> copysign(-1, 2)
1
```

[source](#)

Base.sign – Function.

```
| sign(x)
```

Return zero if $x==0$ and $x/|x|$ otherwise (i.e., ± 1 for real x).

See also [signbit](#), [zero](#), [copysign](#), [flipsign](#).

Examples

```
| julia> sign(-4.0)
-1.0
| julia> sign(99)
1
| julia> sign(-0.0)
-0.0
| julia> sign(0 + im)
0.0 + 1.0im
```

[source](#)

Base.signbit – Function.

```
| signbit(x)
```

Return true if the value of the sign of x is negative, otherwise false.

See also [sign](#) and [copysign](#).

Examples

```
| julia> signbit(-4)
true
| julia> signbit(5)
false
| julia> signbit(5.5)
```

```

false

julia> signbit(-4.1)
true

```

[source](#)

Base.flipsign – Function.

```

flipsign(x, y)

```

Return x with its sign flipped if y is negative. For example `abs(x) = flipsign(x,x)`.

Examples

```

julia> flipsign(5, 3)
5

julia> flipsign(5, -3)
-5

```

[source](#)

Base.sqrt – Method.

```

sqrt(x)

```

Return \sqrt{x} . Throws `DomainError` for negative `Real` arguments. Use complex negative arguments instead. The prefix operator $\sqrt{}$ is equivalent to `sqrt`.

See also: [hypot](#).

Examples

```

julia> sqrt(big(81))
9.0

julia> sqrt(big(-81))
ERROR: DomainError with -81.0:
NaN result for non-NaN input.
Stacktrace:
 [1] sqrt(::BigFloat) at ./mpfr.jl:501
 [...]

julia> sqrt(big(complex(-81)))
0.0 + 9.0im

julia> .√(1:4)
4-element Vector{Float64}:
 1.0
 1.4142135623730951
 1.7320508075688772
 2.0

```

[source](#)

Base.isqrt – Function.

```
| isqrt(n::Integer)
```

Integer square root: the largest integer m such that $m*m \leq n$.

```
| julia> isqrt(5)
| 2
```

[source](#)

Base.Math.cbrt – Function.

```
| cbrt(x::Real)
```

Return the cube root of x , i.e. $x^{1/3}$. Negative values are accepted (returning the negative real root when $x < 0$).

The prefix operator $\sqrt[3]{x}$ is equivalent to `cbrt`.

Examples

```
| julia> cbrt(big(27))
| 3.0
|
| julia> cbrt(big(-27))
| -3.0
```

[source](#)

Base.real – Function.

```
| real(z)
```

Return the real part of the complex number z .

See also: [imag](#), [reim](#), [complex](#), [isreal](#), [Real](#).

Examples

```
| julia> real(1 + 3im)
| 1
```

[source](#)

```
| real(T::Type)
```

Return the type that represents the real part of a value of type T . e.g: for $T == \text{Complex}\{R\}$, returns R . Equivalent to `typeof(real(zero(T)))`.

Examples

```
| julia> real(Complex{Int})
| Int64
|
| julia> real(Float64)
| Float64
```

source

```
| real(A::AbstractArray)
```

Return an array containing the real part of each entry in array A.

Equivalent to `real.(A)`, except that when `eltype(A) <: Real` A is returned without copying, and that when A has zero dimensions, a 0-dimensional array is returned (rather than a scalar).

Examples

```
| julia> real([1, 2im, 3 + 4im])
3-element Vector{Int64}:
 1
 0
 3

| julia> real(fill(2 - im))
0-dimensional Array{Int64, 0}:
 2
```

source

`Base.imag` – Function.

```
| imag(z)
```

Return the imaginary part of the complex number z.

See also: [conj](#), [reim](#), [adjoint](#), [angle](#).

Examples

```
| julia> imag(1 + 3im)
3
```

source

```
| imag(A::AbstractArray)
```

Return an array containing the imaginary part of each entry in array A.

Equivalent to `imag.(A)`, except that when A has zero dimensions, a 0-dimensional array is returned (rather than a scalar).

Examples

```
| julia> imag([1, 2im, 3 + 4im])
3-element Vector{Int64}:
 0
 2
 4

| julia> imag(fill(2 - im))
0-dimensional Array{Int64, 0}:
-1
```

[source](#)

Base.`reim` – Function.

```
| reim(z)
```

Return a tuple of the real and imaginary parts of the complex number `z`.

Examples

```
| julia> reim(1 + 3im)
| (1, 3)
```

[source](#)

```
| reim(A::AbstractArray)
```

Return a tuple of two arrays containing respectively the real and the imaginary part of each entry in `A`.

Equivalent to `(real.(A), imag.(A))`, except that when `eltype(A) <: Real` `A` is returned without copying to represent the real part, and that when `A` has zero dimensions, a 0-dimensional array is returned (rather than a scalar).

Examples

```
| julia> reim([1, 2im, 3 + 4im])
| ([1, 0, 3], [0, 2, 4])

| julia> reim(fill(2 - im))
| (fill(2), fill(-1))
```

[source](#)

Base.`conj` – Function.

```
| conj(z)
```

Compute the complex conjugate of a complex number `z`.

See also: [angle](#), [adjoint](#).

Examples

```
| julia> conj(1 + 3im)
| 1 - 3im
```

[source](#)

```
| conj(A::AbstractArray)
```

Return an array containing the complex conjugate of each entry in array `A`.

Equivalent to `conj.(A)`, except that when `eltype(A) <: Real` `A` is returned without copying, and that when `A` has zero dimensions, a 0-dimensional array is returned (rather than a scalar).

Examples

```
julia> conj([1, 2im, 3 + 4im])
3-element Vector{Complex{Int64}}:
 1 + 0im
 0 - 2im
 3 - 4im

julia> conj(fill(2 - im))
0-dimensional Array{Complex{Int64}, 0}:
 2 + 1im
```

[source](#)

Base.angle – Function.

```
| angle(z)
```

Compute the phase angle in radians of a complex number z .

See also: [atan](#), [cis](#).

Examples

```
julia> rad2deg(angle(1 + im))
45.0

julia> rad2deg(angle(1 - im))
-45.0

julia> rad2deg(angle(-1 - im))
-135.0
```

[source](#)

Base.cis – Function.

```
| cis(x)
```

More efficient method for $\exp(im*x)$ by using Euler's formula: $\cos(x) + i\sin(x) = \exp(ix)$.

See also [cispi](#), [sincos](#), [exp](#), [angle](#).

Examples

```
julia> cis(π) ≈ -1
true
```

[source](#)

Base.cispi – Function.

```
| cispi(x)
```

More accurate method for $\cis(\pi*x)$ (especially for large x).

See also [cis](#), [sincospi](#), [exp](#), [angle](#).

Examples

```
julia> cispi(10000)
1.0 + 0.0im

julia> cispi(0.25 + 1im)
0.030556854645954562 + 0.03055685464595456im
```

Julia 1.6

This function requires Julia 1.6 or later.

[source](#)

`Base.binomial` – Function.

```
| binomial(n::Integer, k::Integer)
```

The binomial coefficient $\binom{n}{k}$, being the coefficient of the k th term in the polynomial expansion of $(1+x)^n$.

If n is non-negative, then it is the number of ways to choose k out of n items:

$$\binom{n}{k} = \frac{n!}{k!(n-k)!}$$

where $n!$ is the [factorial](#) function.

If n is negative, then it is defined in terms of the identity

$$\binom{n}{k} = (-1)^k \binom{k-n-1}{k}$$

See also [factorial](#).

Examples

```
julia> binomial(5, 3)
10

julia> factorial(5) ÷ (factorial(5-3) * factorial(3))
10

julia> binomial(-5, 3)
-35
```

External links

- [Binomial coefficient](#) on Wikipedia.

[source](#)

```
| binomial(x::Number, k::Integer)
```

The generalized binomial coefficient, defined for $k \geq 0$ by the polynomial

$$\frac{1}{k!} \prod_{j=0}^{k-1} (x - j)$$

When $k < 0$ it returns zero.

For the case of integer x , this is equivalent to the ordinary integer binomial coefficient

$$\binom{n}{k} = \frac{n!}{k!(n-k)!}$$

Further generalizations to non-integer k are mathematically possible, but involve the Gamma function and/or the beta function, which are not provided by the Julia standard library but are available in external packages such as [SpecialFunctions.jl](#).

External links

- [Binomial coefficient](#) on Wikipedia.

[source](#)

Base.factorial – Function.

```
| factorial(n::Integer)
```

Factorial of n . If n is an [Integer](#), the factorial is computed as an integer (promoted to at least 64 bits). Note that this may overflow if n is not small, but you can use `factorial(big(n))` to compute the result exactly in arbitrary precision.

See also [binomial](#).

Examples

```
julia> factorial(6)
720

julia> factorial(21)
ERROR: OverflowError: 21 is too large to look up in the table; consider using
↪ `factorial(big(21))` instead
Stacktrace:
[...]

julia> factorial(big(21))
51090942171709440000
```

External links

- [Factorial](#) on Wikipedia.

[source](#)

Base.gcd – Function.

```
| gcd(x, y...)
```

Greatest common (positive) divisor (or zero if all arguments are zero). The arguments may be integer and rational numbers.

Julia 1.4

Rational arguments require Julia 1.4 or later.

Examples

```
julia> gcd(6, 9)
3
julia> gcd(6, -9)
3
julia> gcd(6, 0)
6
julia> gcd(0, 0)
0
julia> gcd(1//3, 2//3)
1//3
julia> gcd(1//3, -2//3)
1//3
julia> gcd(1//3, 2)
1//3
julia> gcd(0, 0, 10, 15)
5
```

[source](#)

Base.lcm – Function.

```
| lcm(x, y...)
```

Least common (positive) multiple (or zero if any argument is zero). The arguments may be integer and rational numbers.

Julia 1.4

Rational arguments require Julia 1.4 or later.

Examples

```
julia> lcm(2, 3)
6

julia> lcm(-2, 3)
6

julia> lcm(0, 3)
0

julia> lcm(0, 0)
0

julia> lcm(1//3, 2//3)
2//3

julia> lcm(1//3, -2//3)
2//3

julia> lcm(1//3, 2)
2//1

julia> lcm(1, 3, 5, 7)
105
```

[source](#)

Base.gcdx – Function.

```
| gcdx(a, b)
```

Computes the greatest common (positive) divisor of a and b and their Bézout coefficients, i.e. the integer coefficients u and v that satisfy $ua + vb = d = \gcd(a, b)$. $\text{gcdx}(a, b)$ returns (d, u, v) .

The arguments may be integer and rational numbers.

Julia 1.4

Rational arguments require Julia 1.4 or later.

Examples

```
julia> gcdx(12, 42)
(6, -3, 1)

julia> gcdx(240, 46)
(2, -9, 47)
```

Note

Bézout coefficients are not uniquely defined. `gcdx` returns the minimal Bézout coefficients that are computed by the extended Euclidean algorithm. (Ref: D. Knuth, TAOCP, 2/e, p. 325, Algorithm X.) For signed integers, these coefficients u and v are minimal in the sense that $|u| < |b/d|$ and $|v| < |a/d|$. Furthermore, the signs of u and v are chosen so that d is positive. For unsigned integers, the coefficients u and v might be near their `typemax`, and the identity then holds only via the unsigned integers' modulo arithmetic.

[source](#)

Base.ispow2 – Function.

```
| ispow2(n::Number) -> Bool
```

Test whether n is an integer power of two.

See also [count_ones](#), [prevpow](#), [nextpow](#).

Examples

```
julia> ispow2(4)
true

julia> ispow2(5)
false

julia> ispow2(4.5)
false

julia> ispow2(0.25)
true

julia> ispow2(1//8)
true
```

Julia 1.6

Support for non-Integer arguments was added in Julia 1.6.

[source](#)

Base.nextpow – Function.

```
| nextpow(a, x)
```

The smallest a^n not less than x, where n is a non-negative integer. a must be greater than 1, and x must be greater than 0.

See also [prevpow](#).

Examples

```
julia> nextpow(2, 7)
8

julia> nextpow(2, 9)
16

julia> nextpow(5, 20)
25

julia> nextpow(4, 16)
16
```

[source](#)

Base.prevpow – Function.

```
| prevpow(a, x)
```

The largest a^n not greater than x , where n is a non-negative integer. a must be greater than 1, and x must not be less than 1.

See also [nextpow](#), [isqrt](#).

Examples

```
julia> prevpow(2, 7)
4

julia> prevpow(2, 9)
8

julia> prevpow(5, 20)
5

julia> prevpow(4, 16)
16
```

[source](#)

Base.nextprod – Function.

```
| nextprod(factors::Union{Tuple, AbstractVector}, n)
```

Next integer greater than or equal to n that can be written as $\prod k_i^{p_i}$ for integers p_1, p_2 , etcetera, for factors k_i in factors.

Examples

```
julia> nextprod((2, 3), 105)
108

julia> 2^2 * 3^3
108
```

Julia 1.6

The method that accepts a tuple requires Julia 1.6 or later.

[source](#)

Base.invmod – Function.

```
| invmod(n, m)
```

Take the inverse of n modulo m : y such that $ny = 1 \pmod{m}$, and $\text{div}(y, m) = 0$. This will throw an error if $m = 0$, or if $\text{gcd}(n, m) \neq 1$.

Examples

```
julia> invmod(2, 5)
3

julia> invmod(2, 3)
2

julia> invmod(5, 6)
5
```

[source](#)

Base.powermod – Function.

```
powermod(x::Integer, p::Integer, m)
```

Compute $x^p \pmod{m}$.

Examples

```
julia> powermod(2, 6, 5)
4

julia> mod(2^6, 5)
4

julia> powermod(5, 2, 20)
5

julia> powermod(5, 2, 19)
6

julia> powermod(5, 3, 19)
11
```

[source](#)

Base.ndigits – Function.

```
ndigits(n::Integer; base::Integer=10, pad::Integer=1)
```

Compute the number of digits in integer n written in base $base$ ($base$ must not be in $[-1, 0, 1]$), optionally padded with zeros to a specified size (the result will never be less than pad).

See also [digits](#), [count_ones](#).

Examples

```
julia> ndigits(0)
1

julia> ndigits(12345)
5

julia> ndigits(1022, base=16)
3
```

```
julia> string(1022, base=16)
"3fe"

julia> ndigits(123, pad=5)
5

julia> ndigits(-123)
3
```

[source](#)

`Base.add_sum` – Function.

```
| Base.add_sum(x, y)
```

The reduction operator used in `sum`. The main difference from `+` is that small integers are promoted to `Int`/`UInt`.

[source](#)

`Base.widemul` – Function.

```
| widemul(x, y)
```

Multiply `x` and `y`, giving the result as a larger type.

See also [promote](#), [Base.add_sum](#).

Examples

```
julia> widemul(Float32(3.0), 4.0) isa BigFloat
true

julia> typemax(Int8) * typemax(Int8)
1

julia> widemul(typemax(Int8), typemax(Int8)) # == 127^2
16129
```

[source](#)

`Base.Math.evalpoly` – Function.

```
| evalpoly(x, p)
```

Evaluate the polynomial $\sum_k x^{k-1} p[k]$ for the coefficients `p[1]`, `p[2]`, ...; that is, the coefficients are given in ascending order by power of `x`. Loops are unrolled at compile time if the number of coefficients is statically known, i.e. when `p` is a `Tuple`. This function generates efficient code using Horner's method if `x` is real, or using a Goertzel-like ¹ algorithm if `x` is complex.

¹Donald Knuth, Art of Computer Programming, Volume 2: Seminumerical Algorithms, Sec. 4.6.4.

Julia 1.4

This function requires Julia 1.4 or later.

Example

```
julia> evalpoly(2, (1, 2, 3))
17
```

[source](#)

Base.Math.@evalpoly – Macro.

```
@evalpoly(z, c...)
```

Evaluate the polynomial $\sum_k z^{k-1} c[k]$ for the coefficients $c[1], c[2], \dots$; that is, the coefficients are given in ascending order by power of z . This macro expands to efficient inline code that uses either Horner's method or, for complex z , a more efficient Goertzel-like algorithm.

See also [evalpoly](#).

Examples

```
julia> @evalpoly(3, 1, 0, 1)
10

julia> @evalpoly(2, 1, 0, 1)
5

julia> @evalpoly(2, 1, 1, 1)
7
```

[source](#)

Base.FastMath.@fastmath – Macro.

```
@fastmath expr
```

Execute a transformed version of the expression, which calls functions that may violate strict IEEE semantics. This allows the fastest possible operation, but results are undefined – be careful when doing this, as it may change numerical results.

This sets the [LLVM Fast-Math flags](#), and corresponds to the `-ffast-math` option in clang. See [the notes on performance annotations](#) for more details.

Examples

```
julia> @fastmath 1+2
3

julia> @fastmath(sin(3))
0.1411200080598672
```

[source](#)

43.3 Customizable binary operators

Some unicode characters can be used to define new binary operators that support infix notation. For example $\otimes(x,y) = \text{kron}(x,y)$ defines the \otimes (otimes) function to be the Kronecker product, and one can call it as binary operator using infix syntax: $C = A \otimes B$ as well as with the usual prefix syntax $C = \otimes(A,B)$.

Other characters that support such extensions include \odot and \oplus .

The complete list is in the parser code: <https://github.com/JuliaLang/julia/blob/master/src/julia-parser.scm>

Those that are parsed like $*$ (in terms of precedence) include $*$ $/$ \div $\%$ $\&$ \cdot \circ \times $|\backslash|$ \cap \wedge \otimes \oslash \ominus \oplus \boxtimes \boxminus Π $*$ \bullet \diamond \star λ \cup \triangleright and those that are parsed like $+$ include $+$ $-$ $|\backslash|$ \oplus \ominus \boxplus \boxminus $|++|$ \cup \vee \sqcup \pm \mp $\dot{+}$ $\dot{-}$ \cup $\underline{\vee}$ γ $\#$ $\#$

There are many others that are related to arrows, comparisons, and powers.

Chapter 44

Numbers

44.1 Standard Numeric Types

A type tree for all subtypes of Number in Base is shown below. Abstract types have been marked, the rest are concrete types.

```
Number (Abstract Type)├
  Complex└
    Real (Abstract Type)
      ├── AbstractFloat (Abstract Type)
      │   ├── Float16
      │   ├── Float32
      │   ├── Float64
      │   └── BigFloat
      ├── Integer (Abstract Type)
      │   ├── Bool
      │   ├── Signed (Abstract Type)
      │   │   ├── Int8
      │   │   ├── Int16
      │   │   ├── Int32
      │   │   ├── Int64
      │   │   ├── Int128
      │   │   └── BigInt
      │   └── Unsigned (Abstract Type)
      │       ├── UInt8
      │       ├── UInt16
      │       ├── UInt32
      │       ├── UInt64
      │       └── UInt128
      ├── Rational
      └── AbstractIrrational (Abstract Type)
          └── Irrational
```

Abstract number types

Core.Number - Type.

| **Number**

Abstract supertype for all number types.

[source](#)

Core.Real – Type.

```
| Real <: Number
```

Abstract supertype for all real numbers.

[source](#)

Core.AbstractFloat – Type.

```
| AbstractFloat <: Real
```

Abstract supertype for all floating point numbers.

[source](#)

Core.Integer – Type.

```
| Integer <: Real
```

Abstract supertype for all integers.

[source](#)

Core.Signed – Type.

```
| Signed <: Integer
```

Abstract supertype for all signed integers.

[source](#)

Core.Unsigned – Type.

```
| Unsigned <: Integer
```

Abstract supertype for all unsigned integers.

[source](#)

Base.AbstractIrrational – Type.

```
| AbstractIrrational <: Real
```

Number type representing an exact irrational value, which is automatically rounded to the correct precision in arithmetic operations with other numeric quantities.

Subtypes `MyIrrational <: AbstractIrrational` should implement at least `==(::MyIrrational, ::MyIrrational)`, `hash(x::MyIrrational, h::UInt)`, and `convert(::Type{F}, x::MyIrrational)` where `{F <: Union{BigFloat, Float32, Float64}}`.

If a subtype is used to represent values that may occasionally be rational (e.g. a square-root type that represents \sqrt{n} for integers n will give a rational result when n is a perfect square), then it should also implement `isinteger`, `iszero`, `isone`, and `==` with `Real` values (since all of these default to `false` for `AbstractIrrational` types), as well as defining `hash` to equal that of the corresponding `Rational`.

[source](#)

Concrete number types

Core.Float16 – Type.

```
| Float16 <: AbstractFloat
```

16-bit floating point number type (IEEE 754 standard).

Binary format: 1 sign, 5 exponent, 10 fraction bits.

[source](#)

Core.Float32 – Type.

```
| Float32 <: AbstractFloat
```

32-bit floating point number type (IEEE 754 standard).

Binary format: 1 sign, 8 exponent, 23 fraction bits.

[source](#)

Core.Float64 – Type.

```
| Float64 <: AbstractFloat
```

64-bit floating point number type (IEEE 754 standard).

Binary format: 1 sign, 11 exponent, 52 fraction bits.

[source](#)

Base.MPFR.BigFloat – Type.

```
| BigFloat <: AbstractFloat
```

Arbitrary precision floating point number type.

[source](#)

Core.Bool – Type.

```
| Bool <: Integer
```

Boolean type, containing the values `true` and `false`.

`Bool` is a kind of number: `false` is numerically equal to 0 and `true` is numerically equal to 1. Moreover, `false` acts as a multiplicative "strong zero":

```
julia> false == 0
true

julia> true == 1
true

julia> 0 * NaN
NaN

julia> false * NaN
0.0
```

See also: [digits](#), [iszero](#), [NaN](#).

[source](#)

Core.Int8 – Type.

| **Int8** <: **Signed**

8-bit signed integer type.

[source](#)

Core.UInt8 – Type.

| **UInt8** <: **Unsigned**

8-bit unsigned integer type.

[source](#)

Core.Int16 – Type.

| **Int16** <: **Signed**

16-bit signed integer type.

[source](#)

Core.UInt16 – Type.

| **UInt16** <: **Unsigned**

16-bit unsigned integer type.

[source](#)

Core.Int32 – Type.

| **Int32** <: **Signed**

32-bit signed integer type.

[source](#)

Core.UInt32 – Type.

| **UInt32** <: **Unsigned**

32-bit unsigned integer type.

[source](#)

Core.Int64 – Type.

| **Int64** <: **Signed**

64-bit signed integer type.

[source](#)

Core.UInt64 – Type.

| **UInt64** <: **Unsigned**

64-bit unsigned integer type.

[source](#)

Core.Int128 – Type.

| **Int128** <: **Signed**

128-bit signed integer type.

[source](#)

Core.UInt128 – Type.

| **UInt128** <: **Unsigned**

128-bit unsigned integer type.

[source](#)

Base.GMP.BigInt – Type.

| **BigInt** <: **Signed**

Arbitrary precision integer type.

[source](#)

Base.Complex – Type.

| **Complex**{T<:Real} <: **Number**

Complex number type with real and imaginary part of type T.

ComplexF16, ComplexF32 and ComplexF64 are aliases for Complex{Float16}, Complex{Float32} and Complex{Float64} respectively.

See also: [Real](#), [complex](#), [real](#).

[source](#)

Base.Rational – Type.

| **Rational**{T<:Integer} <: **Real**

Rational number type, with numerator and denominator of type T. Rationals are checked for overflow.

[source](#)

Base.Irrational – Type.

| **Irrational**{sym} <: AbstractIrrational

Number type representing an exact irrational value denoted by the symbol sym, such as π , and γ .

See also [AbstractIrrational](#).

[source](#)

44.2 Data Formats

Base.digits – Function.

```
| digits([T<:Integer], n::Integer; base::T = 10, pad::Integer = 1)
```

Return an array with element type T (default Int) of the digits of n in the given base, optionally padded with zeros to a specified size. More significant digits are at higher indices, such that $n == \sum(\text{digits}[k] * \text{base}^{(k-1)} \text{ for } k=1:\text{length}(\text{digits}))$.

See also [ndigits](#), [digits!](#), and for base 2 also [bitstring](#), [count_ones](#).

Examples

```
| julia> digits(10)
2-element Vector{Int64}:
 0
 1

julia> digits(10, base = 2)
4-element Vector{Int64}:
 0
 1
 0
 1

julia> digits(-256, base = 10, pad = 5)
5-element Vector{Int64}:
 -6
 -5
 -2
  0
  0

julia> n = rand(-999:999);

julia> n == evalpoly(13, digits(n, base = 13))
true
```

[source](#)

Base.digits! – Function.

```
| digits!(array, n::Integer; base::Integer = 10)
```

Fills an array of the digits of n in the given base. More significant digits are at higher indices. If the array length is insufficient, the least significant digits are filled up to the array length. If the array length is excessive, the excess portion is filled with zeros.

Examples

```
| julia> digits!([2, 2, 2, 2], 10, base = 2)
4-element Vector{Int64}:
 0
```

```
julia> parse{Int, "1234"}
1234

julia> parse{Int, "1234", base = 5}
194

julia> parse{Int, "afc", base = 16}
2812

julia> parse{Float64, "1.2e-3"}
0.0012

julia> parse{Complex{Float64}, "3.2e-1 + 4.5im"}
0.32 + 4.5im
```

[source](#)

`Base.parse` – Function.

```
| parse{type, str; base}
```

Like `parse`, but returns either a value of the requested type, or `nothing` if the string does not contain a valid number.

[source](#)

`Base.big` – Function.

```
| big(x)
```

Convert a number to a maximum precision representation (typically `BigInt` or `BigFloat`). See `BigFloat` for information about some pitfalls with floating-point numbers.

[source](#)

`Base.signed` – Function.

```
| signed{T::Integer}
```

Convert an integer bitstype to the signed type of the same size.

Examples

```
julia> signed{UInt16}
Int16
julia> signed{UInt64}
Int64
```

[source](#)

```
| signed(x)
```

Convert a number to a signed integer. If the argument is unsigned, it is reinterpreted as signed without checking for overflow.

See also: `unsigned`, `sign`, `signbit`.

[source](#)

Base.unsigned – Function.

```
| unsigned(T::Integer)
```

Convert an integer bitstype to the unsigned type of the same size.

Examples

```
| julia> unsigned(Int16)
  UInt16
| julia> unsigned(UInt64)
  UInt64
```

[source](#)

Base.float – Method.

```
| float(x)
```

Convert a number or array to a floating point data type.

See also: [complex](#), [oftype](#), [convert](#).

Examples

```
| julia> float(1:1000)
  1.0:1.0:1000.0
| julia> float(typemax(Int32))
  2.147483647e9
```

[source](#)

Base.Math.significand – Function.

```
| significand(x)
```

Extract the significand (a.k.a. mantissa) of a floating-point number. If x is a non-zero finite number, then the result will be a number of the same type and sign as x , and whose absolute value is on the interval $[1, 2)$. Otherwise x is returned.

Examples

```
| julia> significand(15.2)
  1.9
| julia> significand(-15.2)
 -1.9
| julia> significand(-15.2) * 2^3
 -15.2
| julia> significand(-Inf), significand(Inf), significand(NaN)
 (-Inf, Inf, NaN)
```

[source](#)

Base.Math.exponent – Function.

| exponent(x) -> **Int**

Returns the largest integer y such that $2^y \leq \text{abs}(x)$. For a normalized floating-point number x , this corresponds to the exponent of x .

Examples

```
julia> exponent(8)
3

julia> exponent(64//1)
6

julia> exponent(6.5)
2

julia> exponent(16.0)
4

julia> exponent(3.142e-4)
-12
```

[source](#)

Base.complex – Method.

| complex(r, [i])

Convert real numbers or arrays to complex. i defaults to zero.

Examples

```
julia> complex(7)
7 + 0im

julia> complex([1, 2, 3])
3-element Vector{Complex{Int64}}:
 1 + 0im
 2 + 0im
 3 + 0im
```

[source](#)

Base.bswap – Function.

| bswap(n)

Reverse the byte order of n .

(See also [ntoh](#) and [hton](#) to convert between the current native byte order and big-endian order.)

Examples

[source](#)

`Base.hex2bytes!` – Function.

```
| hex2bytes!(dest::AbstractVector{UInt8}, itr)
```

Convert an iterable `itr` of bytes representing a hexadecimal string to its binary representation, similar to `hex2bytes` except that the output is written in-place to `dest`. The length of `dest` must be half the length of `itr`.

Julia 1.7

Calling `hex2bytes!` with iterators producing `UInt8` requires version 1.7. In earlier versions, you can collect the iterable before calling instead.

[source](#)

`Base.bytes2hex` – Function.

```
| bytes2hex(itr) -> String
| bytes2hex(io::IO, itr)
```

Convert an iterator `itr` of bytes to its hexadecimal string representation, either returning a `String` via `bytes2hex(itr)` or writing the string to an `io` stream via `bytes2hex(io, itr)`. The hexadecimal characters are all lowercase.

Julia 1.7

Calling `bytes2hex` with arbitrary iterators producing `UInt8` values requires Julia 1.7 or later. In earlier versions, you can collect the iterator before calling `bytes2hex`.

Examples

```
| julia> a = string(12345, base = 16)
| "3039"
|
| julia> b = hex2bytes(a)
| 2-element Vector{UInt8}:
| 0x30
| 0x39
|
| julia> bytes2hex(b)
| "3039"
```

[source](#)

44.3 General Number Functions and Constants

`Base.one` – Function.

```
| one(x)
| one(T::type)
```

Return a multiplicative identity for x : a value such that $\text{one}(x) * x == x * \text{one}(x) == x$. Alternatively $\text{one}(T)$ can take a type T , in which case one returns a multiplicative identity for any x of type T .

If possible, $\text{one}(x)$ returns a value of the same type as x , and $\text{one}(T)$ returns a value of type T . However, this may not be the case for types representing dimensionful quantities (e.g. time in days), since the multiplicative identity must be dimensionless. In that case, $\text{one}(x)$ should return an identity value of the same precision (and shape, for matrices) as x .

If you want a quantity that is of the same type as x , or of type T , even if x is dimensionful, use [oneunit](#) instead.

See also the [identity](#) function, and I in [LinearAlgebra](#) for the identity matrix.

Examples

```
julia> one(3.7)
1.0

julia> one{Int}
1

julia> import Dates; one(Dates.Day(1))
1
```

[source](#)

Base.oneunit – Function.

```
oneunit(x::T)
oneunit{T::Type}
```

Return $T(\text{one}(x))$, where T is either the type of the argument or (if a type is passed) the argument. This differs from [one](#) for dimensionful quantities: one is dimensionless (a multiplicative identity) while oneunit is dimensionful (of the same type as x , or of type T).

Examples

```
julia> oneunit(3.7)
1.0

julia> import Dates; oneunit(Dates.Day)
1 day
```

[source](#)

Base.zero – Function.

```
zero(x)
zero{T::Type}
```

Get the additive identity element for the type of x (x can also specify the type itself).

See also [iszero](#), [one](#), [oneunit](#), [oftype](#).

Examples

```
julia> zero(1)
0

julia> zero(big"2.0")
0.0

julia> zero(rand(2,2))
2×2 Matrix{Float64}:
 0.0  0.0
 0.0  0.0
```

[source](#)

Base.im – Constant.

```
| im
```

The imaginary unit.

See also: [imag](#), [angle](#), [complex](#).

Examples

```
julia> im * im
-1 + 0im

julia> (2.0 + 3im)^2
-5.0 + 12.0im
```

[source](#)

Base.MathConstants.pi – Constant.

```
| π
| pi
```

The constant pi.

Unicode π can be typed by writing `\pi` then pressing tab in the Julia REPL, and in many editors.

See also: [sinpi](#), [sincospi](#), [deg2rad](#).

Examples

```
julia> pi
π = 3.1415926535897...

julia> 1/2pi
0.15915494309189535
```

[source](#)

Base.MathConstants.e – Constant.

```
| e
```

The constant e .

Unicode e can be typed by writing `\euler` and pressing tab in the Julia REPL, and in many editors.

See also: [exp](#), [cis](#), [cispi](#).

Examples

```
julia>
= 2.7182818284590...

julia> log()
1

julia> ^{(im)\pi} \approx -1
true
```

[source](#)

`Base.MathConstants.catalan` – Constant.

```
| catalan
```

Catalan's constant.

Examples

```
julia> Base.MathConstants.catalan
catalan = 0.9159655941772...

julia> sum(log(x)/(1+x^2) for x in 1:0.01:10^6) * 0.01
0.9159466120554123
```

[source](#)

`Base.MathConstants.eulergamma` – Constant.

```
| \gamma
| eulergamma
```

Euler's constant.

Examples

```
julia> Base.MathConstants.eulergamma
\gamma = 0.5772156649015...

julia> dx = 10^-6;

julia> sum(-exp(-x) * log(x) for x in dx:dx:100) * dx
0.5772078382499133
```

[source](#)

`Base.MathConstants.golden` – Constant.

```
| φ  
| golden
```

The golden ratio.

Examples

```
| julia> Base.MathConstants.golden  
| φ = 1.6180339887498...  
  
| julia> (2ans - 1)^2 ≈ 5  
| true
```

[source](#)

Base.Inf – Constant.

```
| Inf, Inf64
```

Positive infinity of type `Float64`.

See also: [isfinite](#), [typemax](#), [NaN](#), [Inf32](#).

Examples

```
| julia> π/0  
| Inf  
  
| julia> +1.0 / -0.0  
| -Inf  
  
| julia> ^-Inf  
| 0.0
```

[source](#)

Base.Inf64 – Constant.

```
| Inf, Inf64
```

Positive infinity of type `Float64`.

See also: [isfinite](#), [typemax](#), [NaN](#), [Inf32](#).

Examples

```
| julia> π/0  
| Inf  
  
| julia> +1.0 / -0.0  
| -Inf  
  
| julia> ^-Inf  
| 0.0
```

[source](#)

Base.`Inf32` – Constant.

```
| Inf32
```

Positive infinity of type `Float32`.

[source](#)

Base.`Inf16` – Constant.

```
| Inf16
```

Positive infinity of type `Float16`.

[source](#)

Base.`NaN` – Constant.

```
| NaN, NaN64
```

A not-a-number value of type `Float64`.

See also: `isnan`, `missing`, `NaN32`, `Inf`.

Examples

```
julia> 0/0
NaN

julia> Inf - Inf
NaN

julia> NaN == NaN, isequal(NaN, NaN), NaN === NaN
(false, true, true)
```

[source](#)

Base.`NaN64` – Constant.

```
| NaN, NaN64
```

A not-a-number value of type `Float64`.

See also: `isnan`, `missing`, `NaN32`, `Inf`.

Examples

```
julia> 0/0
NaN

julia> Inf - Inf
NaN

julia> NaN == NaN, isequal(NaN, NaN), NaN === NaN
(false, true, true)
```

[source](#)

Base.NaN32 – Constant.

```
| NaN32
```

A not-a-number value of type `Float32`.

[source](#)

Base.NaN16 – Constant.

```
| NaN16
```

A not-a-number value of type `Float16`.

[source](#)

Base.issubnormal – Function.

```
| issubnormal(f) -> Bool
```

Test whether a floating point number is subnormal.

An IEEE floating point number is **subnormal** when its exponent bits are zero and its significand is not zero.

Examples

```
| julia> floatmin(Float32)
1.1754944f-38

julia> issubnormal(1.0f-37)
false

julia> issubnormal(1.0f-38)
true
```

[source](#)

Base.isfinite – Function.

```
| isfinite(f) -> Bool
```

Test whether a number is finite.

Examples

```
| julia> isfinite(5)
true

julia> isfinite(NaN32)
false
```

[source](#)

Base.isinf – Function.

```
| isinf(f) -> Bool
```

Test whether a number is infinite.

See also: [Inf](#), [iszero](#), [isfinite](#), [isnan](#).

[source](#)

Base.isnan – Function.

```
| isnan(f) -> Bool
```

Test whether a number value is a NaN, an indeterminate value which is neither an infinity nor a finite number ("not a number").

See also: [iszero](#), [isone](#), [isinf](#), [ismissing](#).

[source](#)

Base.iszero – Function.

```
| iszero(x)
```

Return true if `x == zero(x)`; if `x` is an array, this checks whether all of the elements of `x` are zero.

See also: [isone](#), [isinteger](#), [isfinite](#), [isnan](#).

Examples

```
julia> iszero(0.0)
true

julia> iszero([1, 9, 0])
false

julia> iszero([false, 0, 0])
true
```

[source](#)

Base.isone – Function.

```
| isone(x)
```

Return true if `x == one(x)`; if `x` is an array, this checks whether `x` is an identity matrix.

Examples

```
julia> isone(1.0)
true

julia> isone([1 0; 0 2])
false

julia> isone([1 0; 0 true])
true
```

[source](#)

Base.nextfloat – Function.

```
| nextfloat(x::AbstractFloat, n::Integer)
```

The result of n iterative applications of nextfloat to x if $n \geq 0$, or $-n$ applications of prevfloat if $n < 0$.

[source](#)

```
| nextfloat(x::AbstractFloat)
```

Return the smallest floating point number y of the same type as x such $x < y$. If no such y exists (e.g. if x is Inf or NaN), then return x .

See also: [prevfloat](#), [eps](#), [issubnormal](#).

[source](#)

Base.prevfloat – Function.

```
| prevfloat(x::AbstractFloat, n::Integer)
```

The result of n iterative applications of prevfloat to x if $n \geq 0$, or $-n$ applications of nextfloat if $n < 0$.

[source](#)

```
| prevfloat(x::AbstractFloat)
```

Return the largest floating point number y of the same type as x such $y < x$. If no such y exists (e.g. if x is -Inf or NaN), then return x .

[source](#)

Base.isinteger – Function.

```
| isinteger(x) -> Bool
```

Test whether x is numerically equal to some integer.

Examples

```
| julia> isinteger(4.0)
true
```

[source](#)

Base.isreal – Function.

```
| isreal(x) -> Bool
```

Test whether x or all its elements are numerically equal to some real number including infinities and NaNs. isreal(x) is true if isequal(x , real(x)) is true.

Examples

```
julia> isreal(5.)
true

julia> isreal(1 - 3im)
false

julia> isreal(Inf + 0im)
true

julia> isreal([4.; complex(0,1)])
false
```

[source](#)

Core.Float32 – Method.

```
Float32(x [, mode::RoundingMode])
```

Create a Float32 from x. If x is not exactly representable then mode determines how x is rounded.

Examples

```
julia> Float32(1/3, RoundDown)
0.3333333f0

julia> Float32(1/3, RoundUp)
0.33333334f0
```

See [RoundingMode](#) for available rounding modes.

[source](#)

Core.Float64 – Method.

```
Float64(x [, mode::RoundingMode])
```

Create a Float64 from x. If x is not exactly representable then mode determines how x is rounded.

Examples

```
julia> Float64(pi, RoundDown)
3.141592653589793

julia> Float64(pi, RoundUp)
3.1415926535897936
```

See [RoundingMode](#) for available rounding modes.

[source](#)

Base.Rounding.rounding – Function.

```
rounding(T)
```

Get the current floating point rounding mode for type `T`, controlling the rounding of basic arithmetic functions (`+`, `-`, `*`, `/` and `sqrt`) and type conversion.

See [RoundingMode](#) for available modes.

[source](#)

`Base.Rounding.setrounding` – Method.

```
| setrounding(T, mode)
```

Set the rounding mode of floating point type `T`, controlling the rounding of basic arithmetic functions (`+`, `-`, `*`, `/` and `sqrt`) and type conversion. Other numerical functions may give incorrect or invalid values when using rounding modes other than the default [RoundNearest](#).

Note that this is currently only supported for `T == BigInt`.

Warning

This function is not thread-safe. It will affect code running on all threads, but its behavior is undefined if called concurrently with computations that use the setting.

[source](#)

`Base.Rounding.setrounding` – Method.

```
| setrounding(f: Function, T, mode)
```

Change the rounding mode of floating point type `T` for the duration of `f`. It is logically equivalent to:

```
| old = rounding(T)
| setrounding(T, mode)
| f()
| setrounding(T, old)
```

See [RoundingMode](#) for available rounding modes.

[source](#)

`Base.Rounding.get_zero_subnormals` – Function.

```
| get_zero_subnormals() -> Bool
```

Return `false` if operations on subnormal floating-point values ("denormals") obey rules for IEEE arithmetic, and `true` if they might be converted to zeros.

Warning

This function only affects the current thread.

[source](#)

`Base.Rounding.set_zero_subnormals` – Function.

```
| set_zero_subnormals(yes: Bool) -> Bool
```

If `yes` is false, subsequent floating-point operations follow rules for IEEE arithmetic on subnormal values ("denormals"). Otherwise, floating-point operations are permitted (but not required) to convert subnormal inputs or outputs to zero. Returns `true` unless `yes==true` but the hardware does not support zeroing of subnormal numbers.

`set_zero_subnormals(true)` can speed up some computations on some hardware. However, it can break identities such as `(x-y==0) == (x==y)`.

Warning

This function only affects the current thread.

[source](#)

Integers

`Base.count_ones` – Function.

```
| count_ones(x::Integer) -> Integer
```

Number of ones in the binary representation of `x`.

Examples

```
| julia> count_ones(7)
3
| julia> count_ones(Int32(-1))
32
```

[source](#)

`Base.count_zeros` – Function.

```
| count_zeros(x::Integer) -> Integer
```

Number of zeros in the binary representation of `x`.

Examples

```
| julia> count_zeros(Int32(2 ^ 16 - 1))
16
| julia> count_zeros(-1)
0
```

[source](#)

`Base.leading_zeros` – Function.

```
| leading_zeros(x::Integer) -> Integer
```

Number of zeros leading the binary representation of `x`.

Examples

```
| julia> leading_zeros(Int32(1))  
| 31
```

[source](#)

Base.leading_ones – Function.

```
| leading_ones(x::Integer) -> Integer
```

Number of ones leading the binary representation of x.

Examples

```
| julia> leading_ones(UInt32(2 ^ 32 - 2))  
| 31
```

[source](#)

Base.trailing_zeros – Function.

```
| trailing_zeros(x::Integer) -> Integer
```

Number of zeros trailing the binary representation of x.

Examples

```
| julia> trailing_zeros(2)  
| 1
```

[source](#)

Base.trailing_ones – Function.

```
| trailing_ones(x::Integer) -> Integer
```

Number of ones trailing the binary representation of x.

Examples

```
| julia> trailing_ones(3)  
| 2
```

[source](#)

Base.isodd – Function.

```
| isodd(x::Number) -> Bool
```

Return true if x is an odd integer (that is, an integer not divisible by 2), and false otherwise.

Julia 1.7

Non-Integer arguments require Julia 1.7 or later.

Examples

```
julia> isodd(9)
true

julia> isodd(10)
false
```

[source](#)

`Base.iseven` – Function.

```
iseven(x::Number) -> Bool
```

Return true if x is an even integer (that is, an integer divisible by 2), and false otherwise.

Julia 1.7

Non-Integer arguments require Julia 1.7 or later.

Examples

```
julia> iseven(9)
false

julia> iseven(10)
true
```

[source](#)

`Core.@int128_str` – Macro.

```
@int128_str str
```

Parse str as an `Int128`. Throw an `ArgumentError` if the string is not a valid integer.

Examples

```
julia> int128"123456789123"
123456789123

julia> int128"123456789123.4"
ERROR: LoadError: ArgumentError: invalid base 10 digit '.' in "123456789123.4"
[...]
```

[source](#)

`Core.@uint128_str` – Macro.

```
@uint128_str str
```

Parse str as an `UInt128`. Throw an `ArgumentError` if the string is not a valid integer.

Examples

[source](#)

Base.precision – Function.

```
| precision(num::AbstractFloat; base::Integer=2)
| precision(T::Type; base::Integer=2)
```

Get the precision of a floating point number, as defined by the effective number of bits in the significand, or the precision of a floating-point type T (its current default, if T is a variable-precision type like [BigFloat](#)).

If base is specified, then it returns the maximum corresponding number of significand digits in that base.

Julia 1.8

The base keyword requires at least Julia 1.8.

[source](#)

Base.MPFR.setprecision – Function.

```
| setprecision([T=BigFloat,] precision::Int; base=2)
```

Set the precision (in bits, by default) to be used for T arithmetic. If base is specified, then the precision is the minimum required to give at least precision digits in the given base.

Warning

This function is not thread-safe. It will affect code running on all threads, but its behavior is undefined if called concurrently with computations that use the setting.

Julia 1.8

The base keyword requires at least Julia 1.8.

[source](#)

```
| setprecision(f::Function, [T=BigFloat,] precision::Integer; base=2)
```

Change the T arithmetic precision (in the given base) for the duration of f. It is logically equivalent to:

```
| old = precision(BigFloat)
| setprecision(BigFloat, precision)
| f()
| setprecision(BigFloat, old)
```

Often used as `setprecision(T, precision) do ... end`

Note: `nextfloat()`, `prevfloat()` do not use the precision mentioned by `setprecision`.

Julia 1.8

The base keyword requires at least Julia 1.8.

[source](#)

Base.GMP.BigInt – Method.

| **BigInt**(x)

Create an arbitrary precision integer. x may be an Int (or anything that can be converted to an Int). The usual mathematical operators are defined for this type, and results are promoted to a [BigInt](#).

Instances can be constructed from strings via [parse](#), or using the big string literal.

Examples

```
julia> parse(BigInt, "42")
42

julia> big"313"
313

julia> BigInt(10)^19
10000000000000000000
```

[source](#)

Core.@big_str – Macro.

| **@big_str** str

Parse a string into a [BigInt](#) or [BigFloat](#), and throw an ArgumentError if the string is not a valid number. For integers _ is allowed in the string as a separator.

Examples

```
julia> big"123_456"
123456

julia> big"7891.5"
7891.5

julia> big"_"
ERROR: ArgumentError: invalid number format _ for BigInt or BigFloat
[...]
```

[source](#)

Chapter 45

Strings

Core.AbstractString – Type.

The AbstractString type is the supertype of all string implementations in Julia. Strings are encodings of sequences of [Unicode](#) code points as represented by the AbstractChar type. Julia makes a few assumptions about strings:

- Strings are encoded in terms of fixed-size "code units"
 - Code units can be extracted with `codeunit(s, i)`
 - The first code unit has index 1
 - The last code unit has index `ncodeunits(s)`
 - Any index i such that $1 \leq i \leq \text{ncodeunits}(s)$ is in bounds
- String indexing is done in terms of these code units:
 - Characters are extracted by `s[i]` with a valid string index i
 - Each AbstractChar in a string is encoded by one or more code units
 - Only the index of the first code unit of an AbstractChar is a valid index
 - The encoding of an AbstractChar is independent of what precedes or follows it
 - String encodings are [self-synchronizing] – i.e. `isvalid(s, i)` is $O(1)$

[self-synchronizing]: https://en.wikipedia.org/wiki/Self-synchronizing_code

Some string functions that extract code units, characters or substrings from strings error if you pass them out-of-bounds or invalid string indices. This includes `codeunit(s, i)` and `s[i]`. Functions that do string index arithmetic take a more relaxed approach to indexing and give you the closest valid string index when in-bounds, or when out-of-bounds, behave as if there were an infinite number of characters padding each side of the string. Usually these imaginary padding characters have code unit length 1 but string types may choose different "imaginary" character sizes as makes sense for their implementations (e.g. substrings may pass index arithmetic through to the underlying string they provide a view into). Relaxed indexing functions include those intended for index arithmetic: `thisind`, `nextind` and `prevind`. This model allows index arithmetic to work with out-of-bounds indices as intermediate values so long as one never uses them to retrieve a character, which often helps avoid needing to code around edge cases.

See also [codeunit](#), [ncodeunits](#), [thisind](#), [nextind](#), [prevind](#).

[source](#)

Core.AbstractChar – Type.

The `AbstractChar` type is the supertype of all character implementations in Julia. A character represents a Unicode code point, and can be converted to an integer via the `codepoint` function in order to obtain the numerical value of the code point, or constructed from the same integer. These numerical values determine how characters are compared with `<` and `==`, for example. New `T <: AbstractChar` types should define a `codepoint(::T)` method and a `T(::UInt32)` constructor, at minimum.

A given `AbstractChar` subtype may be capable of representing only a subset of Unicode, in which case conversion from an unsupported `UInt32` value may throw an error. Conversely, the built-in `Char` type represents a superset of Unicode (in order to losslessly encode invalid byte streams), in which case conversion of a non-Unicode value to `UInt32` throws an error. The `isvalid` function can be used to check which codepoints are representable in a given `AbstractChar` type.

Internally, an `AbstractChar` type may use a variety of encodings. Conversion via `codepoint(char)` will not reveal this encoding because it always returns the Unicode value of the character. `print(io, c)` of any `c::AbstractChar` produces an encoding determined by `io` (UTF-8 for all built-in IO types), via conversion to `Char` if necessary.

`write(io, c)`, in contrast, may emit an encoding depending on `typeof(c)`, and `read(io, typeof(c))` should read the same encoding as `write`. New `AbstractChar` types must provide their own implementations of `write` and `read`.

[source](#)

Core.Char – Type.

```
| Char(c::Union{Number,AbstractChar})
```

`Char` is a 32-bit `AbstractChar` type that is the default representation of characters in Julia. `Char` is the type used for character literals like `'x'` and it is also the element type of `String`.

In order to losslessly represent arbitrary byte streams stored in a `String`, a `Char` value may store information that cannot be converted to a Unicode codepoint — converting such a `Char` to `UInt32` will throw an error. The `isvalid(c::Char)` function can be used to query whether `c` represents a valid Unicode character.

[source](#)

Base.codepoint – Function.

```
| codepoint(c::AbstractChar) -> Integer
```

Return the Unicode codepoint (an unsigned integer) corresponding to the character `c` (or throw an exception if `c` does not represent a valid character). For `Char`, this is a `UInt32` value, but `AbstractChar` types that represent only a subset of Unicode may return a different-sized integer (e.g. `UInt8`).

[source](#)

Base.length – Method.

```
| length(s::AbstractString) -> Int
| length(s::AbstractString, i::Integer, j::Integer) -> Int
```

Return the number of characters in string `s` from indices `i` through `j`.

This is computed as the number of code unit indices from `i` to `j` which are valid character indices. With only a single string argument, this computes the number of characters in the entire string. With `i` and `j` arguments it computes the number of indices between `i` and `j` inclusive that are valid indices in the string `s`. In addition to in-bounds values, `i` may take the out-of-bounds value `ncodeunits(s) + 1` and `j` may take the out-of-bounds value `0`.

Note

The time complexity of this operation is linear in general. That is, it will take the time proportional to the number of bytes or characters in the string because it counts the value on the fly. This is in contrast to the method for arrays, which is a constant-time operation.

See also [isvalid](#), [ncodeunits](#), [lastindex](#), [thisind](#), [nextind](#), [prevind](#).

Examples

```
julia> length("jμΑΙα")
5
```

[source](#)

`Base.sizeof` – Method.

```
sizeof(str::AbstractString)
```

Size, in bytes, of the string `str`. Equal to the number of code units in `str` multiplied by the size, in bytes, of one code unit in `str`.

Examples

```
julia> sizeof("")
0

julia> sizeof("V")
3
```

[source](#)

`Base.:*` – Method.

```
*(s::Union{AbstractString, AbstractChar}, t::Union{AbstractString, AbstractChar}...) ->
↳ AbstractString
```

Concatenate strings and/or characters, producing a [String](#). This is equivalent to calling the [string](#) function on the arguments. Concatenation of built-in string types always produces a value of type `String` but other string types may choose to return a string of a different type as appropriate.

Examples

```
julia> "Hello " * "world"
"Hello world"

julia> 'j' * "ulia"
"julia"
```

source

Base.:^ – Method.

```
|^(s::Union{AbstractString,AbstractChar}, n::Integer) -> AbstractString
```

Repeat a string or character *n* times. This can also be written as `repeat(s, n)`.

See also [repeat](#).

Examples

```
|julia> "Test" ^3
"Test Test Test "
```

source

Base.string – Function.

```
|string(n::Integer; base::Integer = 10, pad::Integer = 1)
```

Convert an integer *n* to a string in the given base, optionally specifying a number of digits to pad to.

See also [digits](#), [bitstring](#), [count_zeros](#).

Examples

```
|julia> string(5, base = 13, pad = 4)
"0005"

|julia> string(-13, base = 5, pad = 4)
"-0023"
```

source

```
|string(xs...)
```

Create a string from any values using the [print](#) function.

`string` should usually not be defined directly. Instead, define a method `print(io::IO, x::MyType)`. If `string(x)` for a certain type needs to be highly efficient, then it may make sense to add a method to `string` and define `print(io::IO, x::MyType) = print(io, string(x))` to ensure the functions are consistent.

See also: [String](#), [repr](#), [sprint](#), [show](#).

Examples

```
|julia> string("a", 1, true)
"altrue"
```

source

Base.repeat – Method.

```
|repeat(s::AbstractString, r::Integer)
```

Repeat a string `r` times. This can be written as `s^r`.

See also `^`.

Examples

```
julia> repeat("ha", 3)
"hahaha"
```

[source](#)

`Base.repeat` – Method.

```
repeat(c::AbstractChar, r::Integer) -> String
```

Repeat a character `r` times. This can equivalently be accomplished by calling `c^r`.

Examples

```
julia> repeat('A', 3)
"AAA"
```

[source](#)

`Base.repr` – Method.

```
repr(x; context=nothing)
```

Create a string from any value using the `show` function. You should not add methods to `repr`; define a `show` method instead.

The optional keyword argument `context` can be set to a `:key=>value` pair, a tuple of `:key=>value` pairs, or an `I/O` or `IContext` object whose attributes are used for the I/O stream passed to `show`.

Note that `repr(x)` is usually similar to how the value of `x` would be entered in Julia. See also `repr(MIME("text/plain"), x)` to instead return a "pretty-printed" version of `x` designed more for human consumption, equivalent to the REPL display of `x`.

Julia 1.7

Passing a tuple to keyword context requires Julia 1.7 or later.

Examples

```
julia> repr(1)
"1"

julia> repr(zeros(3))
"[0.0, 0.0, 0.0]"

julia> repr(big(1/3))
"0.333333333333333314829616256247390992939472198486328125"

julia> repr(big(1/3), context=:compact => true)
"0.333333"
```

source

Core.String – Method.

```
| String(s::AbstractString)
```

Create a new String from an existing AbstractString.

source

Base.SubString – Type.

```
| SubString(s::AbstractString, i::Integer, j::Integer=lastindex(s))
| SubString(s::AbstractString, r::UnitRange{<:Integer})
```

Like [getindex](#), but returns a view into the parent string `s` within range `i:j` or `r` respectively instead of making a copy.

The [@views](#) macro converts any string slices `s[i:j]` into substrings `SubString(s, i, j)` in a block of code.

Examples

```
julia> SubString("abc", 1, 2)
"ab"

julia> SubString("abc", 1:2)
"ab"

julia> SubString("abc", 2)
"bc"
```

source

Base.LazyString – Type.

```
| LazyString <: AbstractString
```

A lazy representation of string interpolation. This is useful when a string needs to be constructed in a context where performing the actual interpolation and string construction is unnecessary or undesirable (e.g. in error paths of functions).

This type is designed to be cheap to construct at runtime, trying to offload as much work as possible to either the macro or later printing operations.

Examples

```
julia> n = 5; str = LazyString("n is ", n)
"n is 5"
```

See also [@lazy_str](#).

Julia 1.8

LazyString requires Julia 1.8 or later.

Extended help**Safety properties for concurrent programs**

A lazy string itself does not introduce any concurrency problems even if it is printed in multiple Julia tasks. However, if print methods on a captured value can have a concurrency issue when invoked without synchronizations, printing the lazy string may cause an issue. Furthermore, the print methods on the captured values may be invoked multiple times, though only exactly one result will be returned.

Julia 1.9

`LazyString` is safe in the above sense in Julia 1.9 and later.

[source](#)

`Base.@lazy_str` – Macro.

```
| lazy"str"
```

Create a `LazyString` using regular string interpolation syntax. Note that interpolations are evaluated at `LazyString` construction time, but printing is delayed until the first access to the string.

See [LazyString](#) documentation for the safety properties for concurrent programs.

Examples

```
julia> n = 5; str = lazy"n is $n"
"n is 5"

julia> typeof(str)
LazyString
```

Julia 1.8

`lazy"str"` requires Julia 1.8 or later.

[source](#)

`Base.transcode` – Function.

```
| transcode(T, src)
```

Convert string data between Unicode encodings. `src` is either a `String` or a `Vector{UIntXX}` of UTF-XX code units, where XX is 8, 16, or 32. `T` indicates the encoding of the return value: `String` to return a (UTF-8 encoded) `String` or `UIntXX` to return a `Vector{UIntXX}` of UTF-XX data. (The alias `Cwchar_t` can also be used as the integer type, for converting `wchar_t*` strings used by external C libraries.)

The `transcode` function succeeds as long as the input data can be reasonably represented in the target encoding; it always succeeds for conversions between UTF-XX encodings, even for invalid Unicode data.

Only conversion to/from UTF-8 is currently supported.

Examples

```
julia> str = "αβγ"
"αβγ"

julia> transcode(UInt16, str)
3-element Vector{UInt16}:
 0x03b1
 0x03b2
 0x03b3

julia> transcode(String, transcode(UInt16, str))
"αβγ"
```

[source](#)

Base.unsafe_string – Function.

```
unsafe_string(p::Ptr{UInt8}, [length::Integer])
```

Copy a string from the address of a C-style (NUL-terminated) string encoded as UTF-8. (The pointer can be safely freed afterwards.) If length is specified (the length of the data in bytes), the string does not have to be NUL-terminated.

This function is labeled "unsafe" because it will crash if p is not a valid memory address to data of the requested length.

[source](#)

Base.ncodeunits – Method.

```
ncodeunits(s::AbstractString) -> Int
```

Return the number of code units in a string. Indices that are in bounds to access this string must satisfy $1 \leq i \leq \text{ncodeunits}(s)$. Not all such indices are valid – they may not be the start of a character, but they will return a code unit value when calling `codeunit(s,i)`.

Examples

```
julia> ncodeunits("The Julia Language")
18

julia> ncodeunits("fex")
6

julia> ncodeunits('f'), ncodeunits('e'), ncodeunits('x')
(3, 1, 2)
```

See also [codeunit](#), [checkbounds](#), [sizeof](#), [length](#), [lastindex](#).

[source](#)

Base.codeunit – Function.

```
codeunit(s::AbstractString) -> Type{<:Union{UInt8, UInt16, UInt32}}
```

Return the code unit type of the given string object. For ASCII, Latin-1, or UTF-8 encoded strings, this would be `UInt8`; for UCS-2 and UTF-16 it would be `UInt16`; for UTF-32 it would be `UInt32`. The code unit type need not be limited to these three types, but it's hard to think of widely used string encodings that don't use one of these units. `codeunit(s)` is the same as `typeof(codeunit(s,1))` when `s` is a non-empty string.

See also [ncodeunits](#).

[source](#)

```
| codeunit(s::AbstractString, i::Integer) -> Union{UInt8, UInt16, UInt32}
```

Return the code unit value in the string `s` at index `i`. Note that

```
| codeunit(s, i) :: codeunit(s)
```

i.e. the value returned by `codeunit(s, i)` is of the type returned by `codeunit(s)`.

Examples

```
| julia> a = codeunit("Hello", 2)
| 0x65
|
| julia> typeof(a)
| UInt8
```

See also [ncodeunits](#), [checkbounds](#).

[source](#)

`Base.codeunits` – Function.

```
| codeunits(s::AbstractString)
```

Obtain a vector-like object containing the code units of a string. Returns a `CodeUnits` wrapper by default, but `codeunits` may optionally be defined for new string types if necessary.

Examples

```
| julia> codeunits("Julia")
| 6-element Base.CodeUnits{UInt8, String}:
| 0x4a
| 0x75
| 0xce
| 0xbb
| 0x69
| 0x61
```

[source](#)

`Base.ascii` – Function.

```
| ascii(s::AbstractString)
```

Convert a string to `String` type and check that it contains only ASCII data, otherwise throwing an `ArgumentError` indicating the position of the first non-ASCII byte.

See also the `isascii` predicate to filter or replace non-ASCII characters.

Examples

```
julia> ascii("abcdeyfg")
ERROR: ArgumentError: invalid ASCII at index 6 in "abcdeyfg"
Stacktrace:
[...]

julia> ascii("abcdeyfg")
"abcdeyfg"
```

[source](#)

`Base.Regex` – Type.

```
| Regex(pattern[, flags]) <: AbstractPattern
```

A type representing a regular expression. `Regex` objects can be used to match strings with `match`.

`Regex` objects can be created using the `@r_str` string macro. The `Regex(pattern[, flags])` constructor is usually used if the `pattern` string needs to be interpolated. See the documentation of the string macro for details on flags.

Note

To escape interpolated variables use `\Q` and `\E` (e.g. `Regex("\\Q$x\\E")`)

[source](#)

`Base.@r_str` – Macro.

```
| @r_str -> Regex
```

Construct a regex, such as `r"^[a-z]*$"`, without interpolation and unescaping (except for quotation mark `"` which still has to be escaped). The regex also accepts one or more flags, listed after the ending quote, to change its behaviour:

- `i` enables case-insensitive matching
- `m` treats the `^` and `$` tokens as matching the start and end of individual lines, as opposed to the whole string.
- `s` allows the `.` modifier to match newlines.
- `x` enables "comment mode": whitespace is enabled except when escaped with `\`, and `#` is treated as starting a comment.
- `a` enables ASCII mode (disables UTF and UCP modes). By default `\B`, `\b`, `\D`, `\d`, `\S`, `\s`, `\W`, `\w`, etc. match based on Unicode character properties. With this option, these sequences only match ASCII characters. This includes `\u` also, which will emit the specified character value directly as a single byte, and not attempt to encode it into UTF-8. Importantly, this option allows matching against invalid UTF-8 strings, by treating both matcher and target as simple bytes (as if they were ISO/IEC 8859-1 / Latin-1 bytes) instead of as character encodings. In this case, this option is often combined with `s`. This option can be further refined by starting the pattern with `(UCP)` or `(UTF)`.

See [Regex](#) if interpolation is needed.

Examples

```
julia> match(r"a+.*b+.*?d$"ism, "Goodbye,\n0h, angry,\nBad world\n")
RegexMatch("angry,\nBad world")
```

This regex has the first three flags enabled.

[source](#)

Base.SubstitutionString – Type.

```
SubstitutionString(substr) <: AbstractString
```

Stores the given string `substr` as a `SubstitutionString`, for use in regular expression substitutions. Most commonly constructed using the `@s_str` macro.

Examples

```
julia> SubstitutionString("Hello \g<name>, it's \1")
s"Hello \g<name>, it's \1"

julia> subst = s"Hello \g<name>, it's \1"
s"Hello \g<name>, it's \1"

julia> typeof(subst)
SubstitutionString{String}
```

[source](#)

Base.@s_str – Macro.

```
@s_str -> SubstitutionString
```

Construct a substitution string, used for regular expression substitutions. Within the string, sequences of the form `\N` refer to the Nth capture group in the regex, and `\g<groupname>` refers to a named capture group with name `groupname`.

Examples

```
julia> msg = "#Hello# from Julia";

julia> replace(msg, r"#(.+)# from (?<from>\w+)" => s"FROM: \g<from>; MESSAGE: \1")
"FROM: Julia; MESSAGE: Hello"
```

[source](#)

Base.@raw_str – Macro.

```
@raw_str -> String
```

Create a raw string without interpolation and unescaping. The exception is that quotation marks still must be escaped. Backslashes escape both quotation marks and other backslashes, but only when a sequence of backslashes precedes a quote character. Thus, $2n$ backslashes followed by a quote encodes n backslashes and the end of the literal while $2n+1$ backslashes followed by a quote encodes n backslashes followed by a quote character.

Examples

```
julia> println(raw"\ $x")
\ $x

julia> println(raw"\"")
"

julia> println(raw"\\\"")
\"

julia> println(raw"\\x \\\"")
\\x \"
```

[source](#)

Base.@b_str – Macro.

```
| @b_str
```

Create an immutable byte (UInt8) vector using string syntax.

Examples

```
julia> v = b"12\x01\x02"
4-element Base.CodeUnits{UInt8, String}:
 0x31
 0x32
 0x01
 0x02

julia> v[2]
0x32
```

[source](#)

Base.Docs.@html_str – Macro.

```
| @html_str -> Docs.HTML
```

Create an HTML object from a literal string.

Examples

```
julia> html"Julia"
HTML{String}("Julia")
```

[source](#)

Base.Docs.@text_str – Macro.

```
| @text_str -> Docs.Text
```

Create a Text object from a literal string.

Examples

```
| julia> text"Julia"  
Julia
```

[source](#)

Base.isvalid – Method.

```
| isvalid(value) -> Bool
```

Return true if the given value is valid for its type, which currently can be either AbstractChar or String or SubString{String}.

Examples

```
| julia> isvalid(Char(0xd800))  
false  
  
| julia> isvalid(SubString(String(UInt8[0xfe,0x80,0x80,0x80,0x80,0x80]),1,2))  
false  
  
| julia> isvalid(Char(0xd799))  
true
```

[source](#)

Base.isvalid – Method.

```
| isvalid(T, value) -> Bool
```

Return true if the given value is valid for that type. Types currently can be either AbstractChar or String. Values for AbstractChar can be of type AbstractChar or UInt32. Values for String can be of that type, SubString{String}, Vector{UInt8}, or a contiguous subarray thereof.

Examples

```
| julia> isvalid(Char, 0xd800)  
false  
  
| julia> isvalid(String, SubString("thisisvalid",1,5))  
true  
  
| julia> isvalid(Char, 0xd799)  
true
```

Julia 1.6

Support for subarray values was added in Julia 1.6.

[source](#)

`Base.isvalid` – Method.

```
| isvalid(s::AbstractString, i::Integer) -> Bool
```

Predicate indicating whether the given index is the start of the encoding of a character in `s` or not. If `isvalid(s, i)` is true then `s[i]` will return the character whose encoding starts at that index, if it's false, then `s[i]` will raise an invalid index error or a bounds error depending on if `i` is in bounds. In order for `isvalid(s, i)` to be an $O(1)$ function, the encoding of `s` must be [self-synchronizing](#). This is a basic assumption of Julia's generic string support.

See also [getindex](#), [iterate](#), [thisind](#), [nextind](#), [prevind](#), [length](#).

Examples

```
julia> str = "αβγdef";

julia> isvalid(str, 1)
true

julia> str[1]
'α': Unicode U+03B1 (category Ll: Letter, lowercase)

julia> isvalid(str, 2)
false

julia> str[2]
ERROR: StringIndexError: invalid index [2], valid nearby indices [1]==>'α', [3]==>'β'
Stacktrace:
[...]
```

[source](#)

`Base.match` – Function.

```
| match(r::Regex, s::AbstractString[, idx::Integer[, addopts]])
```

Search for the first match of the regular expression `r` in `s` and return a [RegexMatch](#) object containing the match, or nothing if the match failed. The matching substring can be retrieved by accessing `m.match` and the captured sequences can be retrieved by accessing `m.captures`. The optional `idx` argument specifies an index at which to start the search.

Examples

```
julia> rx = r"a(.)a"
r"a(.)a"

julia> m = match(rx, "cabac")
RegexMatch("aba", 1="b")

julia> m.captures
1-element Vector{Union{Nothing, SubString{String}}}:
 "b"
```

```
julia> m.match
"aba"

julia> match(rx, "cabac", 3) === nothing
true
```

[source](#)

Base.eachmatch – Function.

```
eachmatch(r::Regex, s::AbstractString; overlap::Bool=false)
```

Search for all matches of the regular expression `r` in `s` and return an iterator over the matches. If `overlap` is `true`, the matching sequences are allowed to overlap indices in the original string, otherwise they must be from distinct character ranges.

Examples

```
julia> rx = r"a.a"
r"a.a"

julia> m = eachmatch(rx, "a1a2a3a")
Base.RegexMatchIterator{r"a.a", "a1a2a3a", false}

julia> collect(m)
2-element Vector{RegexMatch}:
RegexMatch("a1a")
RegexMatch("a3a")

julia> collect(eachmatch(rx, "a1a2a3a", overlap = true))
3-element Vector{RegexMatch}:
RegexMatch("a1a")
RegexMatch("a2a")
RegexMatch("a3a")
```

[source](#)

Base.RegexMatch – Type.

```
RegexMatch <: AbstractMatch
```

A type representing a single match to a [Regex](#) found in a string. Typically created from the [match](#) function.

The `match` field stores the substring of the entire matched string. The `captures` field stores the substrings for each capture group, indexed by number. To index by capture group name, the entire match object should be indexed instead, as shown in the examples. The location of the start of the match is stored in the `offset` field. The `offsets` field stores the locations of the start of each capture group, with 0 denoting a group that was not captured.

This type can be used as an iterator over the capture groups of the `Regex`, yielding the substrings captured in each group. Because of this, the captures of a match can be destructured. If a group was not captured, nothing will be yielded instead of a substring.

Methods that accept a `RegexMatch` object are defined for `iterate`, `length`, `eltype`, `keys`, `haskey`, and `getindex`, where keys are the the names or numbers of a capture group. See `keys` for more information.

Examples

```
julia> m = match(r"(?<hour>\d+):(?<minute>\d+)(am|pm)?", "11:30 in the morning")
RegexMatch("11:30", hour="11", minute="30", 3=nothing)

julia> m.match
"11:30"

julia> m.captures
3-element Vector{Union{Nothing, SubString{String}}}:
 "11"
 "30"
 nothing

julia> m["minute"]
"30"

julia> hr, min, ampm = m; # destructure capture groups by iteration

julia> hr
"11"
```

[source](#)

`Base.keys` – Method.

```
| keys(m::RegexMatch) -> Vector
```

Return a vector of keys for all capture groups of the underlying regex. A key is included even if the capture group fails to match. That is, `idx` will be in the return value even if `m[idx] == nothing`.

Unnamed capture groups will have integer keys corresponding to their index. Named capture groups will have string keys.

Julia 1.7

This method was added in Julia 1.7

Examples

```
julia> keys(match(r"(?<hour>\d+):(?<minute>\d+)(am|pm)?", "11:30"))
3-element Vector{Any}:
 "hour"
 "minute"
 3
```

[source](#)

`Base.isless` – Method.

```
| isless(a::AbstractString, b::AbstractString) -> Bool
```

Test whether string *a* comes before string *b* in alphabetical order (technically, in lexicographical order by Unicode code points).

Examples

```
julia> isless("a", "b")
true

julia> isless("β", "α")
false

julia> isless("a", "a")
false
```

[source](#)

Base.::= – Method.

```
==(a::AbstractString, b::AbstractString) -> Bool
```

Test whether two strings are equal character by character (technically, Unicode code point by code point).

Examples

```
julia> "abc" == "abc"
true

julia> "abc" == "αβγ"
false
```

[source](#)

Base.cmp – Method.

```
cmp(a::AbstractString, b::AbstractString) -> Int
```

Compare two strings. Return 0 if both strings have the same length and the character at each index is the same in both strings. Return -1 if *a* is a prefix of *b*, or if *a* comes before *b* in alphabetical order. Return 1 if *b* is a prefix of *a*, or if *b* comes before *a* in alphabetical order (technically, lexicographical order by Unicode code points).

Examples

```
julia> cmp("abc", "abc")
0

julia> cmp("ab", "abc")
-1

julia> cmp("abc", "ab")
1

julia> cmp("ab", "ac")
```

```

-1

julia> cmp("ac", "ab")
1

julia> cmp("α", "a")
1

julia> cmp("b", "β")
-1

```

[source](#)

Base.lpad – Function.

```

lpad(s, n::Integer, p::Union{AbstractChar, AbstractString}=' ') -> String

```

Stringify *s* and pad the resulting string on the left with *p* to make it *n* characters (in `textwidth`) long. If *s* is already *n* characters long, an equal string is returned. Pad with spaces by default.

Examples

```

julia> lpad("March", 10)
"      March"

```

Julia 1.7

In Julia 1.7, this function was changed to use `textwidth` rather than a raw character (code-point) count.

[source](#)

Base.rpad – Function.

```

rpad(s, n::Integer, p::Union{AbstractChar, AbstractString}=' ') -> String

```

Stringify *s* and pad the resulting string on the right with *p* to make it *n* characters (in `textwidth`) long. If *s* is already *n* characters long, an equal string is returned. Pad with spaces by default.

Examples

```

julia> rpad("March", 20)
"March          "

```

Julia 1.7

In Julia 1.7, this function was changed to use `textwidth` rather than a raw character (code-point) count.

[source](#)

Base.findfirst – Method.

```

findfirst(pattern::AbstractString, string::AbstractString)
findfirst(pattern::AbstractPattern, string::String)

```

Find the first occurrence of pattern in string. Equivalent to `findnext(pattern, string, firstindex(s))`.

Examples

```
julia> findfirst("z", "Hello to the world") # returns nothing, but not printed in the REPL

julia> findfirst("Julia", "JuliaLang")
1:5
```

[source](#)

Base.findnext – Method.

```
findnext(pattern::AbstractString, string::AbstractString, start::Integer)
findnext(pattern::AbstractPattern, string::String, start::Integer)
```

Find the next occurrence of pattern in string starting at position start. pattern can be either a string, or a regular expression, in which case string must be of type String.

The return value is a range of indices where the matching sequence is found, such that `s[findnext(x, s, i)] == x`:

`findnext("substring", string, i) == start:stop` such that `string[start:stop] == "substring"` and `i <= start`, or nothing if unmatched.

Examples

```
julia> findnext("z", "Hello to the world", 1) === nothing
true

julia> findnext("o", "Hello to the world", 6)
8:8

julia> findnext("Lang", "JuliaLang", 2)
6:9
```

[source](#)

Base.findnext – Method.

```
findnext(ch::AbstractChar, string::AbstractString, start::Integer)
```

Find the next occurrence of character ch in string starting at position start.

Julia 1.3

This method requires at least Julia 1.3.

Examples

```
julia> findnext('z', "Hello to the world", 1) === nothing
true

julia> findnext('o', "Hello to the world", 6)
8
```

[source](#)

Base.findall - Method.

```
| findlast(pattern::AbstractString, string::AbstractString)
```

Find the last occurrence of pattern in string. Equivalent to `findprev(pattern, string, lastindex(string))`.

Examples

```
julia> findlast("o", "Hello to the world")
15:15

julia> findfirst("Julia", "JuliaLang")
1:5
```

[source](#)

Base.findall - Method.

```
| findlast(ch::AbstractChar, string::AbstractString)
```

Find the last occurrence of character ch in string.

Julia 1.3

This method requires at least Julia 1.3.

Examples

```
julia> findlast('p', "happy")
4

julia> findlast('z', "happy") == nothing
true
```

[source](#)

Base.findprev - Method.

```
| findprev(pattern::AbstractString, string::AbstractString, start::Integer)
```

Find the previous occurrence of pattern in string starting at position start.

The return value is a range of indices where the matching sequence is found, such that `s[findprev(x, s, i)] == x`:

`findprev("substring", string, i) == start:stop` such that `string[start:stop] == "substring"` and `stop <= i`, or nothing if unmatched.

Examples

```
julia> findprev("z", "Hello to the world", 18) == nothing
true

julia> findprev("o", "Hello to the world", 18)
15:15

julia> findprev("Julia", "JuliaLang", 6)
1:5
```

[source](#)

Base.occursin – Function.

```
occursin(needle::Union{AbstractString, AbstractPattern, AbstractChar},
↪ haystack::AbstractString)
```

Determine whether the first argument is a substring of the second. If `needle` is a regular expression, checks whether `haystack` contains a match.

Examples

```
julia> occursin("Julia", "JuliaLang is pretty cool!")
true

julia> occursin('a', "JuliaLang is pretty cool!")
true

julia> occursin(r"a.a", "aba")
true

julia> occursin(r"a.a", "abba")
false
```

See also [contains](#).

[source](#)

```
occursin(haystack)
```

Create a function that checks whether its argument occurs in `haystack`, i.e. a function equivalent to `needle -> occursin(needle, haystack)`.

The returned function is of type `Base.Fix2{typeof(occursin)}`.

Julia 1.6

This method requires Julia 1.6 or later.

Examples

```
julia> search_f = occursin("JuliaLang is a programming language");

julia> search_f("JuliaLang")
true

julia> search_f("Python")
false
```

source

Base.reverse – Method.

```
reverse(s::AbstractString) -> AbstractString
```

Reverses a string. Technically, this function reverses the codepoints in a string and its main utility is for reversed-order string processing, especially for reversed regular-expression searches. See also [reverseind](#) to convert indices in `s` to indices in `reverse(s)` and vice-versa, and graphemes from module `Unicode` to operate on user-visible "characters" (graphemes) rather than codepoints. See also [Iterators.reverse](#) for reverse-order iteration without making a copy. Custom string types must implement the `reverse` function themselves and should typically return a string with the same type and encoding. If they return a string with a different encoding, they must also override `reverseind` for that string type to satisfy `s[reverseind(s,i)] == reverse(s)[i]`.

Examples

```
julia> reverse("JuliaLang")
"gnalailuJ"
```

Note

The examples below may be rendered differently on different systems. The comments indicate how they're supposed to be rendered

Combining characters can lead to surprising results:

```
julia> reverse("aĥe") # hat is above x in the input, above e in the output
"ê xa"

julia> using Unicode

julia> join(reverse(collect(graphemes("aĥe")))) # reverses graphemes; hat is above x in both
↔ in- and output
"eĥ a"
```

source

Base.replace – Method.

```
replace([io::IO], s::AbstractString, pat=>r, [pat2=>r2, ...]; [count::Integer])
```

Search for the given pattern `pat` in `s`, and replace each occurrence with `r`. If `count` is provided, replace at most `count` occurrences. `pat` may be a single character, a vector or a set of characters, a string, or a regular expression. If `r` is a function, each occurrence is replaced with `r(s)` where `s` is the matched substring (when `pat` is a `AbstractPattern` or `AbstractString`) or character (when `pat` is an `AbstractChar` or a collection of `AbstractChar`). If `pat` is a regular expression and `r` is a [SubstitutionString](#), then capture group references in `r` are replaced with the corresponding matched text. To remove instances of `pat` from string, set `r` to the empty `String` `""`.

The return value is a new string after the replacements. If the `io::IO` argument is supplied, the transformed string is instead written to `io` (returning `io`). (For example, this can be used in conjunction with an [IOBuffer](#) to re-use a pre-allocated buffer array in-place.)

Multiple patterns can be specified, and they will be applied left-to-right simultaneously, so only one pattern will be applied to any character, and the patterns will only be applied to the input text, not the replacements.

Julia 1.7

Support for multiple patterns requires version 1.7.

Julia 1.10

The `io::IO` argument requires version 1.10.

Examples

```
julia> replace("Python is a programming language.", "Python" => "Julia")
"Julia is a programming language."

julia> replace("The quick foxes run quickly.", "quick" => "slow", count=1)
"The slow foxes run quickly."

julia> replace("The quick foxes run quickly.", "quick" => "", count=1)
"The foxes run quickly."

julia> replace("The quick foxes run quickly.", r"fox(es)?" => s"bus\1")
"The quick buses run quickly."

julia> replace("abcabc", "a" => "b", "b" => "c", r"."+ => "a")
"bca"
```

[source](#)

Base.eachsplit – Function.

```
eachsplit(str::AbstractString, dlm; limit::Integer=0, keepempty::Bool=true)
eachsplit(str::AbstractString; limit::Integer=0, keepempty::Bool=false)
```

Split `str` on occurrences of the delimiter(s) `dlm` and return an iterator over the substrings. `dlm` can be any of the formats allowed by `findnext`'s first argument (i.e. as a string, regular expression or a function), or as a single character or collection of characters.

If `dlm` is omitted, it defaults to `isspace`.

The optional keyword arguments are:

- `limit`: the maximum size of the result. `limit=0` implies no maximum (default)
- `keepempty`: whether empty fields should be kept in the result. Default is `false` without a `dlm` argument, `true` with a `dlm` argument.

See also [split](#).

Julia 1.8

The `eachsplit` function requires at least Julia 1.8.

Examples

```
julia> a = "Ma.rch"
"Ma.rch"

julia> b = eachsplit(a, ".")
Base.SplitIterator{String, String}("Ma.rch", ".", 0, true)

julia> collect(b)
2-element Vector{SubString{String}}:
 "Ma"
 "rch"
```

[source](#)

Base.split – Function.

```
split(str::AbstractString, dlm; limit::Integer=0, keepempty::Bool=true)
split(str::AbstractString; limit::Integer=0, keepempty::Bool=false)
```

Split `str` into an array of substrings on occurrences of the delimiter(s) `dlm`. `dlm` can be any of the formats allowed by `findnext`'s first argument (i.e. as a string, regular expression or a function), or as a single character or collection of characters.

If `dlm` is omitted, it defaults to `isspace`.

The optional keyword arguments are:

- `limit`: the maximum size of the result. `limit=0` implies no maximum (default)
- `keepempty`: whether empty fields should be kept in the result. Default is `false` without a `dlm` argument, `true` with a `dlm` argument.

See also [rsplit](#), [eachsplit](#).

Examples

```
julia> a = "Ma.rch"
"Ma.rch"

julia> split(a, ".")
2-element Vector{SubString{String}}:
 "Ma"
 "rch"
```

[source](#)

Base.rsplit – Function.

```
rsplit(s::AbstractString; limit::Integer=0, keepempty::Bool=false)
rsplit(s::AbstractString, chars; limit::Integer=0, keepempty::Bool=true)
```

Similar to [split](#), but starting from the end of the string.

Examples

```
julia> a = "M.a.r.c.h"
"M.a.r.c.h"

julia> rsplit(a, ".")
5-element Vector{SubString{String}}:
"M"
"a"
"r"
"c"
"h"

julia> rsplit(a, ".", limit=1)
1-element Vector{SubString{String}}:
"M.a.r.c.h"

julia> rsplit(a, ".", limit=2)
2-element Vector{SubString{String}}:
"M.a.r.c"
"h"
```

[source](#)

Base.strip – Function.

```
strip([pred=isspace,] str::AbstractString) -> SubString
strip(str::AbstractString, chars) -> SubString
```

Remove leading and trailing characters from `str`, either those specified by `chars` or those for which the function `pred` returns true.

The default behaviour is to remove leading and trailing whitespace and delimiters: see [isspace](#) for precise details.

The optional `chars` argument specifies which characters to remove: it can be a single character, vector or set of characters.

See also [lstrip](#) and [rstrip](#).

Julia 1.2

The method which accepts a predicate function requires Julia 1.2 or later.

Examples

```
julia> strip("{3, 5}\n", ['{', '}', '\n'])
"3, 5"
```

[source](#)

Base.lstrip – Function.

```
lstrip([pred=isspace,] str::AbstractString) -> SubString
lstrip(str::AbstractString, chars) -> SubString
```

Remove leading characters from `str`, either those specified by `chars` or those for which the function `pred` returns true.

The default behaviour is to remove leading whitespace and delimiters: see [isspace](#) for precise details.

The optional `chars` argument specifies which characters to remove: it can be a single character, or a vector or set of characters.

See also [strip](#) and [rstrip](#).

Examples

```
julia> a = lpad("March", 20)
"          March"

julia> lstrip(a)
"March"
```

[source](#)

`Base.rstrip` – Function.

```
rstrip([pred=isspace,] str::AbstractString) -> SubString
rstrip(str::AbstractString, chars) -> SubString
```

Remove trailing characters from `str`, either those specified by `chars` or those for which the function `pred` returns true.

The default behaviour is to remove trailing whitespace and delimiters: see [isspace](#) for precise details.

The optional `chars` argument specifies which characters to remove: it can be a single character, or a vector or set of characters.

See also [strip](#) and [lstrip](#).

Examples

```
julia> a = rpad("March", 20)
"March          "

julia> rstrip(a)
"March"
```

[source](#)

`Base.startswith` – Function.

```
startswith(s::AbstractString, prefix::AbstractString)
```

Return true if `s` starts with `prefix`. If `prefix` is a vector or set of characters, test whether the first character of `s` belongs to that set.

See also [endswith](#), [contains](#).

Examples

```
julia> startswith("JuliaLang", "Julia")
true
```

source

```
|startswith(io::IO, prefix::Union{AbstractString,Base.Chars})
```

Check if an IO object starts with a prefix. See also [peek](#).

source

```
|startswith(prefix)
```

Create a function that checks whether its argument starts with prefix, i.e. a function equivalent to `y -> startswith(y, prefix)`.

The returned function is of type `Base.Fix2{typeof(startswith)}`, which can be used to implement specialized methods.

Julia 1.5

The single argument `startswith(prefix)` requires at least Julia 1.5.

Examples

```
|julia> startswith("Julia")("JuliaLang")
true
|julia> startswith("Julia")("Ends with Julia")
false
```

source

```
|startswith(s::AbstractString, prefix::Regex)
```

Return true if `s` starts with the regex pattern, `prefix`.

Note

`startswith` does not compile the anchoring into the regular expression, but instead passes the anchoring as `match_option` to PCRE. If compile time is amortized, `occursin(r"^...", s)` is faster than `startswith(s, r"...")`.

See also [occursin](#) and [endswith](#).

Julia 1.2

This method requires at least Julia 1.2.

Examples

```
|julia> startswith("JuliaLang", r"Julia|Romeo")
true
```

source

`Base.endswith` - Function.

```
|endswith(s::AbstractString, suffix::AbstractString)
```

Return true if `s` ends with `suffix`. If `suffix` is a vector or set of characters, test whether the last character of `s` belongs to that set.

See also [startswith](#), [contains](#).

Examples

```
julia> endswith("Sunday", "day")
true
```

source

```
endswith(suffix)
```

Create a function that checks whether its argument ends with `suffix`, i.e. a function equivalent to `y -> endswith(y, suffix)`.

The returned function is of type `Base.Fix2{typeof(endswith)}`, which can be used to implement specialized methods.

Julia 1.5

The single argument `endswith(suffix)` requires at least Julia 1.5.

Examples

```
julia> endswith("Julia")("Ends with Julia")
true

julia> endswith("Julia")("JuliaLang")
false
```

source

```
endswith(s::AbstractString, suffix::Regex)
```

Return true if `s` ends with the regex pattern, `suffix`.

Note

`endswith` does not compile the anchoring into the regular expression, but instead passes the anchoring as `match_option` to PCRE. If compile time is amortized, `occursin(r"...$", s)` is faster than `endswith(s, r"...")`.

See also [occursin](#) and [startswith](#).

Julia 1.2

This method requires at least Julia 1.2.

Examples

```
julia> endswith("JuliaLang", r"Lang|Roberts")
true
```

source

Base.contains – Function.

```
| contains(haystack::AbstractString, needle)
```

Return true if haystack contains needle. This is the same as occursin(needle, haystack), but is provided for consistency with startswith(haystack, needle) and endswith(haystack, needle).

See also [occursin](#), [in](#), [issubset](#).

Examples

```
julia> contains("JuliaLang is pretty cool!", "Julia")
true

julia> contains("JuliaLang is pretty cool!", 'a')
true

julia> contains("aba", r"a.a")
true

julia> contains("abba", r"a.a")
false
```

Julia 1.5

The contains function requires at least Julia 1.5.

source

```
| contains(needle)
```

Create a function that checks whether its argument contains needle, i.e. a function equivalent to haystack -> contains(haystack, needle).

The returned function is of type Base.Fix2{typeof(contains)}, which can be used to implement specialized methods.

source

Base.first – Method.

```
| first(s::AbstractString, n::Integer)
```

Get a string consisting of the first n characters of s.

Examples

```
julia> first("∀ε≠0: ε²>0", 0)
""

julia> first("∀ε≠0: ε²>0", 1)
"∀"

julia> first("∀ε≠0: ε²>0", 3)
"∀ε≠"
```

source

Base.last – Method.

```
| last(s::AbstractString, n::Integer)
```

Get a string consisting of the last n characters of s.

Examples

```
julia> last("∀ε≠0: ε²>0", 0)
""

julia> last("∀ε≠0: ε²>0", 1)
"0"

julia> last("∀ε≠0: ε²>0", 3)
"²>0"
```

source

Base.Unicode.uppercase – Function.

```
| uppercase(c::AbstractChar)
```

Convert c to uppercase.

See also [lowercase](#), [titlecase](#).

Examples

```
julia> uppercase('a')
'A': ASCII/Unicode U+0041 (category Lu: Letter, uppercase)

julia> uppercase('ê')
'Ê': Unicode U+00CA (category Lu: Letter, uppercase)
```

source

```
| uppercase(s::AbstractString)
```

Return s with all characters converted to uppercase.

See also [lowercase](#), [titlecase](#), [uppercasefirst](#).

Examples

```
julia> uppercase("Julia")
"JULIA"
```

source

Base.Unicode.lowercase – Function.

```
| lowercase(c::AbstractChar)
```

Convert `c` to lowercase.

See also [uppercase](#), [titlecase](#).

Examples

```
julia> lowercase('A')
'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)

julia> lowercase('Ö')
'ö': Unicode U+00F6 (category Ll: Letter, lowercase)
```

source

```
lowercase(s::AbstractString)
```

Return `s` with all characters converted to lowercase.

See also [uppercase](#), [titlecase](#), [lowercasefirst](#).

Examples

```
julia> lowercase("STRINGS AND THINGS")
"strings and things"
```

source

`Base.Unicode.titlecase` – Function.

```
titlecase(c::AbstractChar)
```

Convert `c` to titlecase. This may differ from uppercase for digraphs, compare the example below.

See also [uppercase](#), [lowercase](#).

Examples

```
julia> titlecase('a')
'A': ASCII/Unicode U+0041 (category Lu: Letter, uppercase)

julia> titlecase('')
'': Unicode U+01C5 (category Lt: Letter, titlecase)

julia> uppercase('')
'': Unicode U+01C4 (category Lu: Letter, uppercase)
```

source

```
titlecase(s::AbstractString; [wordsep::Function], strict::Bool=true) -> String
```

Capitalize the first character of each word in `s`; if `strict` is true, every other character is converted to lowercase, otherwise they are left unchanged. By default, all non-letters beginning a new grapheme are considered as word separators; a predicate can be passed as the `wordsep` keyword to determine which characters should be considered as word separators. See also [uppercasefirst](#) to capitalize only the first character in `s`.

See also [uppercase](#), [lowercase](#), [uppercasefirst](#).

Examples

```
julia> titlecase("the JULIA programming language")
"The Julia Programming Language"

julia> titlecase("ISS - international space station", strict=false)
"ISS - International Space Station"

julia> titlecase("a-a b-b", wordsep = c->c==' ')
"A-a B-b"
```

[source](#)

Base.Unicode.uppercasefirst – Function.

```
uppercasefirst(s::AbstractString) -> String
```

Return *s* with the first character converted to uppercase (technically "title case" for Unicode). See also [titlecase](#) to capitalize the first character of every word in *s*.

See also [lowercasefirst](#), [uppercase](#), [lowercase](#), [titlecase](#).

Examples

```
julia> uppercasefirst("python")
"Python"
```

[source](#)

Base.Unicode.lowercasefirst – Function.

```
lowercasefirst(s::AbstractString)
```

Return *s* with the first character converted to lowercase.

See also [uppercasefirst](#), [uppercase](#), [lowercase](#), [titlecase](#).

Examples

```
julia> lowercasefirst("Julia")
"julia"
```

[source](#)

Base.join – Function.

```
join([io::IO,] iterator [, delim [, last]])
```

Join any iterator into a single string, inserting the given delimiter (if any) between adjacent items. If *last* is given, it will be used instead of *delim* between the last two items. Each item of iterator is converted to a string via `print(io::IOBuffer, x)`. If *io* is given, the result is written to *io* rather than returned as a String.

Examples

```
julia> join(["apples", "bananas", "pineapples"], ", ", " and ")
"apples, bananas and pineapples"

julia> join([1,2,3,4,5])
"12345"
```

[source](#)

Base.chop – Function.

```
chop(s::AbstractString; head::Integer = 0, tail::Integer = 1)
```

Remove the first head and the last tail characters from s. The call chop(s) removes the last character from s. If it is requested to remove more characters than length(s) then an empty string is returned.

See also [chomp](#), [startswith](#), [first](#).

Examples

```
julia> a = "March"
"March"

julia> chop(a)
"Marc"

julia> chop(a, head = 1, tail = 2)
"ar"

julia> chop(a, head = 5, tail = 5)
""
```

[source](#)

Base.chopprefix – Function.

```
chopprefix(s::AbstractString, prefix::Union{AbstractString,Regex}) -> SubString
```

Remove the prefix prefix from s. If s does not start with prefix, a string equal to s is returned.

See also [chopsuffix](#).

Julia 1.8

This function is available as of Julia 1.8.

Examples

```
julia> chopprefix("Hamburger", "Ham")
"burger"

julia> chopprefix("Hamburger", "hotdog")
"Hamburger"
```

[source](#)

Base.chopsuffix – Function.

```
| chopsuffix(s::AbstractString, suffix::Union{AbstractString,Regex}) -> SubString
```

Remove the suffix suffix from s. If s does not end with suffix, a string equal to s is returned.

See also [chopprefix](#).

Julia 1.8

This function is available as of Julia 1.8.

Examples

```
| julia> chopsuffix("Hamburger", "er")
"Hamburg"

julia> chopsuffix("Hamburger", "hotdog")
"Hamburger"
```

[source](#)

Base.chomp – Function.

```
| chomp(s::AbstractString) -> SubString
```

Remove a single trailing newline from a string.

See also [chop](#).

Examples

```
| julia> chomp("Hello\n")
"Hello"
```

[source](#)

Base.thisind – Function.

```
| thisind(s::AbstractString, i::Integer) -> Int
```

If i is in bounds in s return the index of the start of the character whose encoding code unit i is part of. In other words, if i is the start of a character, return i; if i is not the start of a character, rewind until the start of a character and return that index. If i is equal to 0 or ncodeunits(s)+1 return i. In all other cases throw BoundsError.

Examples

```
| julia> thisind("α", 0)
0

julia> thisind("α", 1)
1

julia> thisind("α", 2)
```

```

1
julia> thisind("α", 3)
3
julia> thisind("α", 4)
ERROR: BoundsError: attempt to access 2-codeunit String at index [4]
[...]
julia> thisind("α", -1)
ERROR: BoundsError: attempt to access 2-codeunit String at index [-1]
[...]

```

[source](#)

Base.nextind – Function.

```
nextind(str::AbstractString, i::Integer, n::Integer=1) -> Int
```

- Case $n == 1$
If i is in bounds in s return the index of the start of the character whose encoding starts after index i . In other words, if i is the start of a character, return the start of the next character; if i is not the start of a character, move forward until the start of a character and return that index. If i is equal to 0 return 1. If i is in bounds but greater or equal to `lastindex(str)` return `ncodeunits(str)+1`. Otherwise throw `BoundsError`.
- Case $n > 1$
Behaves like applying n times `nextind` for $n==1$. The only difference is that if n is so large that applying `nextind` would reach `ncodeunits(str)+1` then each remaining iteration increases the returned value by 1. This means that in this case `nextind` can return a value greater than `ncodeunits(str)+1`.
- Case $n == 0$
Return i only if i is a valid index in s or is equal to 0. Otherwise `StringIndexError` or `BoundsError` is thrown.

Examples

```

julia> nextind("α", 0)
1
julia> nextind("α", 1)
3
julia> nextind("α", 3)
ERROR: BoundsError: attempt to access 2-codeunit String at index [3]
[...]
julia> nextind("α", 0, 2)
3
julia> nextind("α", 1, 2)
4

```

[source](#)

Base.prevind – Function.

```
| prevind(str::AbstractString, i::Integer, n::Integer=1) -> Int
```

- Case $n == 1$
If i is in bounds in s return the index of the start of the character whose encoding starts before index i . In other words, if i is the start of a character, return the start of the previous character; if i is not the start of a character, rewind until the start of a character and return that index. If i is equal to 1 return 0. If i is equal to $\text{ncodeunits}(str)+1$ return $\text{lastindex}(str)$. Otherwise throw `BoundsError`.
- Case $n > 1$
Behaves like applying n times `prevind` for $n==1$. The only difference is that if n is so large that applying `prevind` would reach 0 then each remaining iteration decreases the returned value by 1. This means that in this case `prevind` can return a negative value.
- Case $n == 0$
Return i only if i is a valid index in str or is equal to $\text{ncodeunits}(str)+1$. Otherwise `StringIndexError` or `BoundsError` is thrown.

Examples

```
julia> prevind("α", 3)
1

julia> prevind("α", 1)
0

julia> prevind("α", 0)
ERROR: BoundsError: attempt to access 2-codeunit String at index [0]
[...]

julia> prevind("α", 2, 2)
0

julia> prevind("α", 2, 3)
-1
```

[source](#)

Base.Unicode.textwidth – Function.

```
| textwidth(c)
```

Give the number of columns needed to print a character.

Examples

```
julia> textwidth('α')
1

julia> textwidth('')
2
```

source

```
| textwidth(s::AbstractString)
```

Give the number of columns needed to print a string.

Examples

```
| julia> textwidth("March")
| 5
```

source

Base.isascii – Function.

```
| isascii(c::Union{AbstractChar,AbstractString}) -> Bool
```

Test whether a character belongs to the ASCII character set, or whether this is true for all elements of a string.

Examples

```
| julia> isascii('a')
| true
|
| julia> isascii('α')
| false
|
| julia> isascii("abc")
| true
|
| julia> isascii("αβγ")
| false
```

For example, `isascii` can be used as a predicate function for `filter` or `replace` to remove or replace non-ASCII characters, respectively:

```
| julia> filter(isascii, "abcdeyfgH") # discard non-ASCII chars
| "abcdeyfgH"
|
| julia> replace("abcdeyfgH", !isascii=>' ') # replace non-ASCII chars with spaces
| "abcde fgh"
```

source

```
| isascii(cu::AbstractVector{CU}) where {CU <: Integer} -> Bool
```

Test whether all values in the vector belong to the ASCII character set (0x00 to 0x7f). This function is intended to be used by other string implementations that need a fast ASCII check.

source

Base.Unicode.iscntrl – Function.

```
| iscntrl(c::AbstractChar) -> Bool
```

Tests whether a character is a control character. Control characters are the non-printing characters of the Latin-1 subset of Unicode.

Examples

```
julia> iscntrl('\x01')
true

julia> iscntrl('a')
false
```

[source](#)

Base.Unicode.isdigit – Function.

```
isdigit(c::AbstractChar) -> Bool
```

Tests whether a character is a decimal digit (0-9).

See also: [isletter](#).

Examples

```
julia> isdigit('♥')
false

julia> isdigit('9')
true

julia> isdigit('α')
false
```

[source](#)

Base.Unicode.isletter – Function.

```
isletter(c::AbstractChar) -> Bool
```

Test whether a character is a letter. A character is classified as a letter if it belongs to the Unicode general category Letter, i.e. a character whose category code begins with 'L'.

See also: [isdigit](#).

Examples

```
julia> isletter('♥')
false

julia> isletter('α')
true

julia> isletter('9')
false
```

[source](#)

Base.Unicode.islowercase – Function.

```
| islowercase(c::AbstractChar) -> Bool
```

Tests whether a character is a lowercase letter (according to the Unicode standard's Lowercase derived property).

See also [isuppercase](#).

Examples

```
julia> islowercase('α')
true

julia> islowercase('Γ')
false

julia> islowercase('♥')
false
```

[source](#)

Base.Unicode.isnumeric – Function.

```
| isnumeric(c::AbstractChar) -> Bool
```

Tests whether a character is numeric. A character is classified as numeric if it belongs to the Unicode general category Number, i.e. a character whose category code begins with 'N'.

Note that this broad category includes characters such as $\frac{3}{4}$ and \cdot . Use [isdigit](#) to check whether a character is a decimal digit between 0 and 9.

Examples

```
julia> isnumeric('')
true

julia> isnumeric('9')
true

julia> isnumeric('α')
false

julia> isnumeric('♥')
false
```

[source](#)

Base.Unicode.isprint – Function.

```
| isprint(c::AbstractChar) -> Bool
```

Tests whether a character is printable, including spaces, but not a control character.

Examples

```
julia> isprint('\x01')
false

julia> isprint('A')
true
```

[source](#)

Base.Unicode.ispunct – Function.

```
ispunct(c::AbstractChar) -> Bool
```

Tests whether a character belongs to the Unicode general category Punctuation, i.e. a character whose category code begins with 'P'.

Examples

```
julia> ispunct('α')
false

julia> ispunct('/')
true

julia> ispunct(';')
true
```

[source](#)

Base.Unicode.isspace – Function.

```
isspace(c::AbstractChar) -> Bool
```

Tests whether a character is any whitespace character. Includes ASCII characters '\t', '\n', '\v', '\f', '\r', and ' ', Latin-1 character U+0085, and characters in Unicode category Zs.

Examples

```
julia> isspace('\n')
true

julia> isspace('\r')
true

julia> isspace(' ')
true

julia> isspace('\x20')
true
```

[source](#)

Base.Unicode.isuppercase – Function.

```
isuppercase(c::AbstractChar) -> Bool
```

Tests whether a character is an uppercase letter (according to the Unicode standard's Uppercase derived property).

See also [islowercase](#).

Examples

```
julia> isuppercase('Y')
false

julia> isuppercase('Γ')
true

julia> isuppercase('♥')
false
```

[source](#)

`Base.Unicode.isxdigit` – Function.

```
isxdigit(c::AbstractChar) -> Bool
```

Test whether a character is a valid hexadecimal digit. Note that this does not include x (as in the standard 0x prefix).

Examples

```
julia> isxdigit('a')
true

julia> isxdigit('x')
false
```

[source](#)

`Base.escape_string` – Function.

```
escape_string(str::AbstractString[, esc]; keep = ())::AbstractString
escape_string(io, str::AbstractString[, esc]; keep = ())::Nothing
```

General escaping of traditional C and Unicode escape sequences. The first form returns the escaped string, the second prints the result to `io`.

Backslashes (\) are escaped with a double-backslash ("\\"). Non-printable characters are escaped either with their standard C escape codes, "\0" for NUL (if unambiguous), unicode code point ("\u" prefix) or hex ("\x" prefix).

The optional `esc` argument specifies any additional characters that should also be escaped by a pre-pending backslash (" is also escaped by default in the first form).

The argument `keep` specifies a collection of characters which are to be kept as they are. Notice that `esc` has precedence here.

See also [unescape_string](#) for the reverse operation.

Julia 1.7

The `keep` argument is available as of Julia 1.7.

Examples

```
julia> escape_string("aaa\nbbb")
"aaa\\nbbb"

julia> escape_string("aaa\nbbb"; keep = '\n')
"aaa\nbbb"

julia> escape_string("\xfe\xff") # invalid utf-8
"\\xfe\\xff"

julia> escape_string(string('\u2135', '\0')) # unambiguous
"\\0"

julia> escape_string(string('\u2135', '\0', '\0')) # \0 would be ambiguous
"\\x000"
```

[source](#)

`Base.unescape_string` - Function.

```
unescape_string(str::AbstractString, keep = ())::AbstractString
unescape_string(io, s::AbstractString, keep = ())::Nothing
```

General unescaping of traditional C and Unicode escape sequences. The first form returns the escaped string, the second prints the result to `io`. The argument `keep` specifies a collection of characters which (along with backslashes) are to be kept as they are.

The following escape sequences are recognised:

- Escaped backslash (\\)
- Escaped double-quote (\")
- Standard C escape sequences (\a, \b, \t, \n, \v, \f, \r, \e)
- Unicode BMP code points (\u with 1-4 trailing hex digits)
- All Unicode code points (\U with 1-8 trailing hex digits; max value = 0010ffff)
- Hex bytes (\x with 1-2 trailing hex digits)
- Octal bytes (\ with 1-3 trailing octal digits)

See also [escape_string](#).

Examples

```
julia> unescape_string("aaa\\nbbb") # C escape sequence
"aaa\nbbb"

julia> unescape_string("\\u03c0") # unicode
"π"
```

```
julia> unescape_string("\\101") # octal
"A"

julia> unescape_string("aaa \\g \\n", ['g']) # using `keep` argument
"aaa \\g \\n"
```

[source](#)

Chapter 46

Arrays

46.1 Constructors and Types

Core.AbstractArray – Type.

| **AbstractArray**{T,N}

Supertype for N-dimensional arrays (or array-like types) with elements of type T. [Array](#) and other types are subtypes of this. See the manual section on the [AbstractArray interface](#).

See also: [AbstractVector](#), [AbstractMatrix](#), [eltype](#), [ndims](#).

[source](#)

Base.AbstractVector – Type.

| **AbstractVector**{T}

Supertype for one-dimensional arrays (or array-like types) with elements of type T. Alias for [AbstractArray{T,1}](#).

[source](#)

Base.AbstractMatrix – Type.

| **AbstractMatrix**{T}

Supertype for two-dimensional arrays (or array-like types) with elements of type T. Alias for [AbstractArray{T,2}](#).

[source](#)

Base.AbstractVecOrMat – Type.

| **AbstractVecOrMat**{T}

Union type of [AbstractVector{T}](#) and [AbstractMatrix{T}](#).

[source](#)

Core.Array – Type.

| **Array**{T,N} <: **AbstractArray**{T,N}

N-dimensional dense array with elements of type T.

[source](#)

Core.Array – Method.

```
Array{T}(undef, dims)
Array{T,N}(undef, dims)
```

Construct an uninitialized N-dimensional `Array` containing elements of type T. N can either be supplied explicitly, as in `Array{T,N}(undef, dims)`, or be determined by the length or number of dims. dims may be a tuple or a series of integer arguments corresponding to the lengths in each dimension. If the rank N is supplied explicitly, then it must match the length or number of dims. Here `undef` is the `UndefInitializer`.

Examples

```
julia> A = Array{Float64, 2}(undef, 2, 3) # N given explicitly
2×3 Matrix{Float64}:
 6.90198e-310  6.90198e-310  6.90198e-310
 6.90198e-310  6.90198e-310  0.0

julia> B = Array{Float64}(undef, 4) # N determined by the input
4-element Vector{Float64}:
 2.360075077e-314
 NaN
 2.2671131793e-314
 2.299821756e-314

julia> similar(B, 2, 4, 1) # use typeof(B), and the given size
2×4×1 Array{Float64, 3}:
[:, :, 1] =
 2.26703e-314  2.26708e-314  0.0          2.80997e-314
 0.0          2.26703e-314  2.26708e-314  0.0
```

[source](#)

Core.Array – Method.

```
Array{T}(nothing, dims)
Array{T,N}(nothing, dims)
```

Construct an N-dimensional `Array` containing elements of type T, initialized with `nothing` entries. Element type T must be able to hold these values, i.e. `Nothing <: T`.

Examples

```
julia> Array{Union{Nothing, String}}(nothing, 2)
2-element Vector{Union{Nothing, String}}:
 nothing
 nothing

julia> Array{Union{Nothing, Int}}(nothing, 2, 3)
2×3 Matrix{Union{Nothing, Int64}}:
 nothing  nothing  nothing
 nothing  nothing  nothing
```

[source](#)

Core.Array – Method.

```
Array{T}(missing, dims)
Array{T,N}(missing, dims)
```

Construct an N-dimensional [Array](#) containing elements of type T, initialized with [missing](#) entries. Element type T must be able to hold these values, i.e. `Missing <: T`.

Examples

```
julia> Array{Union{Missing, String}}(missing, 2)
2-element Vector{Union{Missing, String}}:
 missing
 missing

julia> Array{Union{Missing, Int}}(missing, 2, 3)
2×3 Matrix{Union{Missing, Int64}}:
 missing missing missing
 missing missing missing
```

[source](#)

Core.UndefInitializer – Type.

```
UndefInitializer
```

Singleton type used in array initialization, indicating the array-constructor-caller would like an uninitialized array. See also [undef](#), an alias for `UndefInitializer()`.

Examples

```
julia> Array{Float64, 1}(UndefInitializer(), 3)
3-element Array{Float64, 1}:
 2.2752528595e-314
 2.202942107e-314
 2.275252907e-314
```

[source](#)

Core.undef – Constant.

```
undef
```

Alias for `UndefInitializer()`, which constructs an instance of the singleton type [UndefInitializer](#), used in array initialization to indicate the array-constructor-caller would like an uninitialized array.

See also: [missing](#), [similar](#).

Examples

```
julia> Array{Float64, 1}(undef, 3)
3-element Vector{Float64}:
 2.2752528595e-314
 2.202942107e-314
 2.275252907e-314
```

[source](#)

Base.Vector – Type.

```
| Vector{T} <: AbstractVector{T}
```

One-dimensional dense array with elements of type T, often used to represent a mathematical vector. Alias for `Array{T,1}`.

See also [empty](#), [similar](#) and [zero](#) for creating vectors.

[source](#)

Base.Vector – Method.

```
| Vector{T}(undef, n)
```

Construct an uninitialized `Vector{T}` of length n.

Examples

```
julia> Vector{Float64}(undef, 3)
3-element Array{Float64, 1}:
 6.90966e-310
 6.90966e-310
 6.90966e-310
```

[source](#)

Base.Vector – Method.

```
| Vector{T}(nothing, m)
```

Construct a `Vector{T}` of length m, initialized with `nothing` entries. Element type T must be able to hold these values, i.e. `Nothing <: T`.

Examples

```
julia> Vector{Union{Nothing, String}}(nothing, 2)
2-element Vector{Union{Nothing, String}}:
 nothing
 nothing
```

[source](#)

Base.Vector – Method.

```
| Vector{T}(missing, m)
```

Construct a `Vector{T}` of length m, initialized with `missing` entries. Element type T must be able to hold these values, i.e. `Missing <: T`.

Examples

```
julia> Vector{Union{Missing, String}}(missing, 2)
2-element Vector{Union{Missing, String}}:
 missing
 missing
```

[source](#)

Base.Matrix – Type.

```
Matrix{T} <: AbstractMatrix{T}
```

Two-dimensional dense array with elements of type T, often used to represent a mathematical matrix. Alias for `Array{T,2}`.

See also `fill`, `zeros`, `undef` and `similar` for creating matrices.

[source](#)

Base.Matrix – Method.

```
Matrix{T}(undef, m, n)
```

Construct an uninitialized `Matrix{T}` of size `m`×`n`.

Examples

```
julia> Matrix{Float64}(undef, 2, 3)
2×3 Array{Float64, 2}:
 2.36365e-314  2.28473e-314   5.0e-324
 2.26704e-314  2.26711e-314  NaN

julia> similar(ans, Int32, 2, 2)
2×2 Matrix{Int32}:
 490537216  1277177453
      1    1936748399
```

[source](#)

Base.Matrix – Method.

```
Matrix{T}(nothing, m, n)
```

Construct a `Matrix{T}` of size `m`×`n`, initialized with `nothing` entries. Element type T must be able to hold these values, i.e. `Nothing <: T`.

Examples

```
julia> Matrix{Union{Nothing, String}}(nothing, 2, 3)
2×3 Matrix{Union{Nothing, String}}:
 nothing  nothing  nothing
 nothing  nothing  nothing
```

[source](#)

Base.Matrix – Method.

```
| Matrix{T}(missing, m, n)
```

Construct a `Matrix{T}` of size $m \times n$, initialized with `missing` entries. Element type `T` must be able to hold these values, i.e. `Missing <: T`.

Examples

```
| julia> Matrix{Union{Missing, String}}(missing, 2, 3)
2×3 Matrix{Union{Missing, String}}:
 missing missing missing
 missing missing missing
```

[source](#)

`Base.VecOrMat` – Type.

```
| VecOrMat{T}
```

Union type of `Vector{T}` and `Matrix{T}` which allows functions to accept either a Matrix or a Vector.

Examples

```
| julia> Vector{Float64} <: VecOrMat{Float64}
true

julia> Matrix{Float64} <: VecOrMat{Float64}
true

julia> Array{Float64, 3} <: VecOrMat{Float64}
false
```

[source](#)

`Core.DenseArray` – Type.

```
| DenseArray{T, N} <: AbstractArray{T,N}
```

N -dimensional dense array with elements of type `T`. The elements of a dense array are stored contiguously in memory.

[source](#)

`Base.DenseVector` – Type.

```
| DenseVector{T}
```

One-dimensional `DenseArray` with elements of type `T`. Alias for `DenseArray{T,1}`.

[source](#)

`Base.DenseMatrix` – Type.

```
| DenseMatrix{T}
```

Two-dimensional `DenseArray` with elements of type `T`. Alias for `DenseArray{T,2}`.

[source](#)

Base.DenseVecOrMat – Type.

```
| DenseVecOrMat{T}
```

Union type of [DenseVector{T}](#) and [DenseMatrix{T}](#).

[source](#)

Base.StridedArray – Type.

```
| StridedArray{T, N}
```

A hard-coded [Union](#) of common array types that follow the [strided array interface](#), with elements of type T and N dimensions.

If A is a [StridedArray](#), then its elements are stored in memory with offsets, which may vary between dimensions but are constant within a dimension. For example, A could have stride 2 in dimension 1, and stride 3 in dimension 2. Incrementing A along dimension d jumps in memory by [stride(A, d)] slots. Strided arrays are particularly important and useful because they can sometimes be passed directly as pointers to foreign language libraries like BLAS.

[source](#)

Base.StridedVector – Type.

```
| StridedVector{T}
```

One dimensional [StridedArray](#) with elements of type T.

[source](#)

Base.StridedMatrix – Type.

```
| StridedMatrix{T}
```

Two dimensional [StridedArray](#) with elements of type T.

[source](#)

Base.StridedVecOrMat – Type.

```
| StridedVecOrMat{T}
```

Union type of [StridedVector](#) and [StridedMatrix](#) with elements of type T.

[source](#)

Base.Slices – Type.

```
| Slices{P,SM,AX,S,N} <: AbstractSlices{S,N}
```

An [AbstractArray](#) of slices into a parent array over specified dimension(s), returning views that select all the data from the other dimension(s).

These should typically be constructed by [eachslice](#), [eachcol](#) or [eachrow](#).

[parent\(s::Slices\)](#) will return the parent array.

[source](#)

Base.RowSlices – Type.

```
| RowSlices{M,AX,S}
```

A special case of [Slices](#) that is a vector of row slices of a matrix, as constructed by [eachrow](#).

[parent](#) can be used to get the underlying matrix.

[source](#)

Base.ColumnSlices – Type.

```
| ColumnSlices{M,AX,S}
```

A special case of [Slices](#) that is a vector of column slices of a matrix, as constructed by [eachcol](#).

[parent](#) can be used to get the underlying matrix.

[source](#)

Base.getindex – Method.

```
| getindex(type[], elements...)
```

Construct a 1-d array of the specified type. This is usually called with the syntax `Type[]`. Element values can be specified using `Type[a,b,c,...]`.

Examples

```
julia> Int8[1, 2, 3]
3-element Vector{Int8}:
 1
 2
 3

julia> getindex(Int8, 1, 2, 3)
3-element Vector{Int8}:
 1
 2
 3
```

[source](#)

Base.zeros – Function.

```
| zeros([T=Float64,] dims::Tuple)
| zeros([T=Float64,] dims...)
```

Create an Array, with element type T, of all zeros with size specified by dims. See also [fill](#), [ones](#), [zero](#).

Examples

```
julia> zeros{1}
1-element Vector{Float64}:
 0.0
```

```
julia> zeros{Int8, 2, 3}
2×3 Matrix{Int8}:
 0  0  0
 0  0  0
```

[source](#)

Base.ones – Function.

```
ones{[T=Float64,] dims::Tuple}
ones{[T=Float64,] dims...}
```

Create an Array, with element type T, of all ones with size specified by dims. See also [fill](#), [zeros](#).

Examples

```
julia> ones{1,2}
1×2 Matrix{Float64}:
 1.0  1.0

julia> ones{ComplexF64, 2, 3}
2×3 Matrix{ComplexF64}:
 1.0+0.0im  1.0+0.0im  1.0+0.0im
 1.0+0.0im  1.0+0.0im  1.0+0.0im
```

[source](#)

Base.BitArray – Type.

```
BitArray{N} <: AbstractArray{Bool, N}
```

Space-efficient N-dimensional boolean array, using just one bit for each boolean value.

BitArrays pack up to 64 values into every 8 bytes, resulting in an 8x space efficiency over `Array{Bool, N}` and allowing some operations to work on 64 values at once.

By default, Julia returns BitArrays from [broadcasting](#) operations that generate boolean elements (including dotted-comparisons like `==`) as well as from the functions [trues](#) and [falses](#).

Note

Due to its packed storage format, concurrent access to the elements of a BitArray where at least one of them is a write is not thread-safe.

[source](#)

Base.BitArray – Method.

```
BitArray{undef, dims::Integer...}
BitArray{N}(undef, dims::NTuple{N,Int})
```

Construct an undef [BitArray](#) with the given dimensions. Behaves identically to the [Array](#) constructor. See [undef](#).

Examples

```
julia> BitArray(undef, 2, 2)
2×2 BitMatrix:
 0  0
 0  0

julia> BitArray(undef, (3, 1))
3×1 BitMatrix:
 0
 0
 0
```

[source](#)

Base.BitArray – Method.

```
| BitArray(itr)
```

Construct a `BitArray` generated by the given iterable object. The shape is inferred from the `itr` object.

Examples

```
julia> BitArray([1 0; 0 1])
2×2 BitMatrix:
 1  0
 0  1

julia> BitArray(x+y == 3 for x = 1:2, y = 1:3)
2×3 BitMatrix:
 0  1  0
 1  0  0

julia> BitArray(x+y == 3 for x = 1:2 for y = 1:3)
6-element BitVector:
 0
 1
 0
 1
 0
 0
```

[source](#)

Base.trues – Function.

```
| trues(dims)
```

Create a `BitArray` with all values set to true.

Examples

```
julia> trues(2,3)
2×3 BitMatrix:
 1  1  1
 1  1  1
```

[source](#)

Base.falses – Function.

```
| falses(dims)
```

Create a BitArray with all values set to false.

Examples

```
julia> falses(2,3)
2×3 BitMatrix:
 0  0  0
 0  0  0
```

[source](#)

Base.fill – Function.

```
| fill(value, dims::Tuple)
| fill(value, dims...)
```

Create an array of size `dims` with every location set to `value`.

For example, `fill(1.0, (5,5))` returns a 5×5 array of floats, with 1.0 in every location of the array.

The dimension lengths `dims` may be specified as either a tuple or a sequence of arguments. An N-length tuple or N arguments following the value specify an N-dimensional array. Thus, a common idiom for creating a zero-dimensional array with its only location set to `x` is `fill(x)`.

Every location of the returned array is set to (and is thus `===` to) the value that was passed; this means that if the value is itself modified, all elements of the filled array will reflect that modification because they're still that very value. This is of no concern with `fill(1.0, (5,5))` as the value 1.0 is immutable and cannot itself be modified, but can be unexpected with mutable values like — most commonly — arrays. For example, `fill([], 3)` places the very same empty array in all three locations of the returned vector:

```
julia> v = fill([], 3)
3-element Vector{Vector{Any}}:
 []
 []
 []

julia> v[1] === v[2] === v[3]
true

julia> value = v[1]
Any[]

julia> push!(value, 867_5309)
1-element Vector{Any}:
 8675309

julia> v
3-element Vector{Vector{Any}}:
```

```
[8675309]
[8675309]
[8675309]
```

To create an array of many independent inner arrays, use a [comprehension](#) instead. This creates a new and distinct array on each iteration of the loop:

```
julia> v2 = [[] for _ in 1:3]
3-element Vector{Vector{Any}}:
 []
 []
 []

julia> v2[1] === v2[2] === v2[3]
false

julia> push!(v2[1], 8675309)
1-element Vector{Any}:
 8675309

julia> v2
3-element Vector{Vector{Any}}:
 [8675309]
 []
 []
```

See also: [fill!](#), [zeros](#), [ones](#), [similar](#).

Examples

```
julia> fill(1.0, (2,3))
2×3 Matrix{Float64}:
 1.0  1.0  1.0
 1.0  1.0  1.0

julia> fill(42)
0-dimensional Array{Int64, 0}:
 42

julia> A = fill(zeros(2), 2) # sets both elements to the same [0.0, 0.0] vector
2-element Vector{Vector{Float64}}:
 [0.0, 0.0]
 [0.0, 0.0]

julia> A[1][1] = 42; # modifies the filled value to be [42.0, 0.0]

julia> A # both A[1] and A[2] are the very same vector
2-element Vector{Vector{Float64}}:
 [42.0, 0.0]
 [42.0, 0.0]
```

[source](#)

`Base.fill!` – Function.

```
| fill!(A, x)
```

Fill array A with the value x. If x is an object reference, all elements will refer to the same object. `fill!(A, Foo())` will return A filled with the result of evaluating `Foo()` once.

Examples

```
julia> A = zeros(2,3)
2×3 Matrix{Float64}:
 0.0  0.0  0.0
 0.0  0.0  0.0

julia> fill!(A, 2.)
2×3 Matrix{Float64}:
 2.0  2.0  2.0
 2.0  2.0  2.0

julia> a = [1, 1, 1]; A = fill!(Vector{Vector{Int}}(undef, 3), a); a[1] = 2; A
3-element Vector{Vector{Int64}}:
 [2, 1, 1]
 [2, 1, 1]
 [2, 1, 1]

julia> x = 0; f() = (global x += 1; x); fill!(Vector{Int}(undef, 3), f())
3-element Vector{Int64}:
 1
 1
 1
```

[source](#)

`Base.empty` – Function.

```
| empty(x::Tuple)
```

Return an empty tuple, `()`.

[source](#)

```
| empty(v::AbstractVector, [eltype])
```

Create an empty vector similar to v, optionally changing the `eltype`.

See also: [empty!](#), [isempty](#), [isassigned](#).

Examples

```
julia> empty([1.0, 2.0, 3.0])
Float64[]

julia> empty([1.0, 2.0, 3.0], String)
String[]
```

[source](#)

```
| empty(a::AbstractDict, [index_type=keytype(a)], [value_type=valtype(a)])
```

Create an empty `AbstractDict` container which can accept indices of type `index_type` and values of type `value_type`. The second and third arguments are optional and default to the input's `keytype` and `valtype`, respectively. (If only one of the two types is specified, it is assumed to be the `value_type`, and the `index_type` we default to `keytype(a)`).

Custom `AbstractDict` subtypes may choose which specific dictionary type is best suited to return for the given index and value types, by specializing on the three-argument signature. The default is to return an empty `Dict`.

source

`Base.similar` - Function.

```
similar(A::AbstractSparseMatrixCSC{Tv,Ti}, [::Type{TvNew}, ::Type{TiNew}, m::Integer,
↪ n::Integer]) where {Tv,Ti}
```

Create an uninitialized mutable array with the given element type, index type, and size, based upon the given source `SparseMatrixCSC`. The new sparse matrix maintains the structure of the original sparse matrix, except in the case where dimensions of the output matrix are different from the output.

The output matrix has zeros in the same locations as the input, but uninitialized values for the nonzero locations.

source

```
similar(array, [element_type=eltype(array)], [dims=size(array)])
```

Create an uninitialized mutable array with the given element type and size, based upon the given source array. The second and third arguments are both optional, defaulting to the given array's `eltype` and `size`. The dimensions may be specified either as a single tuple argument or as a series of integer arguments.

Custom `AbstractArray` subtypes may choose which specific array type is best-suited to return for the given element type and dimensionality. If they do not specialize this method, the default is an `Array{element_type}(undef, dims...)`.

For example, `similar(1:10, 1, 4)` returns an uninitialized `Array{Int,2}` since ranges are neither mutable nor support 2 dimensions:

```
julia> similar(1:10, 1, 4)
1×4 Matrix{Int64}:
 4419743872  4374413872  4419743888  0
```

Conversely, `similar(trues(10,10), 2)` returns an uninitialized `BitVector` with two elements since `BitArrays` are both mutable and can support 1-dimensional arrays:

```
julia> similar(trues(10,10), 2)
2-element BitVector:
 0
 0
```

Since `BitArrays` can only store elements of type `Bool`, however, if you request a different element type it will create a regular `Array` instead:

```
julia> similar(falses(10), Float64, 2, 4)
2×4 Matrix{Float64}:
 2.18425e-314  2.18425e-314  2.18425e-314  2.18425e-314
 2.18425e-314  2.18425e-314  2.18425e-314  2.18425e-314
```

See also: [undef](#), [isassigned](#).

[source](#)

```
similar(storagetype, axes)
```

Create an uninitialized mutable array analogous to that specified by `storagetype`, but with axes specified by the last argument.

Examples:

```
similar(Array{Int}, axes(A))
```

creates an array that "acts like" an `Array{Int}` (and might indeed be backed by one), but which is indexed identically to `A`. If `A` has conventional indexing, this will be identical to `Array{Int}(undef, size(A))`, but if `A` has unconventional indexing then the indices of the result will match `A`.

```
similar(BitArray, (axes(A, 2),))
```

would create a 1-dimensional logical array whose indices match those of the columns of `A`.

[source](#)

46.2 Basic functions

`Base.ndims` – Function.

```
ndims(A::AbstractArray) -> Integer
```

Return the number of dimensions of `A`.

See also: [size](#), [axes](#).

Examples

```
julia> A = fill(1, (3,4,5));
julia> ndims(A)
3
```

[source](#)

`Base.size` – Function.

```
size(A::AbstractArray, [dim])
```

Return a tuple containing the dimensions of `A`. Optionally you can specify a dimension to just get the length of that dimension.

Note that `size` may not be defined for arrays with non-standard indices, in which case [axes](#) may be useful. See the manual chapter on [arrays with custom indices](#).

See also: [length](#), [ndims](#), [eachindex](#), [sizeof](#).

Examples

```
julia> A = fill(1, (2,3,4));

julia> size(A)
(2, 3, 4)

julia> size(A, 2)
3
```

[source](#)

Base.axes – Method.

```
| axes(A)
```

Return the tuple of valid indices for array A.

See also: [size](#), [keys](#), [eachindex](#).

Examples

```
julia> A = fill(1, (5,6,7));

julia> axes(A)
(Base.OneTo(5), Base.OneTo(6), Base.OneTo(7))
```

[source](#)

Base.axes – Method.

```
| axes(A, d)
```

Return the valid range of indices for array A along dimension d.

See also [size](#), and the manual chapter on [arrays with custom indices](#).

Examples

```
julia> A = fill(1, (5,6,7));

julia> axes(A, 2)
Base.OneTo(6)

julia> axes(A, 4) == 1:1 # all dimensions d > ndims(A) have size 1
true
```

Usage note

Each of the indices has to be an `AbstractUnitRange{<:Integer}`, but at the same time can be a type that uses custom indices. So, for example, if you need a subset, use generalized indexing constructs like `begin/end` or [firstindex/lastindex](#):

```
ix = axes(v, 1)
ix[2:end]           # will work for eg Vector, but may fail in general
ix[(begin+1):end]   # works for generalized indexes
```

[source](#)

`Base.length` – Method.

```
length(A::AbstractArray)
```

Return the number of elements in the array, defaults to `prod(size(A))`.

Examples

```
julia> length([1, 2, 3, 4])
4

julia> length([1 2; 3 4])
4
```

[source](#)

`Base.keys` – Method.

```
keys(a::AbstractArray)
```

Return an efficient array describing all valid indices for `a` arranged in the shape of `a` itself.

The keys of 1-dimensional arrays (vectors) are integers, whereas all other N-dimensional arrays use [CartesianIndex](#) to describe their locations. Often the special array types [LinearIndices](#) and [CartesianIndices](#) are used to efficiently represent these arrays of integers and CartesianIndexes, respectively.

Note that the keys of an array might not be the most efficient index type; for maximum performance use [eachindex](#) instead.

Examples

```
julia> keys([4, 5, 6])
3-element LinearIndices{1, Tuple{Base.OneTo{Int64}}}:
 1
 2
 3

julia> keys([4 5; 6 7])
CartesianIndices{2, 2}()
```

[source](#)

`Base.eachindex` – Function.

```
eachindex(A...)
eachindex(::IndexStyle, A::AbstractArray...)
```

Create an iterable object for visiting each index of an `AbstractArray` `A` in an efficient manner. For array types that have opted into fast linear indexing (like `Array`), this is simply the range `1:length(A)` if they use 1-based indexing. For array types that have not opted into fast linear indexing, a specialized Cartesian range is typically returned to efficiently index into the array with indices specified for every dimension.

In general `eachindex` accepts arbitrary iterables, including strings and dictionaries, and returns an iterator object supporting arbitrary index types (e.g. unevenly spaced or non-integer indices).

If `A` is `AbstractArray` it is possible to explicitly specify the style of the indices that should be returned by `eachindex` by passing a value having `IndexStyle` type as its first argument (typically `IndexLinear()` if linear indices are required or `IndexCartesian()` if Cartesian range is wanted).

If you supply more than one `AbstractArray` argument, `eachindex` will create an iterable object that is fast for all arguments (typically a `UnitRange` if all inputs have fast linear indexing, a `CartesianIndices` otherwise). If the arrays have different sizes and/or dimensionalities, a `DimensionMismatch` exception will be thrown.

See also `pairs(A)` to iterate over indices and values together, and `axes(A, 2)` for valid indices along one dimension.

Examples

```
julia> A = [10 20; 30 40];

julia> for i in eachindex(A) # linear indexing
    println("A[" , i, "] == ", A[i])
end
A[1] == 10
A[2] == 30
A[3] == 20
A[4] == 40

julia> for i in eachindex(view(A, 1:2, 1:1)) # Cartesian indexing
    println(i)
end
CartesianIndex{1, 1}
CartesianIndex{2, 1}
```

[source](#)

`Base.IndexStyle` - Type.

```
IndexStyle(A)
IndexStyle(typeof(A))
```

`IndexStyle` specifies the "native indexing style" for array `A`. When you define a new `AbstractArray` type, you can choose to implement either linear indexing (with `IndexLinear`) or cartesian indexing. If you decide to only implement linear indexing, then you must set this trait for your array type:

```
Base.IndexStyle{::Type{<:MyArray}} = IndexLinear()
```

The default is `IndexCartesian()`.

Julia's internal indexing machinery will automatically (and invisibly) recompute all indexing operations into the preferred style. This allows users to access elements of your array using any indexing style, even when explicit methods have not been provided.

If you define both styles of indexing for your `AbstractArray`, this trait can be used to select the most performant indexing style. Some methods check this trait on their inputs, and dispatch to different algorithms depending on the most efficient access pattern. In particular, `eachindex` creates an iterator whose type depends on the setting of this trait.

[source](#)

`Base.IndexLinear` – Type.

| `IndexLinear()`

Subtype of `IndexStyle` used to describe arrays which are optimally indexed by one linear index.

A linear indexing style uses one integer index to describe the position in the array (even if it's a multi-dimensional array) and column-major ordering is used to efficiently access the elements. This means that requesting `eachindex` from an array that is `IndexLinear` will return a simple one-dimensional range, even if it is multidimensional.

A custom array that reports its `IndexStyle` as `IndexLinear` only needs to implement indexing (and indexed assignment) with a single `Int` index; all other indexing expressions — including multidimensional accesses — will be recomputed to the linear index. For example, if `A` were a 2×3 custom matrix with linear indexing, and we referenced `A[1, 3]`, this would be recomputed to the equivalent linear index and call `A[5]` since $1 + 2 * (3 - 1) = 5$.

See also `IndexCartesian`.

[source](#)

`Base.IndexCartesian` – Type.

| `IndexCartesian()`

Subtype of `IndexStyle` used to describe arrays which are optimally indexed by a Cartesian index. This is the default for new custom `AbstractArray` subtypes.

A Cartesian indexing style uses multiple integer indices to describe the position in a multidimensional array, with exactly one index per dimension. This means that requesting `eachindex` from an array that is `IndexCartesian` will return a range of `CartesianIndices`.

An N -dimensional custom array that reports its `IndexStyle` as `IndexCartesian` needs to implement indexing (and indexed assignment) with exactly N `Int` indices; all other indexing expressions — including linear indexing — will be recomputed to the equivalent Cartesian location. For example, if `A` were a 2×3 custom matrix with cartesian indexing, and we referenced `A[5]`, this would be recomputed to the equivalent Cartesian index and call `A[1, 3]` since $5 = 1 + 2 * (3 - 1)$.

It is significantly more expensive to compute Cartesian indices from a linear index than it is to go the other way. The former operation requires division — a very costly operation — whereas the latter only uses multiplication and addition and is essentially free. This asymmetry means it is far more costly to use linear indexing with an `IndexCartesian` array than it is to use Cartesian indexing with an `IndexLinear` array.

See also `IndexLinear`.

[source](#)

`Base.conj!` – Function.

```
| conj!(A)
```

Transform an array to its complex conjugate in-place.

See also [conj](#).

Examples

```
julia> A = [1+im 2-im; 2+2im 3+im]
2×2 Matrix{Complex{Int64}}:
 1+1im  2-1im
 2+2im  3+1im

julia> conj!(A);

julia> A
2×2 Matrix{Complex{Int64}}:
 1-1im  2+1im
 2-2im  3-1im
```

[source](#)

`Base.stride` – Function.

```
| stride(A, k::Integer)
```

Return the distance in memory (in number of elements) between adjacent elements in dimension `k`.

See also: [strides](#).

Examples

```
julia> A = fill(1, (3,4,5));

julia> stride(A,2)
3

julia> stride(A,3)
12
```

[source](#)

`Base.strides` – Function.

```
| strides(A)
```

Return a tuple of the memory strides in each dimension.

See also: [stride](#).

Examples

```
julia> A = fill(1, (3,4,5));

julia> strides(A)
(1, 3, 12)
```

source

46.3 Broadcast and vectorization

See also the [dot syntax for vectorizing functions](#); for example, `f.(args...)` implicitly calls `broadcast(f, args...)`. Rather than relying on "vectorized" methods of functions like `sin` to operate on arrays, you should use `sin.(a)` to vectorize via broadcast.

`Base.Broadcast.broadcast` – Function.

```
| broadcast(f, As...)
```

Broadcast the function `f` over the arrays, tuples, collections, [Refs](#) and/or scalars `As`.

Broadcasting applies the function `f` over the elements of the container arguments and the scalars themselves in `As`. Singleton and missing dimensions are expanded to match the extents of the other arguments by virtually repeating the value. By default, only a limited number of types are considered scalars, including Numbers, Strings, Symbols, Types, Functions and some common singletons like [missing](#) and [nothing](#). All other arguments are iterated over or indexed into elementwise.

The resulting container type is established by the following rules:

- If all the arguments are scalars or zero-dimensional arrays, it returns an unwrapped scalar.
- If at least one argument is a tuple and all others are scalars or zero-dimensional arrays, it returns a tuple.
- All other combinations of arguments default to returning an `Array`, but custom container types can define their own implementation and promotion-like rules to customize the result when they appear as arguments.

A special syntax exists for broadcasting: `f.(args...)` is equivalent to `broadcast(f, args...)`, and nested `f.(g.(args...))` calls are fused into a single broadcast loop.

Examples

```
julia> A = [1, 2, 3, 4, 5]
5-element Vector{Int64}:
 1
 2
 3
 4
 5

julia> B = [1 2; 3 4; 5 6; 7 8; 9 10]
5×2 Matrix{Int64}:
 1  2
 3  4
 5  6
 7  8
 9 10

julia> broadcast(+, A, B)
5×2 Matrix{Int64}:
```

```

2 3
5 6
8 9
11 12
14 15

julia> parse.(Int, ["1", "2"])
2-element Vector{Int64}:
 1
 2

julia> abs.((1, -2))
(1, 2)

julia> broadcast(+, 1.0, (0, -2.0))
(1.0, -1.0)

julia> (+).([0,2], [1,3], Ref{Vector{Int}}{([1,-1])})
2-element Vector{Vector{Int64}}:
 [1, 1]
 [2, 2]

julia> string.(("one","two","three","four"), ": ", 1:4)
4-element Vector{String}:
 "one: 1"
 "two: 2"
 "three: 3"
 "four: 4"

```

[source](#)

Base.Broadcast.broadcast! – Function.

```
| broadcast!(f, dest, As...)
```

Like `broadcast`, but store the result of `broadcast(f, As...)` in the `dest` array. Note that `dest` is only used to store the result, and does not supply arguments to `f` unless it is also listed in the `As`, as in `broadcast!(f, A, A, B)` to perform `A[:] = broadcast(f, A, B)`.

Examples

```

julia> A = [1.0; 0.0]; B = [0.0; 0.0];

julia> broadcast!(+, B, A, (0, -2.0));

julia> B
2-element Vector{Float64}:
 1.0
-2.0

julia> A
2-element Vector{Float64}:
 1.0
 0.0

```

```
julia> broadcast!(+, A, A, (0, -2.0));
```

```
julia> A
2-element Vector{Float64}:
 1.0
-2.0
```

[source](#)

`Base.Broadcast.__dot__` – Macro.

```
| @. expr
```

Convert every function call or operator in `expr` into a "dot call" (e.g. convert `f(x)` to `f.(x)`), and convert every assignment in `expr` to a "dot assignment" (e.g. convert `+=` to `.+=`).

If you want to avoid adding dots for selected function calls in `expr`, splice those function calls in with `$`. For example, `@. sqrt(abs($sort(x)))` is equivalent to `sqrt.(abs.(sort(x)))` (no dot for `sort`).

(`@.` is equivalent to a call to `@__dot__`.)

Examples

```
julia> x = 1.0:3.0; y = similar(x);
```

```
julia> @. y = x + 3 * sin(x)
3-element Vector{Float64}:
 3.5244129544236893
 4.727892280477045
 3.4233600241796016
```

[source](#)

For specializing broadcast on custom types, see

`Base.Broadcast.BroadcastStyle` – Type.

`BroadcastStyle` is an abstract type and trait-function used to determine behavior of objects under broadcasting. `BroadcastStyle(typeof(x))` returns the style associated with `x`. To customize the broadcasting behavior of a type, one can declare a style by defining a type/method pair

```
struct MyContainerStyle <: BroadcastStyle end
Base.BroadcastStyle{::Type{<:MyContainer}} = MyContainerStyle()
```

One then writes method(s) (at least [similar](#)) operating on `Broadcasted{MyContainerStyle}`. There are also several pre-defined subtypes of `BroadcastStyle` that you may be able to leverage; see the [Interfaces chapter](#) for more information.

[source](#)

`Base.Broadcast.AbstractArrayStyle` – Type.

`Broadcast.AbstractArrayStyle{N} <: BroadcastStyle` is the abstract supertype for any style associated with an `AbstractArray` type. The `N` parameter is the dimensionality, which can be handy for `AbstractArray` types that only support specific dimensionalities:

```
| struct SparseMatrixStyle <: Broadcast.AbstractArrayStyle{2} end
| Base.BroadcastStyle{::Type{<:SparseMatrixCSC}} = SparseMatrixStyle()
```

For `AbstractArray` types that support arbitrary dimensionality, `N` can be set to `Any`:

```
| struct MyArrayStyle <: Broadcast.AbstractArrayStyle{Any} end
| Base.BroadcastStyle{::Type{<:MyArray}} = MyArrayStyle()
```

In cases where you want to be able to mix multiple `AbstractArrayStyle`s and keep track of dimensionality, your style needs to support a `Val` constructor:

```
| struct MyArrayStyleDim{N} <: Broadcast.AbstractArrayStyle{N} end
| (::Type{<:MyArrayStyleDim})(::Val{N}) where N = MyArrayStyleDim{N}()
```

Note that if two or more `AbstractArrayStyle` subtypes conflict, broadcasting machinery will fall back to producing `Arrays`. If this is undesirable, you may need to define binary `BroadcastStyle` rules to control the output type.

See also `Broadcast.DefaultArrayStyle`.

[source](#)

`Base.Broadcast.ArrayStyle - Type.`

`Broadcast.ArrayStyle{MyArrayType}()` is a `BroadcastStyle` indicating that an object behaves as an array for broadcasting. It presents a simple way to construct `Broadcast.AbstractArrayStyles` for specific `AbstractArray` container types. Broadcast styles created this way lose track of dimensionality; if keeping track is important for your type, you should create your own custom `Broadcast.AbstractArrayStyle`.

[source](#)

`Base.Broadcast.DefaultArrayStyle - Type.`

`Broadcast.DefaultArrayStyle{N}()` is a `BroadcastStyle` indicating that an object behaves as an `N`-dimensional array for broadcasting. Specifically, `DefaultArrayStyle` is used for any `AbstractArray` type that hasn't defined a specialized style, and in the absence of overrides from other broadcast arguments the resulting output type is `Array`. When there are multiple inputs to broadcast, `DefaultArrayStyle` "loses" to any other `Broadcast.ArrayStyle`.

[source](#)

`Base.Broadcast.broadcastable - Function.`

```
| Broadcast.broadcastable(x)
```

Return either `x` or an object like `x` such that it supports `axes`, indexing, and its type supports `ndims`.

If `x` supports iteration, the returned value should have the same axes and indexing behaviors as `collect(x)`.

If `x` is not an `AbstractArray` but it supports axes, indexing, and its type supports `ndims`, then `broadcastable(::typeof(x))` may be implemented to just return itself. Further, if `x` defines its own `BroadcastStyle`, then it must define its `broadcastable` method to return itself for the custom style to have any effect.

Examples

```

julia> Broadcast.broadcastable([1,2,3]) # like `identity` since arrays already support axes
↳ and indexing
3-element Vector{Int64}:
 1
 2
 3

julia> Broadcast.broadcastable{Int} # Types don't support axes, indexing, or iteration but
↳ are commonly used as scalars
Base.RefValue{Type{Int64}}{Int64}

julia> Broadcast.broadcastable("hello") # Strings break convention of matching iteration and
↳ act like a scalar instead
Base.RefValue{String}{"hello"}

```

[source](#)

Base.Broadcast.combine_axes – Function.

```

| combine_axes(As...) -> Tuple

```

Determine the result axes for broadcasting across all values in As.

```

julia> Broadcast.combine_axes([1], [1 2; 3 4; 5 6])
(Base.OneTo(3), Base.OneTo(2))

julia> Broadcast.combine_axes(1, 1, 1)
()

```

[source](#)

Base.Broadcast.combine_styles – Function.

```

| combine_styles(cs...) -> BroadcastStyle

```

Decides which BroadcastStyle to use for any number of value arguments. Uses BroadcastStyle to get the style for each argument, and uses result_style to combine styles.

Examples

```

julia> Broadcast.combine_styles([1], [1 2; 3 4])
Base.Broadcast.DefaultArrayStyle{2}()

```

[source](#)

Base.Broadcast.result_style – Function.

```

| result_style(s1::BroadcastStyle[, s2::BroadcastStyle]) -> BroadcastStyle

```

Takes one or two BroadcastStyles and combines them using BroadcastStyle to determine a common BroadcastStyle.

Examples

```

julia> Broadcast.result_style(Broadcast.DefaultArrayStyle{0}()),
↪ Broadcast.DefaultArrayStyle{3}()
Base.Broadcast.DefaultArrayStyle{3}()

julia> Broadcast.result_style(Broadcast.Unknown(), Broadcast.DefaultArrayStyle{1}())
Base.Broadcast.DefaultArrayStyle{1}()

```

[source](#)

46.4 Indexing and assignment

Base.getindex – Method.

```
getindex(A, inds...)
```

Return a subset of array A as specified by inds, where each ind may be, for example, an Int, an [AbstractRange](#), or a [Vector](#). See the manual section on [array indexing](#) for details.

Examples

```

julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> getindex(A, 1)
1

julia> getindex(A, [2, 1])
2-element Vector{Int64}:
 3
 1

julia> getindex(A, 2:4)
3-element Vector{Int64}:
 3
 2
 4

```

[source](#)

Base.setindex! – Method.

```

setindex!(A, X, inds...)
A[inds...] = X

```

Store values from array X within some subset of A as specified by inds. The syntax `A[inds...] = X` is equivalent to `(setindex!(A, X, inds...); X)`.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```
julia> A = zeros(2,2);

julia> setindex!(A, [10, 20], [1, 2]);

julia> A[[3, 4]] = [30, 40];

julia> A
2×2 Matrix{Float64}:
 10.0  30.0
 20.0  40.0
```

[source](#)**Base.copyto!** – Method.

```
copyto!(dest, Rdest::CartesianIndices, src, Rsrc::CartesianIndices) -> dest
```

Copy the block of `src` in the range of `Rsrc` to the block of `dest` in the range of `Rdest`. The sizes of the two regions must match.

Examples

```
julia> A = zeros(5, 5);

julia> B = [1 2; 3 4];

julia> Ainds = CartesianIndices((2:3, 2:3));

julia> Binds = CartesianIndices(B);

julia> copyto!(A, Ainds, B, Binds)
5×5 Matrix{Float64}:
 0.0  0.0  0.0  0.0  0.0
 0.0  1.0  2.0  0.0  0.0
 0.0  3.0  4.0  0.0  0.0
 0.0  0.0  0.0  0.0  0.0
 0.0  0.0  0.0  0.0  0.0
```

[source](#)**Base.copy!** – Function.

```
copy!(dst, src) -> dst
```

In-place [copy](#) of `src` into `dst`, discarding any pre-existing elements in `dst`. If `dst` and `src` are of the same type, `dst == src` should hold after the call. If `dst` and `src` are multidimensional arrays, they must have equal [axes](#).

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

See also [copyto!](#).

Julia 1.1

This method requires at least Julia 1.1. In Julia 1.0 this method is available from the Future standard library as `Future.copy!`.

[source](#)

`Base.isassigned` – Function.

```
| isassigned(array, i) -> Bool
```

Test whether the given array has a value associated with index `i`. Return `false` if the index is out of bounds, or has an undefined reference.

Examples

```
julia> isassigned(rand(3, 3), 5)
true

julia> isassigned(rand(3, 3), 3 * 3 + 1)
false

julia> mutable struct Foo end

julia> v = similar(rand(3), Foo)
3-element Vector{Foo}:
#undef
#undef
#undef

julia> isassigned(v, 1)
false
```

[source](#)

`Base.Colon` – Type.

```
| Colon()
```

Colons (`:`) are used to signify indexing entire objects or dimensions at once.

Very few operations are defined on Colons directly; instead they are converted by [to_indices](#) to an internal vector type (`Base.Slice`) to represent the collection of indices they span before being used.

The singleton instance of `Colon` is also a function used to construct ranges; see [:](#).

[source](#)

`Base.IteratorsMD.CartesianIndex` – Type.

```
| CartesianIndex(i, j, k...) -> I
| CartesianIndex((i, j, k...)) -> I
```

Create a multidimensional index `I`, which can be used for indexing a multidimensional array `A`. In particular, `A[I]` is equivalent to `A[i, j, k, ...]`. One can freely mix integer and `CartesianIndex` indices; for example, `A[Ipre, i, Ipost]` (where `Ipre` and `Ipost` are `CartesianIndex` indices and `i` is an `Int`) can be a useful expression when writing algorithms that work along a single dimension of an array of arbitrary dimensionality.

A `CartesianIndex` is sometimes produced by `eachindex`, and always when iterating with an explicit `CartesianIndices`.

An `I::CartesianIndex` is treated as a "scalar" (not a container) for broadcast. In order to iterate over the components of a `CartesianIndex`, convert it to a tuple with `Tuple(I)`.

Examples

```
julia> A = reshape(Vector{Int64}(1:16), (2, 2, 2, 2))
2×2×2×2 Array{Int64, 4}:
[:, :, 1, 1] =
 1  3
 2  4

[:, :, 2, 1] =
 5  7
 6  8

[:, :, 1, 2] =
 9 11
10 12

[:, :, 2, 2] =
13 15
14 16

julia> A[CartesianIndex((1, 1, 1, 1))]
1

julia> A[CartesianIndex((1, 1, 1, 2))]
9

julia> A[CartesianIndex((1, 1, 2, 1))]
5
```

Julia 1.10

Using a `CartesianIndex` as a "scalar" for broadcast requires Julia 1.10; in previous releases, use `Ref(I)`.

[source](#)

`Base.IteratorsMD.CartesianIndices` – Type.

```
CartesianIndices{sz::Dims} -> R
CartesianIndices((istart:[istep:]istop, jstart:[jstep:]jstop, ...)) -> R
```

Define a region `R` spanning a multidimensional rectangular range of integer indices. These are most commonly encountered in the context of iteration, where for `I in R ... end` will return `CartesianIndex` indices `I` equivalent to the nested loops

```

for j = jstart:jstep:jstop
    for i = istart:istep:istop
        ...
    end
end
end

```

Consequently these can be useful for writing algorithms that work in arbitrary dimensions.

```
CartesianIndices(A::AbstractArray) -> R
```

As a convenience, constructing a `CartesianIndices` from an array makes a range of its indices.

Julia 1.6

The step range method `CartesianIndices((istart:istep:istop, jstart:[jstep:]jstop, ...))` requires at least Julia 1.6.

Examples

```

julia> foreach(println, CartesianIndices((2, 2, 2)))
CartesianIndex{1, 1, 1}
CartesianIndex{2, 1, 1}
CartesianIndex{1, 2, 1}
CartesianIndex{2, 2, 1}
CartesianIndex{1, 1, 2}
CartesianIndex{2, 1, 2}
CartesianIndex{1, 2, 2}
CartesianIndex{2, 2, 2}

julia> CartesianIndices(fill(1, (2,3)))
CartesianIndices{2, 3}

```

Conversion between linear and cartesian indices

Linear index to cartesian index conversion exploits the fact that a `CartesianIndices` is an `AbstractArray` and can be indexed linearly:

```

julia> cartesian = CartesianIndices((1:3, 1:2))
CartesianIndices{1:3, 1:2}

julia> cartesian[4]
CartesianIndex{1, 2}

julia> cartesian = CartesianIndices((1:2:5, 1:2))
CartesianIndices{1:2:5, 1:2}

julia> cartesian[2, 2]
CartesianIndex{3, 2}

```

Broadcasting

`CartesianIndices` support broadcasting arithmetic (+ and -) with a `CartesianIndex`.

Julia 1.1

Broadcasting of `CartesianIndices` requires at least Julia 1.1.

```
julia> CIs = CartesianIndices((2:3, 5:6))
CartesianIndices{2, Tuple{UnitRange{Int64}, UnitRange{Int64}}}:
  1  4
  5  8

julia> CI = CartesianIndex(3, 4)
CartesianIndex{2, Tuple{Int64, Int64}}:
  3  4

julia> CIs .+ CI
CartesianIndices{2, Tuple{UnitRange{Int64}, UnitRange{Int64}}}:
  4  5
  6  9
```

For cartesian to linear index conversion, see [LinearIndices](#).

[source](#)

Base.Dims – Type.

```
| Dims{N}
```

An NTuple of N Ints used to represent the dimensions of an [AbstractArray](#).

[source](#)

Base.LinearIndices – Type.

```
| LinearIndices(A::AbstractArray)
```

Return a LinearIndices array with the same shape and [axes](#) as A, holding the linear index of each entry in A. Indexing this array with cartesian indices allows mapping them to linear indices.

For arrays with conventional indexing (indices start at 1), or any multidimensional array, linear indices range from 1 to length(A). However, for AbstractVectors linear indices are axes(A, 1), and therefore do not start at 1 for vectors with unconventional indexing.

Calling this function is the "safe" way to write algorithms that exploit linear indexing.

Examples

```
julia> A = fill(1, (5,6,7));

julia> b = LinearIndices(A);

julia> extrema(b)
(1, 210)

LinearIndices(inds::CartesianIndices) -> R
LinearIndices(sz::Dims) -> R
LinearIndices((istart:istop, jstart:jstop, ...)) -> R
```

Return a LinearIndices array with the specified shape or [axes](#).

Example

The main purpose of this constructor is intuitive conversion from cartesian to linear indexing:

```
julia> linear = LinearIndices((1:3, 1:2))
3×2 LinearIndices{2, Tuple{UnitRange{Int64}, UnitRange{Int64}}}:
 1  4
```

```

2 5
3 6

julia> linear[1,2]
4

```

[source](#)

`Base.to_indices` – Function.

```
to_indices(A, I::Tuple)
```

Convert the tuple `I` to a tuple of indices for use in indexing into array `A`.

The returned tuple must only contain either `Ints` or `AbstractArrays` of scalar indices that are supported by array `A`. It will error upon encountering a novel index type that it does not know how to process.

For simple index types, it defers to the unexported `Base.to_index(A, i)` to process each index `i`. While this internal function is not intended to be called directly, `Base.to_index` may be extended by custom array or index types to provide custom indexing behaviors.

More complicated index types may require more context about the dimension into which they index. To support those cases, `to_indices(A, I)` calls `to_indices(A, axes(A), I)`, which then recursively walks through both the given tuple of indices and the dimensional indices of `A` in tandem. As such, not all index types are guaranteed to propagate to `Base.to_index`.

Examples

```

julia> A = zeros(1,2,3,4);

julia> to_indices(A, (1,1,2,2))
(1, 1, 2, 2)

julia> to_indices(A, (1,1,2,20)) # no bounds checking
(1, 1, 2, 20)

julia> to_indices(A, (CartesianIndex((1,)), 2, CartesianIndex((3,4)))) # exotic index
(1, 2, 3, 4)

julia> to_indices(A, ([1,1], 1:2, 3, 4))
([1, 1], 1:2, 3, 4)

julia> to_indices(A, (1,2)) # no shape checking
(1, 2)

```

[source](#)

`Base.checkbounds` – Function.

```
checkbounds(Bool, A, I...)
```

Return `true` if the specified indices `I` are in bounds for the given array `A`. Subtypes of `AbstractArray` should specialize this method if they need to provide custom bounds checking behaviors; however, in many cases one can rely on `A`'s indices and [checkindex](#).

See also [checkindex](#).

Examples

```
julia> A = rand(3, 3);

julia> checkbounds(Bool, A, 2)
true

julia> checkbounds(Bool, A, 3, 4)
false

julia> checkbounds(Bool, A, 1:3)
true

julia> checkbounds(Bool, A, 1:3, 2:4)
false
```

[source](#)

```
checkbounds(A, I...)
```

Throw an error if the specified indices I are not in bounds for the given array A.

[source](#)

Base.checkindex – Function.

```
checkindex(Bool, inds::AbstractUnitRange, index)
```

Return true if the given index is within the bounds of inds. Custom types that would like to behave as indices for all arrays can extend this method in order to provide a specialized bounds checking implementation.

See also [checkbounds](#).

Examples

```
julia> checkindex(Bool, 1:20, 8)
true

julia> checkindex(Bool, 1:20, 21)
false
```

[source](#)

Base.elsize – Function.

```
elsize(type)
```

Compute the memory stride in bytes between consecutive elements of [eltype](#) stored inside the given type, if the array elements are stored densely with a uniform linear stride.

Examples

```
julia> Base.elsize(rand(Float32, 10))
4
```

[source](#)

46.5 Views (SubArrays and other view types)

A “view” is a data structure that acts like an array (it is a subtype of `AbstractArray`), but the underlying data is actually part of another array.

For example, if `x` is an array and `v = @view x[1:10]`, then `v` acts like a 10-element array, but its data is actually accessing the first 10 elements of `x`. Writing to a view, e.g. `v[3] = 2`, writes directly to the underlying array `x` (in this case modifying `x[3]`).

Slicing operations like `x[1:10]` create a copy by default in Julia. `@view x[1:10]` changes it to make a view. The `@views` macro can be used on a whole block of code (e.g. `@views function foo() ... end` or `@views begin ... end`) to change all the slicing operations in that block to use views. Sometimes making a copy of the data is faster and sometimes using a view is faster, as described in the [performance tips](#).

`Base.view` – Function.

```
| view(A, inds...)
```

Like [getindex](#), but returns a lightweight array that lazily references (or is effectively a view into) the parent array `A` at the given index or indices `inds` instead of eagerly extracting elements or constructing a copied subset. Calling [getindex](#) or [setindex!](#) on the returned value (often a [SubArray](#)) computes the indices to access or modify the parent array on the fly. The behavior is undefined if the shape of the parent array is changed after `view` is called because there is no bound check for the parent array; e.g., it may cause a segmentation fault.

Some immutable parent arrays (like ranges) may choose to simply recompute a new array in some circumstances instead of returning a `SubArray` if doing so is efficient and provides compatible semantics.

Julia 1.6

In Julia 1.6 or later, `view` can be called on an `AbstractString`, returning a `SubString`.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> b = view(A, :, 1)
2-element view(::Matrix{Int64}, :, 1) with eltype Int64:
 1
 3

julia> fill!(b, 0)
2-element view(::Matrix{Int64}, :, 1) with eltype Int64:
 0
 0

julia> A # Note A has changed even though we modified b
2×2 Matrix{Int64}:
 0  2
 0  4

julia> view(2:5, 2:3) # returns a range as type is immutable
3:4
```

[source](#)

Base.@view – Macro.

```
| @view A[inds...]
```

Transform the indexing expression `A[inds...]` into the equivalent `view` call.

This can only be applied directly to a single indexing expression and is particularly helpful for expressions that include the special `begin` or `end` indexing syntaxes like `A[begin, 2:end-1]` (as those are not supported by the normal `view` function).

Note that `@view` cannot be used as the target of a regular assignment (e.g., `@view(A[1, 2:end]) = ...`), nor would the un-decorated `indexed assignment` (`A[1, 2:end] = ...`) or broadcasted indexed assignment (`A[1, 2:end] .= ...`) make a copy. It can be useful, however, for updating broadcasted assignments like `@view(A[1, 2:end]) += 1` because this is a simple syntax for `@view(A[1, 2:end]) .= @view(A[1, 2:end]) + 1`, and the indexing expression on the right-hand side would otherwise make a copy without the `@view`.

See also [@views](#) to switch an entire block of code to use views for non-scalar indexing.

Julia 1.5

Using `begin` in an indexing expression to refer to the first index requires at least Julia 1.5.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> b = @view A[:, 1]
2-element view(::Matrix{Int64}, :, 1) with eltype Int64:
 1
 3

julia> fill!(b, 0)
2-element view(::Matrix{Int64}, :, 1) with eltype Int64:
 0
 0

julia> A
2×2 Matrix{Int64}:
 0  2
 0  4
```

[source](#)

Base.@views – Macro.

```
| @views expression
```

Convert every array-slicing operation in the given expression (which may be a begin/end block, loop, function, etc.) to return a view. Scalar indices, non-array types, and explicit `getindex` calls (as opposed to `array[...]`) are unaffected.

Similarly, `@views` converts string slices into `SubString` views.

Note

The `@views` macro only affects `array[...]` expressions that appear explicitly in the given expression, not array slicing that occurs in functions called by that code.

Julia 1.5

Using `begin` in an indexing expression to refer to the first index requires at least Julia 1.5.

Examples

```
julia> A = zeros(3, 3);

julia> @views for row in 1:3
           b = A[row, :]
           b[:] .= row
       end

julia> A
3×3 Matrix{Float64}:
 1.0  1.0  1.0
 2.0  2.0  2.0
 3.0  3.0  3.0
```

[source](#)

`Base.parent` – Function.

```
| parent(A)
```

Return the underlying parent object of the view. This parent of objects of types `SubArray`, `SubString`, `ReshapedArray` or `LinearAlgebra.Transpose` is what was passed as an argument to `view`, `reshape`, `transpose`, etc. during object creation. If the input is not a wrapped object, return the input itself. If the input is wrapped multiple times, only the outermost wrapper will be removed.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> V = view(A, 1:2, :)
2×2 view(::Matrix{Int64}, 1:2, :) with eltype Int64:
 1  2
 3  4

julia> parent(V)
2×2 Matrix{Int64}:
```

```
| 1 2
| 3 4
```

[source](#)

Base.parentindices – Function.

```
| parentindices(A)
```

Return the indices in the [parent](#) which correspond to the view A.

Examples

```
julia> A = [1 2; 3 4];

julia> V = view(A, 1, :)
2-element view(::Matrix{Int64}, 1, :) with eltype Int64:
 1
 2

julia> parentindices(V)
(1, Base.Slice(Base.OneTo(2)))
```

[source](#)

Base.selectdim – Function.

```
| selectdim(A, d::Integer, i)
```

Return a view of all the data of A where the index for dimension d equals i.

Equivalent to `view(A, :, :, ..., i, :, :, ...)` where i is in position d.

See also: [eachslice](#).

Examples

```
julia> A = [1 2 3 4; 5 6 7 8]
2×4 Matrix{Int64}:
 1  2  3  4
 5  6  7  8

julia> selectdim(A, 2, 3)
2-element view(::Matrix{Int64}, :, 3) with eltype Int64:
 3
 7

julia> selectdim(A, 2, 3:4)
2×2 view(::Matrix{Int64}, :, 3:4) with eltype Int64:
 3  4
 7  8
```

[source](#)

Base.reinterpret – Function.

```
| reinterpret(::Type{Out}, x::In)
```

Change the type-interpretation of the binary data in the isbits value `x` to that of the isbits type `Out`. The size (ignoring padding) of `Out` has to be the same as that of the type of `x`. For example, `reinterpret(Float32, UInt32(7))` interprets the 4 bytes corresponding to `UInt32(7)` as a `Float32`.

```
julia> reinterpret(Float32, UInt32(7))
1.0f-44

julia> reinterpret(NTuple{2, UInt8}, 0x1234)
(0x34, 0x12)

julia> reinterpret(UInt16, (0x34, 0x12))
0x1234

julia> reinterpret(Tuple{UInt16, UInt8}, (0x01, 0x0203))
(0x0301, 0x02)
```

Warning

Use caution if some combinations of bits in `Out` are not considered valid and would otherwise be prevented by the type's constructors and methods. Unexpected behavior may result without additional validation.

source

```
| reinterpret(T::DataType, A::AbstractArray)
```

Construct a view of the array with the same binary data as the given array, but with `T` as element type.

This function also works on "lazy" array whose elements are not computed until they are explicitly retrieved. For instance, `reinterpret` on the range `1:6` works similarly as on the dense vector `collect(1:6)`:

```
julia> reinterpret(Float32, UInt32[1 2 3 4 5])
1×5 reinterpret(Float32, ::Matrix{UInt32}):
 1.0f-45  3.0f-45  4.0f-45  6.0f-45  7.0f-45

julia> reinterpret(Complex{Int}, 1:6)
3-element reinterpret(Complex{Int64}, ::UnitRange{Int64}):
 1 + 2im
 3 + 4im
 5 + 6im
```

source

```
| reinterpret(reshape, T, A::AbstractArray{S}) -> B
```

Change the type-interpretation of `A` while consuming or adding a "channel dimension."

If `sizeof(T) = n*sizeof(S)` for `n>1`, `A`'s first dimension must be of size `n` and `B` lacks `A`'s first dimension. Conversely, if `sizeof(S) = n*sizeof(T)` for `n>1`, `B` gets a new first dimension of size `n`. The dimensionality is unchanged if `sizeof(T) == sizeof(S)`.

Julia 1.6

This method requires at least Julia 1.6.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> reinterpret(reshape, Complex{Int}, A)    # the result is a vector
2-element reinterpret(reshape, Complex{Int64}, ::Matrix{Int64}) with eltype Complex{Int64}:
 1 + 3im
 2 + 4im

julia> a = [(1,2,3), (4,5,6)]
2-element Vector{Tuple{Int64, Int64, Int64}}:
 (1, 2, 3)
 (4, 5, 6)

julia> reinterpret(reshape, Int, a)              # the result is a matrix
3×2 reinterpret(reshape, Int64, ::Vector{Tuple{Int64, Int64, Int64}}) with eltype Int64:
 1  4
 2  5
 3  6
```

[source](#)

Base.reshape – Function.

```
reshape(A, dims...) -> AbstractArray
reshape(A, dims) -> AbstractArray
```

Return an array with the same data as A, but with different dimension sizes or number of dimensions. The two arrays share the same underlying data, so that the result is mutable if and only if A is mutable, and setting elements of one alters the values of the other.

The new dimensions may be specified either as a list of arguments or as a shape tuple. At most one dimension may be specified with a :, in which case its length is computed such that its product with all the specified dimensions is equal to the length of the original array A. The total number of elements must not change.

Examples

```
julia> A = Vector{Int64}(1:16)
16-element Vector{Int64}:
 1
 2
 3
 4
 5
 6
 7
```

```

 8
 9
10
11
12
13
14
15
16

julia> reshape(A, (4, 4))
4×4 Matrix{Int64}:
 1  5  9 13
 2  6 10 14
 3  7 11 15
 4  8 12 16

julia> reshape(A, 2, :)
2×8 Matrix{Int64}:
 1  3  5  7  9 11 13 15
 2  4  6  8 10 12 14 16

julia> reshape(1:6, 2, 3)
2×3 reshape{::UnitRange{Int64}, 2, 3} with eltype Int64:
 1  3  5
 2  4  6

```

[source](#)

Base.dropdims – Function.

```
dropdims(A; dims)
```

Return an array with the same data as *A*, but with the dimensions specified by *dims* removed. `size(A, d)` must equal 1 for every *d* in *dims*, and repeated dimensions or numbers outside `1:ndims(A)` are forbidden.

The result shares the same underlying data as *A*, such that the result is mutable if and only if *A* is mutable, and setting elements of one alters the values of the other.

See also: [reshape](#), [vec](#).

Examples

```

julia> a = reshape(Vector{Int64}(1:4), (2,2,1,1))
2×2×1×1 Array{Int64, 4}:
[:, :, 1, 1] =
 1  3
 2  4

julia> b = dropdims(a; dims=3)
2×2×1 Array{Int64, 3}:
[:, :, 1] =
 1  3

```

```

2 4

julia> b[1,1,1] = 5; a
2×2×1×1 Array{Int64, 4}:
[:, :, 1, 1] =
 5 3
 2 4

```

[source](#)

Base.vec – Function.

```
vec(a::AbstractArray) -> AbstractVector
```

Reshape the array `a` as a one-dimensional column vector. Return `a` if it is already an `AbstractVector`. The resulting array shares the same underlying data as `a`, so it will only be mutable if `a` is mutable, in which case modifying one will also modify the other.

Examples

```

julia> a = [1 2 3; 4 5 6]
2×3 Matrix{Int64}:
 1 2 3
 4 5 6

julia> vec(a)
6-element Vector{Int64}:
 1
 4
 2
 5
 3
 6

julia> vec(1:3)
1:3

```

See also [reshape](#), [dropdims](#).

[source](#)

Base.SubArray – Type.

```
SubArray{T,N,P,I,L} <: AbstractArray{T,N}
```

N-dimensional view into a parent array (of type `P`) with an element type `T`, restricted by a tuple of indices (of type `I`). `L` is true for types that support fast linear indexing, and false otherwise.

Construct SubArrays using the [view](#) function.

[source](#)

46.6 Concatenation and permutation

Base.cat – Function.

```
| cat(A...; dims)
```

Concatenate the input arrays along the dimensions specified in `dims`.

Along a dimension `d` in `dims`, the size of the output array is `sum(size(a,d) for a in A)`. Along other dimensions, all input arrays should have the same size, which will also be the size of the output array along those dimensions.

If `dims` is a single number, the different arrays are tightly packed along that dimension. If `dims` is an iterable containing several dimensions, the positions along these dimensions are increased simultaneously for each input array, filling with zero elsewhere. This allows one to construct block-diagonal matrices as `cat(matrices...; dims=(1,2))`, and their higher-dimensional analogues.

The special case `dims=1` is `vcat`, and `dims=2` is `hcat`. See also `hvcat`, `hvncat`, `stack`, `repeat`.

The keyword also accepts `Val(dims)`.

Julia 1.8

For multiple dimensions `dims = Val{::Tuple}` was added in Julia 1.8.

Examples

```
julia> cat([1 2; 3 4], [pi, pi], fill(10, 2,3,1); dims=2) # same as hcat
2×6×1 Array{Float64, 3}:
[:, :, 1] =
 1.0  2.0  3.14159  10.0  10.0  10.0
 3.0  4.0  3.14159  10.0  10.0  10.0

julia> cat(true, trues(2,2), trues(4)', dims=(1,2)) # block-diagonal
4×7 Matrix{Bool}:
 1  0  0  0  0  0  0
 0  1  1  0  0  0  0
 0  1  1  0  0  0  0
 0  0  0  1  1  1  1

julia> cat(1, [2], [3;;]; dims=Val(2))
1×3 Matrix{Int64}:
 1  2  3
```

[source](#)

Base.vcat – Function.

```
| vcat(A...)
```

Concatenate arrays or numbers vertically. Equivalent to `cat(A...; dims=1)`, and to the syntax `[a; b; c]`.

To concatenate a large vector of arrays, `reduce(vcat, A)` calls an efficient method when `A` is a `AbstractVector{<:AbstractArray{...}}` rather than working pairwise.

See also [hcat](#), [Iterators.flatten](#), [stack](#).

Examples

```
julia> v = vcat([1,2], [3,4])
4-element Vector{Int64}:
 1
 2
 3
 4

julia> v == vcat(1, 2, [3,4]) # accepts numbers
true

julia> v == [1; 2; [3,4]] # syntax for the same operation
true

julia> summary(ComplexF64[1; 2; [3,4]]) # syntax for supplying the element type
"4-element Vector{ComplexF64}"

julia> vcat(range(1, 2, length=3)) # collects lazy ranges
3-element Vector{Float64}:
 1.0
 1.5
 2.0

julia> two = ([10, 20, 30]', Float64[4 5 6; 7 8 9]) # row vector and a matrix
([10 20 30], [4.0 5.0 6.0; 7.0 8.0 9.0])

julia> vcat(two...)
3×3 Matrix{Float64}:
10.0 20.0 30.0
 4.0  5.0  6.0
 7.0  8.0  9.0

julia> vs = [[1, 2], [3, 4], [5, 6]];

julia> reduce(vcat, vs) # more efficient than vcat(vs...)
6-element Vector{Int64}:
 1
 2
 3
 4
 5
 6

julia> ans == collect(Iterators.flatten(vs))
true
```

[source](#)

Base.hcat – Function.

```
| hcat(A...)
```

Concatenate arrays or numbers horizontally. Equivalent to `cat(A...; dims=2)`, and to the syntax `[a b c]` or `[a;; b;; c]`.

For a large vector of arrays, `reduce(hcat, A)` calls an efficient method when `A` is a `AbstractVector{<:AbstractVecOrMat}`. For a vector of vectors, this can also be written `stack(A)`.

See also `vcats`, `hvcats`.

Examples

```
julia> hcat([1,2], [3,4], [5,6])
2×3 Matrix{Int64}:
 1  3  5
 2  4  6

julia> hcat(1, 2, [30 40], [5, 6, 7]') # accepts numbers
1×7 Matrix{Int64}:
 1  2 30 40  5  6  7

julia> ans == [1 2 [30 40] [5, 6, 7]'] # syntax for the same operation
true

julia> Float32[1 2 [30 40] [5, 6, 7]'] # syntax for supplying the eltype
1×7 Matrix{Float32}:
 1.0  2.0 30.0 40.0  5.0  6.0  7.0

julia> ms = [zeros(2,2), [1 2; 3 4], [50 60; 70 80]];

julia> reduce(hcat, ms) # more efficient than hcat(ms...)
2×6 Matrix{Float64}:
 0.0  0.0  1.0  2.0 50.0 60.0
 0.0  0.0  3.0  4.0 70.0 80.0

julia> stack(ms) |> summary # disagrees on a vector of matrices
"2×2×3 Array{Float64, 3}"

julia> hcat{Int[], Int[], Int[]} # empty vectors, each of size (0,)
0×3 Matrix{Int64}

julia> hcat([1.1, 9.9], Matrix{undef, 2, 0}) # hcat with empty 2×0 Matrix
2×1 Matrix{Any}:
 1.1
 9.9
```

[source](#)

Base.hvcats – Function.

```
| hvcats(blocks_per_row::Union{Tuple{Vararg{Int}}}, Int, values...)
```

Horizontal and vertical concatenation in one call. This function is called for block matrix syntax. The first argument specifies the number of arguments to concatenate in each block row. If the first argument is a single integer `n`, then all block rows are assumed to have `n` block columns.

Examples

```

julia> a, b, c, d, e, f = 1, 2, 3, 4, 5, 6
(1, 2, 3, 4, 5, 6)

julia> [a b c; d e f]
2×3 Matrix{Int64}:
 1  2  3
 4  5  6

julia> hvcat((3,3), a,b,c,d,e,f)
2×3 Matrix{Int64}:
 1  2  3
 4  5  6

julia> [a b; c d; e f]
3×2 Matrix{Int64}:
 1  2
 3  4
 5  6

julia> hvcat((2,2,2), a,b,c,d,e,f)
3×2 Matrix{Int64}:
 1  2
 3  4
 5  6
julia> hvcat((2,2,2), a,b,c,d,e,f) == hvcat(2, a,b,c,d,e,f)
true

```

[source](#)

Base.hvncat – Function.

```

hvncat(dim::Int, row_first, values...)
hvncat(dims::Tuple{Vararg{Int}}, row_first, values...)
hvncat(shape::Tuple{Vararg{Tuple}}, row_first, values...)

```

Horizontal, vertical, and n-dimensional concatenation of many values in one call.

This function is called for block matrix syntax. The first argument either specifies the shape of the concatenation, similar to `hvcat`, as a tuple of tuples, or the dimensions that specify the key number of elements along each axis, and is used to determine the output dimensions. The `dims` form is more performant, and is used by default when the concatenation operation has the same number of elements along each axis (e.g., `[a b; c d;; e f; g h]`). The `shape` form is used when the number of elements along each axis is unbalanced (e.g., `[a b; c]`). Unbalanced syntax needs additional validation overhead. The `dim` form is an optimization for concatenation along just one dimension. `row_first` indicates how values are ordered. The meaning of the first and second elements of `shape` are also swapped based on `row_first`.

Examples

```

julia> a, b, c, d, e, f = 1, 2, 3, 4, 5, 6
(1, 2, 3, 4, 5, 6)

julia> [a b c;;; d e f]
1×3×2 Array{Int64, 3}:

```

```

[:, :, 1] =
 1  2  3

[:, :, 2] =
 4  5  6

julia> hvncat((2,1,3), false, a,b,c,d,e,f)
2×1×3 Array{Int64, 3}:
[:, :, 1] =
 1
 2

[:, :, 2] =
 3
 4

[:, :, 3] =
 5
 6

julia> [a b;;; c d;;; e f]
1×2×3 Array{Int64, 3}:
[:, :, 1] =
 1  2

[:, :, 2] =
 3  4

[:, :, 3] =
 5  6

julia> hvncat((3, 3), (3, 3), (6,)), true, a, b, c, d, e, f)
1×3×2 Array{Int64, 3}:
[:, :, 1] =
 1  2  3

[:, :, 2] =
 4  5  6

```

Examples for construction of the arguments

```

[a b c ; d e f ;;;
 g h i ; j k l ;;;
 m n o ; p q r ;;;
 s t u ; v w x]⇒
 dims = (2, 3, 4)

[a b ; c ;;; d ;;;;]

 $\overline{2} \quad \overline{1} \quad \overline{1}$  = elements in each row (2, 1, 1)

 $\overline{3} \quad \overline{1}$  = elements in each column (3, 1)

 $\overline{4}$  = elements in each 3d slice (4,)
```

```

4 _____ = elements in each 4d slice (4,)⇒
shape = ((2, 1, 1), (3, 1), (4,), (4,)) with `row_first` = true

```

source

Base.stack – Function.

```
stack(iter; [dims])
```

Combine a collection of arrays (or other iterable objects) of equal size into one larger array, by arranging them along one or more new dimensions.

By default the axes of the elements are placed first, giving `size(result) = (size(first(iter))..., size(iter)...) .` This has the same order of elements as `Iterators.flatten(iter)`.

With keyword `dims::Integer`, instead the *i*th element of `iter` becomes the slice `selectdim(result, dims, i)`, so that `size(result, dims) == length(iter)`. In this case `stack` reverses the action of `eachslice` with the same `dims`.

The various `cat` functions also combine arrays. However, these all extend the arrays' existing (possibly trivial) dimensions, rather than placing the arrays along new dimensions. They also accept arrays as separate arguments, rather than a single collection.

Julia 1.9

This function requires at least Julia 1.9.

Examples

```

julia> vecs = (1:2, [30, 40], Float32[500, 600]);

julia> mat = stack(vecs)
2×3 Matrix{Float32}:
 1.0  30.0  500.0
 2.0  40.0  600.0

julia> mat == hcat(vecs...) == reduce(hcat, collect(vecs))
true

julia> vec(mat) == vcat(vecs...) == reduce(vcat, collect(vecs))
true

julia> stack(zip(1:4, 10:99)) # accepts any iterators of iterators
2×4 Matrix{Int64}:
 1  2  3  4
10 11 12 13

julia> vec(ans) == collect(Iterators.flatten(zip(1:4, 10:99)))
true

julia> stack(vecs; dims=1) # unlike any cat function, 1st axis of vecs[1] is 2nd axis of
↪ result
3×2 Matrix{Float32}:
 1.0  2.0

```

```

30.0  40.0
500.0 600.0

julia> x = rand(3,4);

julia> x == stack(eachcol(x)) == stack(eachrow(x), dims=1) # inverse of eachslice
true

```

Higher-dimensional examples:

```

julia> A = rand(5, 7, 11);

julia> E = eachslice(A, dims=2); # a vector of matrices

julia> (element = size(first(E)), container = size(E))
(element = (5, 11), container = (7,))

julia> stack(E) |> size
(5, 11, 7)

julia> stack(E) == stack(E; dims=3) == cat(E...; dims=3)
true

julia> A == stack(E; dims=2)
true

julia> M = (fill(10i+j, 2, 3) for i in 1:5, j in 1:7);

julia> (element = size(first(M)), container = size(M))
(element = (2, 3), container = (5, 7))

julia> stack(M) |> size # keeps all dimensions
(2, 3, 5, 7)

julia> stack(M; dims=1) |> size # vec(container) along dims=1
(35, 2, 3)

julia> hvcats(5, M...) |> size # hvcats puts matrices next to each other
(14, 15)

```

source

```
stack(f, args...; [dims])
```

Apply a function to each element of a collection, and stack the result. Or to several collections, [zipped](#) together.

The function should return arrays (or tuples, or other iterators) all of the same size. These become slices of the result, each separated along `dims` (if given) or by default along the last dimensions.

See also [mapslices](#), [eachcol](#).

Examples

```
julia> stack(c -> (c, c-32), "julia")
2×5 Matrix{Char}:
 'j'  'u'  'l'  'i'  'a'
 'J'  'U'  'L'  'I'  'A'

julia> stack(eachrow([1 2 3; 4 5 6]), (10, 100); dims=1) do row, n
    vcat(row, row .* n, row ./ n)
end
2×9 Matrix{Float64}:
 1.0  2.0  3.0  10.0  20.0  30.0  0.1  0.2  0.3
 4.0  5.0  6.0  40.0  50.0  60.0  0.04 0.05 0.06
```

[source](#)

Base.vect – Function.

```
| vect(X...)
```

Create a **Vector** with element type computed from the `promote_typeof` of the argument, containing the argument list.

Examples

```
julia> a = Base.vect{UInt8}(1), 2.5, 1//2)
3-element Vector{Float64}:
 1.0
 2.5
 0.5
```

[source](#)

Base.circshift – Function.

```
| circshift(A, shifts)
```

Circularly shift, i.e. rotate, the data in an array. The second argument is a tuple or vector giving the amount to shift in each dimension, or an integer to shift only in the first dimension.

See also: [circshift!](#), [circcopy!](#), [bitrotate](#), [<<](#).

Examples

```
julia> b = reshape{Vector}(1:16), (4,4))
4×4 Matrix{Int64}:
 1  5  9 13
 2  6 10 14
 3  7 11 15
 4  8 12 16

julia> circshift(b, (0,2))
4×4 Matrix{Int64}:
 9 13 1 5
10 14 2 6
11 15 3 7
```

```

12 16 4 8

julia> circshift(b, (-1,0))
4×4 Matrix{Int64}:
 2  6 10 14
 3  7 11 15
 4  8 12 16
 1  5  9 13

julia> a = BitArray([true, true, false, false, true])
5-element BitVector:
 1
 1
 0
 0
 1

julia> circshift(a, 1)
5-element BitVector:
 1
 1
 1
 0
 0

julia> circshift(a, -1)
5-element BitVector:
 1
 0
 0
 1
 1

```

[source](#)

`Base.circshift!` – Function.

```
| circshift!(dest, src, shifts)
```

Circularly shift, i.e. rotate, the data in `src`, storing the result in `dest`. `shifts` specifies the amount to shift in each dimension.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

See also [circshift](#).

[source](#)

`Base.circrcopy!` – Function.

```
| circrcopy!(dest, src)
```

Copy `src` to `dest`, indexing each dimension modulo its length. `src` and `dest` must have the same size, but can be offset in their indices; any offset results in a (circular) wraparound. If the arrays have overlapping indices, then on the domain of the overlap `dest` agrees with `src`.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

See also: [circshift](#).

Examples

```
julia> src = reshape(Vector{Int64}(1:16), (4,4))
4×4 Array{Int64,2}:
 1  5  9 13
 2  6 10 14
 3  7 11 15
 4  8 12 16

julia> dest = OffsetArray{Int}(undef, (0:3,2:5))

julia> circcopy!(dest, src)
OffsetArrays.OffsetArray{Int64,2,Array{Int64,2}} with indices 0:3×2:5:
 8 12 16  4
 5  9 13  1
 6 10 14  2
 7 11 15  3

julia> dest[1:3,2:4] == src[1:3,2:4]
true
```

[source](#)

`Base.findall` – Method.

```
| findall(A)
```

Return a vector `I` of the `true` indices or keys of `A`. If there are no such elements of `A`, return an empty array. To search for other kinds of values, pass a predicate as the first argument.

Indices or keys are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

See also: [findfirst](#), [searchsorted](#).

Examples

```
julia> A = [true, false, false, true]
4-element Vector{Bool}:
 1
 0
 0
 1

julia> findall(A)
```

```

2-element Vector{Int64}:
 1
 4

julia> A = [true false; false true]
2×2 Matrix{Bool}:
 1  0
 0  1

julia> findall(A)
2-element Vector{CartesianIndex{2}}:
 CartesianIndex(1, 1)
 CartesianIndex(2, 2)

julia> findall(falses(3))
Int64[]

```

[source](#)

Base.findall – Method.

```

| findall(f::Function, A)

```

Return a vector *I* of the indices or keys of *A* where *f*(*A*[*I*]) returns *true*. If there are no such elements of *A*, return an empty array.

Indices or keys are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

Examples

```

julia> x = [1, 3, 4]
3-element Vector{Int64}:
 1
 3
 4

julia> findall(isodd, x)
2-element Vector{Int64}:
 1
 2

julia> A = [1 2 0; 3 4 0]
2×3 Matrix{Int64}:
 1  2  0
 3  4  0

julia> findall(isodd, A)
2-element Vector{CartesianIndex{2}}:
 CartesianIndex(1, 1)
 CartesianIndex(2, 1)

julia> findall(!iszero, A)
4-element Vector{CartesianIndex{2}}:
 CartesianIndex(1, 1)
 CartesianIndex(2, 1)

```

```

    CartesianIndex(1, 2)
    CartesianIndex(2, 2)

julia> d = Dict{:A => 10, :B => -1, :C => 0}
Dict{Symbol, Int64} with 3 entries:
  :A => 10
  :B => -1
  :C => 0

julia> findall(x -> x >= 0, d)
2-element Vector{Symbol}:
 :A
 :C

```

[source](#)

Base.findfirst – Method.

```
findfirst(A)
```

Return the index or key of the first true value in A. Return nothing if no such value is found. To search for other kinds of values, pass a predicate as the first argument.

Indices or keys are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

See also: [findall](#), [findnext](#), [findlast](#), [searchsortedfirst](#).

Examples

```

julia> A = [false, false, true, false]
4-element Vector{Bool}:
 0
 0
 1
 0

julia> findfirst(A)
3

julia> findfirst(falses(3)) # returns nothing, but not printed in the REPL

julia> A = [false false; true false]
2×2 Matrix{Bool}:
 0  0
 1  0

julia> findfirst(A)
CartesianIndex{2, 1}

```

[source](#)

Base.findfirst – Method.

```
findfirst(predicate::Function, A)
```

Return the index or key of the first element of *A* for which predicate returns true. Return nothing if there is no such element.

Indices or keys are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

Examples

```
julia> A = [1, 4, 2, 2]
4-element Vector{Int64}:
 1
 4
 2
 2

julia> findfirst(iseven, A)
2

julia> findfirst(x -> x>10, A) # returns nothing, but not printed in the REPL

julia> findfirst(isequal(4), A)
2

julia> A = [1 4; 2 2]
2×2 Matrix{Int64}:
 1  4
 2  2

julia> findfirst(iseven, A)
CartesianIndex{2, 1}
```

[source](#)

Base.findlast – Method.

```
| findlast(A)
```

Return the index or key of the last true value in *A*. Return nothing if there is no true value in *A*.

Indices or keys are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

See also: [findfirst](#), [findprev](#), [findall](#).

Examples

```
julia> A = [true, false, true, false]
4-element Vector{Bool}:
 1
 0
 1
 0

julia> findlast(A)
3

julia> A = falses(2,2);
```

```
julia> findlast(A) # returns nothing, but not printed in the REPL

julia> A = [true false; true false]
2×2 Matrix{Bool}:
 1  0
 1  0

julia> findlast(A)
CartesianIndex{2}(2, 1)
```

[source](#)

Base.findlast – Method.

```
findlast(predicate::Function, A)
```

Return the index or key of the last element of A for which predicate returns true. Return nothing if there is no such element.

Indices or keys are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

Examples

```
julia> A = [1, 2, 3, 4]
4-element Vector{Int64}:
 1
 2
 3
 4

julia> findlast(isodd, A)
3

julia> findlast(x -> x > 5, A) # returns nothing, but not printed in the REPL

julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> findlast(isodd, A)
CartesianIndex{2}(2, 1)
```

[source](#)

Base.findnext – Method.

```
findnext(A, i)
```

Find the next index after or including i of a true element of A, or nothing if not found.

Indices are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

Examples

```

julia> A = [false, false, true, false]
4-element Vector{Bool}:
 0
 0
 1
 0

julia> findnext(A, 1)
3

julia> findnext(A, 4) # returns nothing, but not printed in the REPL

julia> A = [false false; true false]
2×2 Matrix{Bool}:
 0  0
 1  0

julia> findnext(A, CartesianIndex(1, 1))
CartesianIndex(2, 1)

```

[source](#)

Base.findnext - Method.

```
| findnext(predicate::Function, A, i)
```

Find the next index after or including *i* of an element of *A* for which *predicate* returns true, or nothing if not found.

Indices are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

Examples

```

julia> A = [1, 4, 2, 2];

julia> findnext(isodd, A, 1)
1

julia> findnext(isodd, A, 2) # returns nothing, but not printed in the REPL

julia> A = [1 4; 2 2];

julia> findnext(isodd, A, CartesianIndex(1, 1))
CartesianIndex(1, 1)

```

[source](#)

Base.findprev - Method.

```
| findprev(A, i)
```

Find the previous index before or including *i* of a true element of *A*, or nothing if not found.

Indices are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

See also: [findnext](#), [findfirst](#), [findall](#).

Examples

```
julia> A = [false, false, true, true]
4-element Vector{Bool}:
 0
 0
 1
 1

julia> findprev(A, 3)
3

julia> findprev(A, 1) # returns nothing, but not printed in the REPL

julia> A = [false false; true true]
2×2 Matrix{Bool}:
 0  0
 1  1

julia> findprev(A, CartesianIndex(2, 1))
CartesianIndex{2, 1}
```

[source](#)

Base.findprev – Method.

```
findprev(predicate::Function, A, i)
```

Find the previous index before or including *i* of an element of *A* for which *predicate* returns true, or nothing if not found.

Indices are of the same type as those returned by [keys\(A\)](#) and [pairs\(A\)](#).

Examples

```
julia> A = [4, 6, 1, 2]
4-element Vector{Int64}:
 4
 6
 1
 2

julia> findprev(isodd, A, 1) # returns nothing, but not printed in the REPL

julia> findprev(isodd, A, 3)
3

julia> A = [4 6; 1 2]
2×2 Matrix{Int64}:
 4  6
 1  2

julia> findprev(isodd, A, CartesianIndex(1, 2))
CartesianIndex{2, 1}
```

[source](#)

Base.permutedims – Function.

```
| permutedims(A::AbstractArray, perm)
```

Permute the dimensions of array A. perm is a vector or a tuple of length ndims(A) specifying the permutation.

See also [permutedims!](#), [PermutedDimsArray](#), [transpose](#), [invperm](#).

Examples

```
julia> A = reshape(Vector{Int64}(1:8), (2,2,2))
2×2×2 Array{Int64, 3}:
[:, :, 1] =
 1  3
 2  4

[:, :, 2] =
 5  7
 6  8

julia> perm = (3, 1, 2); # put the last dimension first

julia> B = permutedims(A, perm)
2×2×2 Array{Int64, 3}:
[:, :, 1] =
 1  2
 5  6

[:, :, 2] =
 3  4
 7  8

julia> A == permutedims(B, invperm(perm)) # the inverse permutation
true
```

For each dimension *i* of `B = permutedims(A, perm)`, its corresponding dimension of `A` will be `perm[i]`. This means the equality `size(B, i) == size(A, perm[i])` holds.

```
julia> A = randn(5, 7, 11, 13);

julia> perm = [4, 1, 3, 2];

julia> B = permutedims(A, perm);

julia> size(B)
(13, 5, 11, 7)

julia> size(A)[perm] == ans
true
```

[source](#)

```
| permutedims(m::AbstractMatrix)
```

Permute the dimensions of the matrix `m`, by flipping the elements across the diagonal of the matrix. Differs from LinearAlgebra's `transpose` in that the operation is not recursive.

Examples

```
julia> a = [1 2; 3 4];

julia> b = [5 6; 7 8];

julia> c = [9 10; 11 12];

julia> d = [13 14; 15 16];

julia> X = [[a] [b]; [c] [d]]
2×2 Matrix{Matrix{Int64}}:
 [1 2; 3 4]  [5 6; 7 8]
 [9 10; 11 12] [13 14; 15 16]

julia> permutedims(X)
2×2 Matrix{Matrix{Int64}}:
 [1 2; 3 4]  [9 10; 11 12]
 [5 6; 7 8]  [13 14; 15 16]

julia> transpose(X)
2×2 transpose(::Matrix{Matrix{Int64}}) with eltype Transpose{Int64, Matrix{Int64}}:
 [1 3; 2 4]  [9 11; 10 12]
 [5 7; 6 8]  [13 15; 14 16]
```

source

```
| permutedims(v::AbstractVector)
```

Reshape vector `v` into a $1 \times \text{length}(v)$ row matrix. Differs from LinearAlgebra's `transpose` in that the operation is not recursive.

Examples

```
julia> permutedims([1, 2, 3, 4])
1×4 Matrix{Int64}:
 1  2  3  4

julia> V = [[[1 2; 3 4]]; [[5 6; 7 8]]]
2-element Vector{Matrix{Int64}}:
 [1 2; 3 4]
 [5 6; 7 8]

julia> permutedims(V)
1×2 Matrix{Matrix{Int64}}:
 [1 2; 3 4]  [5 6; 7 8]

julia> transpose(V)
1×2 transpose(::Vector{Matrix{Int64}}) with eltype Transpose{Int64, Matrix{Int64}}:
 [1 3; 2 4]  [5 7; 6 8]
```

[source](#)

`Base.permutedims!` – Function.

```
| permutedims!(dest, src, perm)
```

Permute the dimensions of array `src` and store the result in the array `dest`. `perm` is a vector specifying a permutation of length `ndims(src)`. The preallocated array `dest` should have `size(dest) == size(src)[perm]` and is completely overwritten. No in-place permutation is supported and unexpected results will happen if `src` and `dest` have overlapping memory regions.

See also [permutedims](#).

[source](#)

`Base.PermutedDimsArrays.PermutedDimsArray` – Type.

```
| PermutedDimsArray(A, perm) -> B
```

Given an `AbstractArray` `A`, create a view `B` such that the dimensions appear to be permuted. Similar to `permutedims`, except that no copying occurs (`B` shares storage with `A`).

See also [permutedims](#), [invperm](#).

Examples

```
julia> A = rand(3,5,4);

julia> B = PermutedDimsArray(A, (3,1,2));

julia> size(B)
(4, 3, 5)

julia> B[3,1,2] == A[1,2,3]
true
```

[source](#)

`Base.promote_shape` – Function.

```
| promote_shape(s1, s2)
```

Check two array shapes for compatibility, allowing trailing singleton dimensions, and return whichever shape has more dimensions.

Examples

```
julia> a = fill(1, (3,4,1,1,1));

julia> b = fill(1, (3,4));

julia> promote_shape(a,b)
(Base.OneTo(3), Base.OneTo(4), Base.OneTo(1), Base.OneTo(1), Base.OneTo(1))

julia> promote_shape((2,3,1,4), (2, 3, 1, 4, 1))
(2, 3, 1, 4, 1)
```

[source](#)

46.7 Array functions

Base.accumulate – Function.

```
| accumulate(op, A; dims::Integer, [init])
```

Cumulative operation `op` along the dimension `dims` of `A` (providing `dims` is optional for vectors). An initial value `init` may optionally be provided by a keyword argument. See also [accumulate!](#) to use a preallocated output array, both for performance and to control the precision of the output (e.g. to avoid overflow).

For common operations there are specialized variants of `accumulate`, see [cumsum](#), [cumprod](#). For a lazy version, see [Iterators.accumulate](#).

Julia 1.5

`accumulate` on a non-array iterator requires at least Julia 1.5.

Examples

```
julia> accumulate(+, [1,2,3])
3-element Vector{Int64}:
 1
 3
 6

julia> accumulate(min, (1, -2, 3, -4, 5), init=0)
(0, -2, -2, -4, -4)

julia> accumulate(/, (2, 4, Inf), init=100)
(50.0, 12.5, 0.0)

julia> accumulate(=>, i^2 for i in 1:3)
3-element Vector{Any}:
 1
 1 => 4
 (1 => 4) => 9

julia> accumulate(+, fill(1, 3, 4))
3×4 Matrix{Int64}:
 1  4  7 10
 2  5  8 11
 3  6  9 12

julia> accumulate(+, fill(1, 2, 5), dims=2, init=100.0)
2×5 Matrix{Float64}:
101.0 102.0 103.0 104.0 105.0
101.0 102.0 103.0 104.0 105.0
```

[source](#)

Base.accumulate! – Function.

```
| accumulate!(op, B, A; [dims], [init])
```

Cumulative operation `op` on `A` along the dimension `dims`, storing the result in `B`. Providing `dims` is optional for vectors. If the keyword argument `init` is given, its value is used to instantiate the accumulation.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

See also [accumulate](#), [cumsum!](#), [cumprod!](#).

Examples

```
julia> x = [1, 0, 2, 0, 3];

julia> y = rand(5);

julia> accumulate!(+, y, x);

julia> y
5-element Vector{Float64}:
 1.0
 1.0
 3.0
 3.0
 6.0

julia> A = [1 2 3; 4 5 6];

julia> B = similar(A);

julia> accumulate!(-, B, A, dims=1)
2×3 Matrix{Int64}:
 1  2  3
-3 -3 -3

julia> accumulate!(*, B, A, dims=2, init=10)
2×3 Matrix{Int64}:
10  20  60
40 200 1200
```

[source](#)

`Base.cumprod` – Function.

```
| cumprod(A; dims::Integer)
```

Cumulative product along the dimension `dim`. See also [cumprod!](#) to use a preallocated output array, both for performance and to control the precision of the output (e.g. to avoid overflow).

Examples

```
julia> a = Int8[1 2 3; 4 5 6];
```

```
julia> cumprod(a, dims=1)
2×3 Matrix{Int64}:
 1  2  3
 4 10 18

julia> cumprod(a, dims=2)
2×3 Matrix{Int64}:
 1  2  6
 4 20 120
```

[source](#)

```
cumprod(itr)
```

Cumulative product of an iterator.

See also [cumprod!](#), [accumulate](#), [cumsum](#).

Julia 1.5

`cumprod` on a non-array iterator requires at least Julia 1.5.

Examples

```
julia> cumprod(fill(1//2, 3))
3-element Vector{Rational{Int64}}:
 1//2
 1//4
 1//8

julia> cumprod((1, 2, 1, 3, 1))
(1, 2, 2, 6, 6)

julia> cumprod("julia")
5-element Vector{String}:
 "j"
 "ju"
 "jul"
 "juli"
 "julia"
```

[source](#)

`Base.cumprod!` – Function.

```
cumprod!(B, A; dims::Integer)
```

Cumulative product of `A` along the dimension `dims`, storing the result in `B`. See also [cumprod](#).

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

```
| cumprod!(y::AbstractVector, x::AbstractVector)
```

Cumulative product of a vector `x`, storing the result in `y`. See also [cumprod](#).

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

Base.cumsum – Function.

```
| cumsum(A; dims::Integer)
```

Cumulative sum along the dimension `dims`. See also [cumsum!](#) to use a preallocated output array, both for performance and to control the precision of the output (e.g. to avoid overflow).

Examples

```
julia> a = [1 2 3; 4 5 6]
2×3 Matrix{Int64}:
 1  2  3
 4  5  6

julia> cumsum(a, dims=1)
2×3 Matrix{Int64}:
 1  2  3
 5  7  9

julia> cumsum(a, dims=2)
2×3 Matrix{Int64}:
 1  3  6
 4  9 15
```

Note

The return array's `eltype` is `Int` for signed integers of less than system word size and `UInt` for unsigned integers of less than system word size. To preserve `eltype` of arrays with small signed or unsigned integer accumulate(+, A) should be used.

```
julia> cumsum{Int8}(100, 28)
2-element Vector{Int64}:
 100
 128

julia> accumulate(+, Int8(100), 28)
2-element Vector{Int8}:
 100
 -128
```

In the former case, the integers are widened to system word size and therefore the result is `Int64[100, 128]`. In the latter case, no such widening happens and integer overflow results in `Int8[100, -128]`.

[source](#)

```
| cumsum(itr)
```

Cumulative sum of an iterator.

See also [accumulate](#) to apply functions other than +.

Julia 1.5

cumsum on a non-array iterator requires at least Julia 1.5.

Examples

```
julia> cumsum(1:3)
3-element Vector{Int64}:
 1
 3
 6

julia> cumsum((true, false, true, false, true))
(1, 1, 2, 2, 3)

julia> cumsum(fill(1, 2) for i in 1:3)
3-element Vector{Vector{Int64}}:
 [1, 1]
 [2, 2]
 [3, 3]
```

[source](#)

Base.cumsum! – Function.

```
| cumsum!(B, A; dims::Integer)
```

Cumulative sum of A along the dimension dims, storing the result in B. See also [cumsum](#).

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

Base.diff – Function.

```
| diff(A::AbstractVector)
| diff(A::AbstractArray; dims::Integer)
```

Finite difference operator on a vector or a multidimensional array A. In the latter case the dimension to operate on needs to be specified with the dims keyword argument.

Julia 1.1

diff for arrays with dimension higher than 2 requires at least Julia 1.1.

Examples

```
julia> a = [2 4; 6 16]
2×2 Matrix{Int64}:
 2  4
 6 16

julia> diff(a, dims=2)
2×1 Matrix{Int64}:
 2
10

julia> diff(vec(a))
3-element Vector{Int64}:
 4
-2
12
```

[source](#)

Base.repeat – Function.

```
| repeat(A::AbstractArray, counts::Integer...)
```

Construct an array by repeating array A a given number of times in each dimension, specified by counts.

See also: [fill](#), [Iterators.repeated](#), [Iterators.cycle](#).

Examples

```
julia> repeat([1, 2, 3], 2)
6-element Vector{Int64}:
 1
 2
 3
 1
 2
 3

julia> repeat([1, 2, 3], 2, 3)
6×3 Matrix{Int64}:
 1  1  1
 2  2  2
 3  3  3
 1  1  1
 2  2  2
 3  3  3
```

[source](#)

```
| repeat(A::AbstractArray; inner=ntuple(Returns(1), ndims(A)), outer=ntuple(Returns(1), ndims(A)))
```

Construct an array by repeating the entries of A. The i-th element of inner specifies the number of times that the individual entries of the i-th dimension of A should be repeated. The i-th element of

outer specifies the number of times that a slice along the i-th dimension of A should be repeated. If inner or outer are omitted, no repetition is performed.

Examples

```
julia> repeat(1:2, inner=2)
4-element Vector{Int64}:
 1
 1
 2
 2

julia> repeat(1:2, outer=2)
4-element Vector{Int64}:
 1
 2
 1
 2

julia> repeat([1 2; 3 4], inner=(2, 1), outer=(1, 3))
4×6 Matrix{Int64}:
 1  2  1  2  1  2
 1  2  1  2  1  2
 3  4  3  4  3  4
 3  4  3  4  3  4
```

[source](#)

```
| repeat(s::AbstractString, r::Integer)
```

Repeat a string *r* times. This can be written as s^r .

See also [^](#).

Examples

```
julia> repeat("ha", 3)
"hahaha"
```

[source](#)

```
| repeat(c::AbstractChar, r::Integer) -> String
```

Repeat a character *r* times. This can equivalently be accomplished by calling c^r .

Examples

```
julia> repeat('A', 3)
"AAA"
```

[source](#)

Base.rot180 - Function.

```
| rot180(A)
```

Rotate matrix A 180 degrees.

Examples

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> rot180(a)
2×2 Matrix{Int64}:
 4  3
 2  1
```

[source](#)

```
| rot180(A, k)
```

Rotate matrix A 180 degrees an integer k number of times. If k is even, this is equivalent to a copy.

Examples

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> rot180(a,1)
2×2 Matrix{Int64}:
 4  3
 2  1

julia> rot180(a,2)
2×2 Matrix{Int64}:
 1  2
 3  4
```

[source](#)

Base.rotl90 - Function.

```
| rotl90(A)
```

Rotate matrix A left 90 degrees.

Examples

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4
```

```
julia> rotl90(a)
2×2 Matrix{Int64}:
 2  4
 1  3
```

[source](#)

```
rotl90(A, k)
```

Left-rotate matrix A 90 degrees counterclockwise an integer k number of times. If k is a multiple of four (including zero), this is equivalent to a copy.

Examples

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4
```

```
julia> rotl90(a,1)
2×2 Matrix{Int64}:
 2  4
 1  3
```

```
julia> rotl90(a,2)
2×2 Matrix{Int64}:
 4  3
 2  1
```

```
julia> rotl90(a,3)
2×2 Matrix{Int64}:
 3  1
 4  2
```

```
julia> rotl90(a,4)
2×2 Matrix{Int64}:
 1  2
 3  4
```

[source](#)

Base.rotr90 – Function.

```
rotr90(A)
```

Rotate matrix A right 90 degrees.

Examples

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4
```

```
julia> rotr90(a)
2×2 Matrix{Int64}:
 3  1
 4  2
```

[source](#)

```
rotr90(A, k)
```

Right-rotate matrix A 90 degrees clockwise an integer k number of times. If k is a multiple of four (including zero), this is equivalent to a copy.

Examples

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> rotr90(a,1)
2×2 Matrix{Int64}:
 3  1
 4  2

julia> rotr90(a,2)
2×2 Matrix{Int64}:
 4  3
 2  1

julia> rotr90(a,3)
2×2 Matrix{Int64}:
 2  4
 1  3

julia> rotr90(a,4)
2×2 Matrix{Int64}:
 1  2
 3  4
```

[source](#)

Base.mapslices – Function.

```
mapslices(f, A; dims)
```

Transform the given dimensions of array A by applying a function f on each slice of the form A[... , :, ..., :, ...], with a colon at each d in dims. The results are concatenated along the remaining dimensions.

For example, if dims = [1,2] and A is 4-dimensional, then f is called on x = A[:, :, i, j] for all i and j, and f(x) becomes R[:, :, i, j] in the result R.

See also [eachcol](#) or [eachslice](#), used with [map](#) or [stack](#).

Examples

```

julia> A = reshape(1:30,(2,5,3))
2×5×3 reshape{::UnitRange{Int64}, 2, 5, 3} with eltype Int64:
[:, :, 1] =
 1  3  5  7  9
 2  4  6  8 10

[:, :, 2] =
11 13 15 17 19
12 14 16 18 20

[:, :, 3] =
21 23 25 27 29
22 24 26 28 30

julia> f(x::Matrix) = fill(x[1,1], 1,4); # returns a 1×4 matrix

julia> B = mapslices(f, A, dims=(1,2))
1×4×3 Array{Int64, 3}:
[:, :, 1] =
 1  1  1  1

[:, :, 2] =
11 11 11 11

[:, :, 3] =
21 21 21 21

julia> f2(x::AbstractMatrix) = fill(x[1,1], 1,4);

julia> B == stack(f2, eachslice(A, dims=3))
true

julia> g(x) = x[begin] // x[end-1]; # returns a number

julia> mapslices(g, A, dims=[1,3])
1×5×1 Array{Rational{Int64}, 3}:
[:, :, 1] =
 1//21  3//23  1//5  7//27  9//29

julia> map(g, eachslice(A, dims=2))
5-element Vector{Rational{Int64}}:
 1//21
 3//23
 1//5
 7//27
 9//29

julia> mapslices(sum, A; dims=(1,3)) == sum(A; dims=(1,3))
true

```

Notice that in `eachslice(A; dims=2)`, the specified dimension is the one without a colon in the slice. This is `view(A, :, i, :)`, whereas `mapslices(f, A; dims=(1,3))` uses `A[:, i, :]`. The function `f` may mutate values in the slice without affecting `A`.

[source](#)

`Base.eachrow` – Function.

```
eachrow(A::AbstractVecOrMat) <: AbstractVector
```

Create a [RowSlices](#) object that is a vector of rows of matrix or vector A. Row slices are returned as `AbstractVector` views of A.

For the inverse, see [stack](#)(rows; dims=1).

See also [eachcol](#), [eachslice](#) and [mapslices](#).

Julia 1.1

This function requires at least Julia 1.1.

Julia 1.9

Prior to Julia 1.9, this returned an iterator.

Example

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> s = eachrow(a)
2-element RowSlices{Matrix{Int64}, Tuple{Base.OneTo{Int64}}, SubArray{Int64, 1,
↪ Matrix{Int64}, Tuple{Int64, Base.Slice{Base.OneTo{Int64}}}, true}}:
 [1, 2]
 [3, 4]

julia> s[1]
2-element view(::Matrix{Int64}, 1, :) with eltype Int64:
 1
 2
```

[source](#)

`Base.eachcol` – Function.

```
eachcol(A::AbstractVecOrMat) <: AbstractVector
```

Create a [ColumnSlices](#) object that is a vector of columns of matrix or vector A. Column slices are returned as `AbstractVector` views of A.

For the inverse, see [stack](#)(cols) or [reduce](#)([hcat](#), cols).

See also [eachrow](#), [eachslice](#) and [mapslices](#).

Julia 1.1

This function requires at least Julia 1.1.

Julia 1.9

Prior to Julia 1.9, this returned an iterator.

Example

```
julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> s = eachcol(a)
2-element ColumnSlices{Matrix{Int64}, Tuple{Base.OneTo{Int64}}, SubArray{Int64, 1,
↪ Matrix{Int64}, Tuple{Base.Slice{Base.OneTo{Int64}}}, Int64}, true}}:
 [1, 3]
 [2, 4]

julia> s[1]
2-element view(::Matrix{Int64}, :, 1) with eltype Int64:
 1
 3
```

[source](#)

Base.eachslice – Function.

```
eachslice(A::AbstractArray; dims, drop=true)
```

Create a [Slices](#) object that is an array of slices over dimensions `dims` of `A`, returning views that select all the data from the other dimensions in `A`. `dims` can either be an integer or a tuple of integers.

If `drop = true` (the default), the outer `Slices` will drop the inner dimensions, and the ordering of the dimensions will match those in `dims`. If `drop = false`, then the `Slices` will have the same dimensionality as the underlying array, with inner dimensions having size 1.

See [stack\(slices; dims\)](#) for the inverse of `eachslice(A; dims::Integer)`.

See also [eachrow](#), [eachcol](#), [mapslices](#) and [selectdim](#).

Julia 1.1

This function requires at least Julia 1.1.

Julia 1.9

Prior to Julia 1.9, this returned an iterator, and only a single dimension `dims` was supported.

Example

```
julia> m = [1 2 3; 4 5 6; 7 8 9]
3×3 Matrix{Int64}:
 1  2  3
 4  5  6
 7  8  9

julia> s = eachslice(m, dims=1)
```

```

3-element RowSlices{Matrix{Int64}, Tuple{Base.OneTo{Int64}}, SubArray{Int64, 1,
↪ Matrix{Int64}, Tuple{Int64, Base.Slice{Base.OneTo{Int64}}}, true}}:
 [1, 2, 3]
 [4, 5, 6]
 [7, 8, 9]

julia> s[1]
3-element view(::Matrix{Int64}, 1, :) with eltype Int64:
 1
 2
 3

julia> eachslice(m, dims=1, drop=false)
3×1 Slices{Matrix{Int64}, Tuple{Int64, Colon}, Tuple{Base.OneTo{Int64}, Base.OneTo{Int64}}},
↪ SubArray{Int64, 1, Matrix{Int64}, Tuple{Int64, Base.Slice{Base.OneTo{Int64}}}, true}, 2}:
 [1, 2, 3]
 [4, 5, 6]
 [7, 8, 9]

```

[source](#)

46.8 Combinatorics

`Base.invperm` – Function.

```
| invperm(v)
```

Return the inverse permutation of `v`. If `B = A[v]`, then `A == B[invperm(v)]`.

See also [sortperm](#), [invpermute!](#), [isperm](#), [permutedims](#).

Examples

```

julia> p = (2, 3, 1);

julia> invperm(p)
(3, 1, 2)

julia> v = [2; 4; 3; 1];

julia> invperm(v)
4-element Vector{Int64}:
 4
 1
 3
 2

julia> A = ['a', 'b', 'c', 'd'];

julia> B = A[v]
4-element Vector{Char}:
 'b': ASCII/Unicode U+0062 (category Ll: Letter, lowercase)
 'd': ASCII/Unicode U+0064 (category Ll: Letter, lowercase)
 'c': ASCII/Unicode U+0063 (category Ll: Letter, lowercase)

```

```
'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)

julia> B[invperm(v)]
4-element Vector{Char}:
 'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)
 'b': ASCII/Unicode U+0062 (category Ll: Letter, lowercase)
 'c': ASCII/Unicode U+0063 (category Ll: Letter, lowercase)
 'd': ASCII/Unicode U+0064 (category Ll: Letter, lowercase)
```

[source](#)

Base.isperm – Function.

```
isperm(v) -> Bool
```

Return true if v is a valid permutation.

Examples

```
julia> isperm([1; 2])
true

julia> isperm([1; 3])
false
```

[source](#)

Base.permute! – Method.

```
permute!(v, p)
```

Permute vector v in-place, according to permutation p. No checking is done to verify that p is a permutation.

To return a new permutation, use v[p]. This is generally faster than permute!(v, p); it is even faster to write into a pre-allocated output array with u .= @view v[p]. (Even though permute! overwrites v in-place, it internally requires some allocation to keep track of which elements have been moved.)

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

See also [invpermute!](#).

Examples

```
julia> A = [1, 1, 3, 4];

julia> perm = [2, 4, 3, 1];

julia> permute!(A, perm);

julia> A
4-element Vector{Int64}:
```

```

1
4
3
1

```

[source](#)

`Base.invpermute!` – Function.

```
invpermute!(v, p)
```

Like [permute!](#), but the inverse of the given permutation is applied.

Note that if you have a pre-allocated output array (e.g. `u = similar(v)`), it is quicker to instead employ `u[p] = v`. (`invpermute!` internally allocates a copy of the data.)

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```

julia> A = [1, 1, 3, 4];

julia> perm = [2, 4, 3, 1];

julia> invpermute!(A, perm);

julia> A
4-element Vector{Int64}:
 4
 1
 3
 1

```

[source](#)

`Base.reverse` – Method.

```
reverse(A; dims=:)
```

Reverse `A` along dimension `dims`, which can be an integer (a single dimension), a tuple of integers (a tuple of dimensions) or `:` (reverse along all the dimensions, the default). See also [reverse!](#) for in-place reversal.

Examples

```

julia> b = Int64[1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> reverse(b, dims=2)

```

```

2×2 Matrix{Int64}:
 2  1
 4  3

julia> reverse(b)
2×2 Matrix{Int64}:
 4  3
 2  1

```

Julia 1.6

Prior to Julia 1.6, only single-integer dims are supported in `reverse`.

[source](#)

`Base.reverseind` – Function.

```
| reverseind(v, i)
```

Given an index `i` in `reverse(v)`, return the corresponding index in `v` so that `v[reverseind(v,i)] == reverse(v)[i]`. (This can be nontrivial in cases where `v` contains non-ASCII characters.)

Examples

```

julia> s = "Julia"
"Julia"

julia> r = reverse(s)
"ailuJ"

julia> for i in eachindex(s)
           print(r[reverseind(r, i)])
       end
Julia

```

[source](#)

`Base.reverse!` – Function.

```
| reverse!(v [, start=firstindex(v) [, stop=lastindex(v) ]]) -> v
```

In-place version of `reverse`.

Examples

```

julia> A = Vector{Int64}(1:5)
5-element Vector{Int64}:
 1
 2
 3
 4
 5

julia> reverse!(A);

```

```
julia> A
5-element Vector{Int64}:
 5
 4
 3
 2
 1
```

[source](#)

```
reverse!(A; dims=:)
```

Like [reverse](#), but operates in-place in A.

Julia 1.6

Multidimensional `reverse!` requires Julia 1.6.

[source](#)

Chapter 47

Tasks

Core.Task – Type.

| `Task(func)`

Create a Task (i.e. coroutine) to execute the given function `func` (which must be callable with no arguments). The task exits when this function returns. The task will run in the "world age" from the parent at construction when `scheduled`.

Warning

By default tasks will have the sticky bit set to true `t.sticky`. This models the historic default for `@async`. Sticky tasks can only be run on the worker thread they are first scheduled on. To obtain the behavior of `Threads.@spawn` set the sticky bit manually to `false`.

Examples

```
julia> a() = sum(i for i in 1:1000);  
julia> b = Task(a);
```

In this example, `b` is a runnable Task that hasn't started yet.

[source](#)

Base.@task – Macro.

| `@task`

Wrap an expression in a Task without executing it, and return the Task. This only creates a task, and does not run it.

Examples

```
julia> a1() = sum(i for i in 1:1000);  
julia> b = @task a1();  
julia> istaskstarted(b)
```

```

false

julia> schedule(b);

julia> yield();

julia> istaskdone(b)
true

```

source

Base.@async – Macro.

```
| @async
```

Wrap an expression in a [Task](#) and add it to the local machine's scheduler queue.

Values can be interpolated into @async via \$, which copies the value directly into the constructed underlying closure. This allows you to insert the value of a variable, isolating the asynchronous code from changes to the variable's value in the current task.

Warning

It is strongly encouraged to favor `Threads.spawn` over `@async` always **even when no parallelism is required** especially in publicly distributed libraries. This is because a use of `@async` disables the migration of the parent task across worker threads in the current implementation of Julia. Thus, seemingly innocent use of `@async` in a library function can have a large impact on the performance of very different parts of user applications.

Julia 1.4

Interpolating values via \$ is available as of Julia 1.4.

source

Base.asyncmap – Function.

```
| asyncmap(f, c...; ntasks=0, batch_size=nothing)
```

Uses multiple concurrent tasks to map `f` over a collection (or multiple equal length collections). For multiple collection arguments, `f` is applied elementwise.

`ntasks` specifies the number of tasks to run concurrently. Depending on the length of the collections, if `ntasks` is unspecified, up to 100 tasks will be used for concurrent mapping.

`ntasks` can also be specified as a zero-arg function. In this case, the number of tasks to run in parallel is checked before processing every element and a new task started if the value of `ntasks_func` is greater than the current number of tasks.

If `batch_size` is specified, the collection is processed in batch mode. `f` must then be a function that must accept a `Vector` of argument tuples and must return a vector of results. The input vector will have a length of `batch_size` or less.

The following examples highlight execution in different tasks by returning the `object.id` of the tasks in which the mapping function is executed.

First, with `ntasks` undefined, each element is processed in a different task.

```
julia> tskoid() = objectid(current_task());

julia> asyncmap(x->tskoid(), 1:5)
5-element Array{UInt64,1}:
 0x6e15e66c75c75853
 0x440f8819a1baa682
 0x9fb3eeadd0c83985
 0xebd3e35fe90d4050
 0x29efc93edce2b961

julia> length(unique(asyncmap(x->tskoid(), 1:5)))
5
```

With `ntasks=2` all elements are processed in 2 tasks.

```
julia> asyncmap(x->tskoid(), 1:5; ntasks=2)
5-element Array{UInt64,1}:
 0x027ab1680df7ae94
 0xa23d2f80cd7cf157
 0x027ab1680df7ae94
 0xa23d2f80cd7cf157
 0x027ab1680df7ae94

julia> length(unique(asyncmap(x->tskoid(), 1:5; ntasks=2)))
2
```

With `batch_size` defined, the mapping function needs to be changed to accept an array of argument tuples and return an array of results. `map` is used in the modified mapping function to achieve this.

```
julia> batch_func(input) = map(x->string("args_tuple: ", x, ", element_val: ", x[1], ", task: ",
    tskoid()), input)
batch_func (generic function with 1 method)

julia> asyncmap(batch_func, 1:5; ntasks=2, batch_size=2)
5-element Array{String,1}:
 "args_tuple: (1,), element_val: 1, task: 9118321258196414413"
 "args_tuple: (2,), element_val: 2, task: 4904288162898683522"
 "args_tuple: (3,), element_val: 3, task: 9118321258196414413"
 "args_tuple: (4,), element_val: 4, task: 4904288162898683522"
 "args_tuple: (5,), element_val: 5, task: 9118321258196414413"
```

[source](#)

Base.asyncmap! – Function.

```
asyncmap!(f, results, c...; ntasks=0, batch_size=nothing)
```

Like [asyncmap](#), but stores output in `results` rather than returning a collection.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

Base.current_task – Function.

```
| current_task()
```

Get the currently running [Task](#).

[source](#)

Base.istaskdone – Function.

```
| istaskdone(t::Task) -> Bool
```

Determine whether a task has exited.

Examples

```
julia> a2() = sum(i for i in 1:1000);  
  
julia> b = Task(a2);  
  
julia> istaskdone(b)  
false  
  
julia> schedule(b);  
  
julia> yield();  
  
julia> istaskdone(b)  
true
```

[source](#)

Base.istaskstarted – Function.

```
| istaskstarted(t::Task) -> Bool
```

Determine whether a task has started executing.

Examples

```
julia> a3() = sum(i for i in 1:1000);  
  
julia> b = Task(a3);  
  
julia> istaskstarted(b)  
false
```

[source](#)

Base.istaskfailed – Function.

```
| istaskfailed(t::Task) -> Bool
```

Determine whether a task has exited because an exception was thrown.

Examples

```
julia> a4() = error("task failed");

julia> b = Task(a4);

julia> istaskfailed(b)
false

julia> schedule(b);

julia> yield();

julia> istaskfailed(b)
true
```

Julia 1.3

This function requires at least Julia 1.3.

[source](#)

Base.task_local_storage – Method.

```
| task_local_storage(key)
```

Look up the value of a key in the current task's task-local storage.

[source](#)

Base.task_local_storage – Method.

```
| task_local_storage(key, value)
```

Assign a value to a key in the current task's task-local storage.

[source](#)

Base.task_local_storage – Method.

```
| task_local_storage(body, key, value)
```

Call the function body with a modified task-local storage, in which value is assigned to key; the previous value of key, or lack thereof, is restored afterwards. Useful for emulating dynamic scoping.

[source](#)

47.1 Scheduling

Base.yield – Function.

```
| yield()
```

Switch to the scheduler to allow another scheduled task to run. A task that calls this function is still runnable, and will be restarted immediately if there are no other runnable tasks.

[source](#)

```
| yield(t::Task, arg = nothing)
```

A fast, unfair-scheduling version of `schedule(t, arg); yield()` which immediately yields to `t` before calling the scheduler.

[source](#)

`Base.yieldto` – Function.

```
| yieldto(t::Task, arg = nothing)
```

Switch to the given task. The first time a task is switched to, the task's function is called with no arguments. On subsequent switches, `arg` is returned from the task's last call to `yieldto`. This is a low-level call that only switches tasks, not considering states or scheduling in any way. Its use is discouraged.

[source](#)

`Base.sleep` – Function.

```
| sleep(seconds)
```

Block the current task for a specified number of seconds. The minimum sleep time is 1 millisecond or input of `0.001`.

[source](#)

`Base.schedule` – Function.

```
| schedule(t::Task, [val]; error=false)
```

Add a `Task` to the scheduler's queue. This causes the task to run constantly when the system is otherwise idle, unless the task performs a blocking operation such as `wait`.

If a second argument `val` is provided, it will be passed to the task (via the return value of `yieldto`) when it runs again. If `error` is `true`, the value is raised as an exception in the woken task.

Warning

It is incorrect to use `schedule` on an arbitrary `Task` that has already been started. See [the API reference](#) for more information.

Examples

```
julia> a5() = sum(i for i in 1:1000);
julia> b = Task(a5);
julia> istaskstarted(b)
false
julia> schedule(b);
julia> yield();
```

```
julia> istaskstarted(b)
true

julia> istaskdone(b)
true
```

[source](#)

47.2 Synchronization

`Base.errormonitor` – Function.

```
| errormonitor(t::Task)
```

Print an error log to `stderr` if task `t` fails.

Examples

```
julia> Base._wait(errormonitor(Threads.@spawn error("task failed")))
Unhandled Task ERROR: task failed
Stacktrace:
[...]

julia> 
```

[source](#)

`Base.@sync` – Macro.

```
| @sync
```

Wait until all lexically-enclosed uses of `@async`, `@spawn`, `@spawnat` and `@distributed` are complete. All exceptions thrown by enclosed async operations are collected and thrown as a [CompositeException](#).

Examples

```
julia> Threads.nthreads()
4

julia> @sync begin
    Threads.@spawn println("Thread-id $(Threads.threadid()), task 1")
    Threads.@spawn println("Thread-id $(Threads.threadid()), task 2")
end;
Thread-id 3, task 1
Thread-id 1, task 2
```

[source](#)

`Base.wait` – Function.

Special note for [Threads.Condition](#):

The caller must be holding the [lock](#) that owns a `Threads.Condition` before calling this method. The calling task will be blocked until some other task wakes it, usually by calling [notify](#) on the same `Threads.Condition` object. The lock will be atomically released when blocking (even if it was locked recursively), and will be reacquired before returning.

[source](#)

```
| wait(r::Future)
```

Wait for a value to become available for the specified [Future](#).

source

```
| wait(r::RemoteChannel, args...)
```

Wait for a value to become available on the specified [RemoteChannel](#).

source

```
| wait([x])
```

Block the current task until some event occurs, depending on the type of the argument:

- [Channel](#): Wait for a value to be appended to the channel.
- [Condition](#): Wait for [notify](#) on a condition and return the `val` parameter passed to `notify`. Waiting on a condition additionally allows passing `first=true` which results in the waiter being put first in line to wake up on `notify` instead of the usual first-in-first-out behavior.
- [Process](#): Wait for a process or process chain to exit. The `exitcode` field of a process can be used to determine success or failure.
- [Task](#): Wait for a Task to finish. If the task fails with an exception, a `TaskFailedException` (which wraps the failed task) is thrown.
- [RawFD](#): Wait for changes on a file descriptor (see the `FileWatching` package).

If no argument is passed, the task blocks for an undefined period. A task can only be restarted by an explicit call to [schedule](#) or [yieldto](#).

Often `wait` is called within a while loop to ensure a waited-for condition is met before proceeding.

source

```
| wait(c::Channel)
```

Blocks until the Channel [isready](#).

```
julia> c = Channel{1};

julia> isready(c)
false

julia> task = Task{() -> wait(c)};

julia> schedule(task);

julia> istaskdone(task) # task is blocked because channel is not ready
false

julia> put!(c, 1);

julia> istaskdone(task) # task is now unblocked
true
```

source

Base.fetch – Method.

```
| fetch(t: Task)
```

Wait for a [Task](#) to finish, then return its result value. If the task fails with an exception, a [TaskFailedException](#) (which wraps the failed task) is thrown.

source

Base.fetch – Method.

```
| fetch(x: Any)
```

Return x.

source

Base.timedwait – Function.

```
| timedwait(testcb, timeout: Real; pollint: Real=0.1)
```

Waits until `testcb()` returns true or `timeout` seconds have passed, whichever is earlier. The test function is polled every `pollint` seconds. The minimum value for `pollint` is 0.001 seconds, that is, 1 millisecond.

Return `:ok` or `:timed_out`.

source

Base.Condition – Type.

```
| Condition()
```

Create an edge-triggered event source that tasks can wait for. Tasks that call [wait](#) on a [Condition](#) are suspended and queued. Tasks are woken up when [notify](#) is later called on the [Condition](#). Edge triggering means that only tasks waiting at the time [notify](#) is called can be woken up. For level-triggered notifications, you must keep extra state to keep track of whether a notification has happened. The [Channel](#) and [Threads.Event](#) types do this, and can be used for level-triggered events.

This object is NOT thread-safe. See [Threads.Condition](#) for a thread-safe version.

source

Base.Threads.Condition – Type.

```
| Threads.Condition([lock])
```

A thread-safe version of [Base.Condition](#).

To call [wait](#) or [notify](#) on a [Threads.Condition](#), you must first call [lock](#) on it. When [wait](#) is called, the lock is atomically released during blocking, and will be reacquired before [wait](#) returns. Therefore idiomatic use of a [Threads.Condition](#) `c` looks like the following:

```

lock(c)
try
    while !thing_we_are_waiting_for
        wait(c)
    end
finally
    unlock(c)
end

```

Julia 1.2

This functionality requires at least Julia 1.2.

source

Base.Event – Type.

```
| Event([autoreset=false])
```

Create a level-triggered event source. Tasks that call `wait` on an Event are suspended and queued until `notify` is called on the Event. After `notify` is called, the Event remains in a signaled state and tasks will no longer block when waiting for it, until `reset` is called.

If `autoreset` is true, at most one task will be released from `wait` for each call to `notify`.

This provides an acquire & release memory ordering on `notify/wait`.

Julia 1.1

This functionality requires at least Julia 1.1.

Julia 1.8

The `autoreset` functionality and memory ordering guarantee requires at least Julia 1.8.

source

Base.notify – Function.

```
| notify(condition, val=nothing; all=true, error=false)
```

Wake up tasks waiting for a condition, passing them `val`. If `all` is true (the default), all waiting tasks are woken, otherwise only one is. If `error` is true, the passed value is raised as an exception in the woken tasks.

Return the count of tasks woken up. Return 0 if no tasks are waiting on condition.

source

Base.reset – Method.

```
| reset(::Event)
```

Reset an `Event` back into an un-set state. Then any future calls to `wait` will block until `notify` is called again.

source

`Base.Semaphore` – Type.

```
| Semaphore(sem_size)
```

Create a counting semaphore that allows at most `sem_size` acquires to be in use at any time. Each acquire must be matched with a release.

This provides a acquire & release memory ordering on acquire/release calls.

[source](#)

`Base.acquire` – Function.

```
| acquire(s::Semaphore)
```

Wait for one of the `sem_size` permits to be available, blocking until one can be acquired.

[source](#)

```
| acquire(f, s::Semaphore)
```

Execute `f` after acquiring from Semaphore `s`, and release on completion or error.

For example, a do-block form that ensures only 2 calls of `foo` will be active at the same time:

```
s = Base.Semaphore(2)
@sync for _ in 1:100
    Threads.@spawn begin
        Base.acquire(s) do
            foo()
        end
    end
end
end
```

Julia 1.8

This method requires at least Julia 1.8.

[source](#)

`Base.release` – Function.

```
| release(s::Semaphore)
```

Return one permit to the pool, possibly allowing another task to acquire it and resume execution.

[source](#)

`Base.AbstractLock` – Type.

```
| AbstractLock
```

Abstract supertype describing types that implement the synchronization primitives: `lock`, `trylock`, `unlock`, and `islocked`.

[source](#)

`Base.lock` – Function.

```
| lock(lock)
```

Acquire the lock when it becomes available. If the lock is already locked by a different task/thread, wait for it to become available.

Each lock must be matched by an `unlock`.

[source](#)

```
| lock(f::Function, lock)
```

Acquire the lock, execute `f` with the lock held, and release the lock when `f` returns. If the lock is already locked by a different task/thread, wait for it to become available.

When this function returns, the lock has been released, so the caller should not attempt to `unlock` it.

Julia 1.7

Using a `Channel` as the second argument requires Julia 1.7 or later.

[source](#)

`Base.unlock` – Function.

```
| unlock(lock)
```

Releases ownership of the lock.

If this is a recursive lock which has been acquired before, decrement an internal counter and return immediately.

[source](#)

`Base.trylock` – Function.

```
| trylock(lock) -> Success (Boolean)
```

Acquire the lock if it is available, and return `true` if successful. If the lock is already locked by a different task/thread, return `false`.

Each successful `trylock` must be matched by an `unlock`.

Function `trylock` combined with `islocked` can be used for writing the test-and-test-and-set or exponential backoff algorithms if it is supported by the `typeof(lock)` (read its documentation).

[source](#)

`Base.islocked` – Function.

```
| islocked(lock) -> Status (Boolean)
```

Check whether the lock is held by any task/thread. This function alone should not be used for synchronization. However, `islocked` combined with `trylock` can be used for writing the test-and-test-and-set or exponential backoff algorithms if it is supported by the `typeof(lock)` (read its documentation).

Extended help

For example, an exponential backoff can be implemented as follows if the `lock` implementation satisfied the properties documented below.

```

nspins = 0
while true
  while islocked(lock)
    GC.safepoint()
    nspins += 1
    nspins > LIMIT && error("timeout")
  end
  trylock(lock) && break
  backoff()
end

```

Implementation

A lock implementation is advised to define `islocked` with the following properties and note it in its docstring.

- `islocked(lock)` is data-race-free.
- If `islocked(lock)` returns false, an immediate invocation of `trylock(lock)` must succeed (returns true) if there is no interference from other tasks.

source

`Base.ReentrantLock` – Type.

ReentrantLock()

Creates a re-entrant lock for synchronizing [Tasks](#). The same task can acquire the lock as many times as required (this is what the "Reentrant" part of the name means). Each [lock](#) must be matched with an [unlock](#).

Calling 'lock' will also inhibit running of finalizers on that thread until the corresponding 'unlock'. Use of the standard lock pattern illustrated below should naturally be supported, but beware of inverting the try/lock order or missing the try block entirely (e.g. attempting to return with the lock still held):

This provides a acquire/release memory ordering on lock/unlock calls.

```

lock(l)
try
  <atomic work>
finally
  unlock(l)
end

```

If `!islocked(lck::ReentrantLock)` holds, `trylock(lck)` succeeds unless there are other tasks attempting to hold the lock "at the same time."

source

47.3 Channels

`Base.AbstractChannel` – Type.

AbstractChannel{T}

Representation of a channel passing objects of type T.

source

Base.Channel – Type.

```
| Channel{T=Any}(size::Int=0)
```

Constructs a Channel with an internal buffer that can hold a maximum of size objects of type T. `put!` calls on a full channel block until an object is removed with `take!`.

`Channel(0)` constructs an unbuffered channel. `put!` blocks until a matching `take!` is called. And vice-versa.

Other constructors:

- `Channel()`: default constructor, equivalent to `Channel{Any}(0)`
- `Channel(Inf)`: equivalent to `Channel{Any}(typemax(Int))`
- `Channel(sz)`: equivalent to `Channel{Any}(sz)`

Julia 1.3

The default constructor `Channel()` and default `size=0` were added in Julia 1.3.

source

Base.Channel – Method.

```
| Channel{T=Any}(func::Function, size=0; taskref=nothing, spawn=false, threadpool=nothing)
```

Create a new task from `func`, bind it to a new channel of type T and size `size`, and schedule the task, all in a single call. The channel is automatically closed when the task terminates.

`func` must accept the bound channel as its only argument.

If you need a reference to the created task, pass a `Ref{Task}` object via the keyword argument `taskref`.

If `spawn=true`, the Task created for `func` may be scheduled on another thread in parallel, equivalent to creating a task via `Threads.spawn`.

If `spawn=true` and the `threadpool` argument is not set, it defaults to `:default`.

If the `threadpool` argument is set (to `:default` or `:interactive`), this implies that `spawn=true` and the new Task is spawned to the specified threadpool.

Return a Channel.

Examples

```
julia> chnl = Channel() do ch
    foreach(i -> put!(ch, i), 1:4)
end;

julia> typeof(chnl)
Channel{Any}

julia> for i in chnl
```

```

        @show i
    end;
i = 1
i = 2
i = 3
i = 4

```

Referencing the created task:

```

julia> taskref = Ref{Task}{};

julia> chnl = Channel(taskref=taskref) do ch
    println(take!(ch))
end;

julia> istaskdone(taskref[])
false

julia> put!(chnl, "Hello");
Hello

julia> istaskdone(taskref[])
true

```

Julia 1.3

The `spawn=` parameter was added in Julia 1.3. This constructor was added in Julia 1.3. In earlier versions of Julia, `Channel` used keyword arguments to set `size` and `T`, but those constructors are deprecated.

Julia 1.9

The `threadpool=` argument was added in Julia 1.9.

```

julia> chnl = Channel{Char}(1, spawn=true) do ch
    for c in "hello world"
        put!(ch, c)
    end
end
Channel{Char}(1) (2 items available)

julia> String(collect(chnl))
"hello world"

```

source

`Base.put!` – Method.

```

put!(c::Channel, v)

```

Append an item `v` to the channel `c`. Blocks if the channel is full.

For unbuffered channels, blocks until a `take!` is performed by a different task.

Julia 1.1

`v` now gets converted to the channel's type with `convert` as `put!` is called.

[source](#)

`Base.take!` – Method.

```
| take!(c::Channel)
```

Removes and returns a value from a `Channel` in order. Blocks until data is available. For unbuffered channels, blocks until a `put!` is performed by a different task.

Examples

Buffered channel:

```
| julia> c = Channel{1};  
|  
| julia> put!(c, 1);  
|  
| julia> take!(c)  
| 1
```

Unbuffered channel:

```
| julia> c = Channel{0};  
|  
| julia> task = Task{() -> put!(c, 1)};  
|  
| julia> schedule(task);  
|  
| julia> take!(c)  
| 1
```

[source](#)

`Base.isready` – Method.

```
| isready(c::Channel)
```

Determines whether a `Channel` has a value stored in it. Returns immediately, does not block.

For unbuffered channels returns `true` if there are tasks waiting on a `put!`.

Examples

Buffered channel:

```
| julia> c = Channel{1};  
|  
| julia> isready(c)  
| false  
|  
| julia> put!(c, 1);  
|  
| julia> isready(c)  
| true
```

Unbuffered channel:

```
julia> c = Channel();

julia> isready(c) # no tasks waiting to put!
false

julia> task = Task(() -> put!(c, 1));

julia> schedule(task); # schedule a put! task

julia> isready(c)
true
```

[source](#)

Base.fetch – Method.

```
| fetch(c::Channel)
```

Waits for and returns (without removing) the first available item from the Channel. Note: fetch is unsupported on an unbuffered (0-size) Channel.

Examples

Buffered channel:

```
julia> c = Channel{3} do ch
    foreach(i -> put!(ch, i), 1:3)
end;

julia> fetch(c)
1

julia> collect(c) # item is not removed
3-element Vector{Any}:
 1
 2
 3
```

[source](#)

Base.close – Method.

```
| close(c::Channel[, excp::Exception])
```

Close a channel. An exception (optionally given by excp), is thrown by:

- `put!` on a closed channel.
- `take!` and `fetch` on an empty, closed channel.

[source](#)

Base.bind – Method.

```
| bind(chnl::Channel, task::Task)
```

Associate the lifetime of `chnl` with a task. Channel `chnl` is automatically closed when the task terminates. Any uncaught exception in the task is propagated to all waiters on `chnl`.

The `chnl` object can be explicitly closed independent of task termination. Terminating tasks have no effect on already closed Channel objects.

When a channel is bound to multiple tasks, the first task to terminate will close the channel. When multiple channels are bound to the same task, termination of the task will close all of the bound channels.

Examples

```
julia> c = Channel{0};

julia> task = @async foreach(i->put!(c, i), 1:4);

julia> bind(c, task);

julia> for i in c
           @show i
       end;
i = 1
i = 2
i = 3
i = 4

julia> isopen(c)
false
```

```
julia> c = Channel{0};

julia> task = @async (put!(c, 1); error("foo"));

julia> bind(c, task);

julia> take!(c)
1

julia> put!(c, 1);
ERROR: TaskFailedException
Stacktrace:
[...]
  nested task error: foo
[...]
```

[source](#)

47.4 Low-level synchronization using `schedule` and `wait`

The easiest correct use of `schedule` is on a Task that is not started (scheduled) yet. However, it is possible to use `schedule` and `wait` as a very low-level building block for constructing synchronization interfaces. A

crucial pre-condition of calling `schedule(task)` is that the caller must "own" the task; i.e., it must know that the call to `wait` in the given task is happening at the locations known to the code calling `schedule(task)`. One strategy for ensuring such pre-condition is to use atomics, as demonstrated in the following example:

```
@enum OWESState begin
    OWE_EMPTY
    OWE_WAITING
    OWE_NOTIFYING
end

mutable struct OneWayEvent
    @atomic state::OWESState
    task::Task
    OneWayEvent() = new(OWE_EMPTY)
end

function Base.notify(ev::OneWayEvent)
    state = @atomic ev.state
    while state != OWE_NOTIFYING
        # Spin until we successfully update the state to OWE_NOTIFYING:
        state, ok = @atomicreplace(ev.state, state => OWE_NOTIFYING)
        if ok
            if state == OWE_WAITING
                # OWE_WAITING -> OWE_NOTIFYING transition means that the waiter task is
                # already waiting or about to call `wait`. The notifier task must wake up
                # the waiter task.
                schedule(ev.task)
            else
                @assert state == OWE_EMPTY
                # Since we are assuming that there is only one notifier task (for
                # simplicity), we know that the other possible case here is OWE_EMPTY.
                # We do not need to do anything because we know that the waiter task has
                # not called `wait(ev::OneWayEvent)` yet.
            end
            break
        end
    end
    return
end

function Base.wait(ev::OneWayEvent)
    ev.task = current_task()
    state, ok = @atomicreplace(ev.state, OWE_EMPTY => OWE_WAITING)
    if ok
        # OWE_EMPTY -> OWE_WAITING transition means that the notifier task is guaranteed to
        # invoke OWE_WAITING -> OWE_NOTIFYING transition. The waiter task must call
        # `wait()` immediately. In particular, it MUST NOT invoke any function that may
        # yield to the scheduler at this point in code.
        wait()
    else
        @assert state == OWE_NOTIFYING
        # Otherwise, the `state` must have already been moved to OWE_NOTIFYING by the
        # notifier task.
    end
end
```

```
        end
        return
    end
end

ev = OneWayEvent()
@sync begin
    @async begin
        wait(ev)
        println("done")
    end
    println("notifying...")
    notify(ev)
end

# output
notifying...
done
```

`OneWayEvent` lets one task to wait for another task's notify. It is a limited communication interface since `wait` can only be used once from a single task (note the non-atomic assignment of `ev.task`)

In this example, `notify(ev:OneWayEvent)` is allowed to call `schedule(ev.task)` if and only if it modifies the state from `OWE_WAITING` to `OWE_NOTIFYING`. This lets us know that the task executing `wait(ev:OneWayEvent)` is now in the ok branch and that there cannot be other tasks that tries to `schedule(ev.task)` since their `@atomicreplace(ev.state, state => OWE_NOTIFYING)` will fail.

Chapter 48

Multi-Threading

Base.Threads.@threads – Macro.

```
| Threads.@threads [schedule] for ... end
```

A macro to execute a for loop in parallel. The iteration space is distributed to coarse-grained tasks. This policy can be specified by the `schedule` argument. The execution of the loop waits for the evaluation of all iterations.

See also: [@spawn](#) and `pmap` in [Distributed](#).

Extended help

Semantics

Unless stronger guarantees are specified by the scheduling option, the loop executed by `@threads` macro have the following semantics.

The `@threads` macro executes the loop body in an unspecified order and potentially concurrently. It does not specify the exact assignments of the tasks and the worker threads. The assignments can be different for each execution. The loop body code (including any code transitively called from it) must not make any assumptions about the distribution of iterations to tasks or the worker thread in which they are executed. The loop body for each iteration must be able to make forward progress independent of other iterations and be free from data races. As such, invalid synchronizations across iterations may deadlock while unsynchronized memory accesses may result in undefined behavior.

For example, the above conditions imply that:

- A lock taken in an iteration must be released within the same iteration.
- Communicating between iterations using blocking primitives like `Channels` is incorrect.
- Write only to locations not shared across iterations (unless a lock or atomic operation is used).
- Unless the `:static` schedule is used, the value of `threadid()` may change even within a single iteration. See [Task Migration](#).

Schedulers

Without the scheduler argument, the exact scheduling is unspecified and varies across Julia releases. Currently, `:dynamic` is used when the scheduler is not specified.

Julia 1.5

The `schedule` argument is available as of Julia 1.5.

:dynamic (default)

:dynamic scheduler executes iterations dynamically to available worker threads. Current implementation assumes that the workload for each iteration is uniform. However, this assumption may be removed in the future.

This scheduling option is merely a hint to the underlying execution mechanism. However, a few properties can be expected. The number of Tasks used by :dynamic scheduler is bounded by a small constant multiple of the number of available worker threads (`Threads.threadpoolsize()`). Each task processes contiguous regions of the iteration space. Thus, `@threads :dynamic for x in xs; f(x); end` is typically more efficient than `@sync for x in xs; @spawn f(x); end` if `length(xs)` is significantly larger than the number of the worker threads and the run-time of `f(x)` is relatively smaller than the cost of spawning and synchronizing a task (typically less than 10 microseconds).

Julia 1.8

The :dynamic option for the `schedule` argument is available and the default as of Julia 1.8.

:static

:static scheduler creates one task per thread and divides the iterations equally among them, assigning each task specifically to each thread. In particular, the value of `threadid()` is guaranteed to be constant within one iteration. Specifying :static is an error if used from inside another `@threads` loop or from a thread other than 1.

Note

:static scheduling exists for supporting transition of code written before Julia 1.3. In newly written library functions, :static scheduling is discouraged because the functions using this option cannot be called from arbitrary worker threads.

Example

To illustrate of the different scheduling strategies, consider the following function `busywait` containing a non-yielding timed loop that runs for a given number of seconds.

```
julia> function busywait(seconds)
    tstart = time_ns()
    while (time_ns() - tstart) / 1e9 < seconds
        end
    end

julia> @time begin
    Threads.@spawn busywait(5)
    Threads.@threads :static for i in 1:Threads.threadpoolsize()
        busywait(1)
    end
end
6.003001 seconds (16.33 k allocations: 899.255 KiB, 0.25% compilation time)

julia> @time begin
```

```

Threads.@spawn busywait(5)
Threads.@threads :dynamic for i in 1:Threads.threadpoolsize()
    busywait(1)
end
end
2.012056 seconds (16.05 k allocations: 883.919 KiB, 0.66% compilation time)

```

The `:dynamic` example takes 2 seconds since one of the non-occupied threads is able to run two of the 1-second iterations to complete the for loop.

[source](#)

`Base.Threads.foreach` – Function.

```

Threads.foreach(f, channel::Channel;
    schedule::Threads.AbstractSchedule=Threads.FairSchedule(),
    ntasks=Threads.threadpoolsize())

```

Similar to `foreach(f, channel)`, but iteration over `channel` and calls to `f` are split across `ntasks` tasks spawned by `Threads.@spawn`. This function will wait for all internally spawned tasks to complete before returning.

If `schedule isa FairSchedule`, `Threads.foreach` will attempt to spawn tasks in a manner that enables Julia's scheduler to more freely load-balance work items across threads. This approach generally has higher per-item overhead, but may perform better than `StaticSchedule` in concurrence with other multithreaded workloads.

If `schedule isa StaticSchedule`, `Threads.foreach` will spawn tasks in a manner that incurs lower per-item overhead than `FairSchedule`, but is less amenable to load-balancing. This approach thus may be more suitable for fine-grained, uniform workloads, but may perform worse than `FairSchedule` in concurrence with other multithreaded workloads.

Examples

```

julia> n = 20

julia> c = Channel{Int}(ch -> foreach(i -> put!(ch, i), 1:n), 1)

julia> d = Channel{Int}(n) do ch
    f = i -> put!(ch, i^2)
    Threads.foreach(f, c)
end

julia> collect(d)
collect(d) = [1, 4, 9, 16, 25, 36, 49, 64, 81, 100, 121, 144, 169, 196, 225, 256, 289, 324,
↪ 361, 400]

```

Julia 1.6

This function requires Julia 1.6 or later.

[source](#)

`Base.Threads.@spawn` – Macro.

```

Threads.@spawn [:default|:interactive] expr

```

Create a [Task](#) and [schedule](#) it to run on any available thread in the specified threadpool (:default if unspecified). The task is allocated to a thread once one becomes available. To wait for the task to finish, call [wait](#) on the result of this macro, or call [fetch](#) to wait and then obtain its return value.

Values can be interpolated into `@spawn` via `$`, which copies the value directly into the constructed underlying closure. This allows you to insert the value of a variable, isolating the asynchronous code from changes to the variable's value in the current task.

Note

The thread that the task runs on may change if the task yields, therefore `threadid()` should not be treated as constant for a task. See [Task Migration](#), and the broader [multi-threading](#) manual for further important caveats. See also the chapter on [threadpools](#).

Julia 1.3

This macro is available as of Julia 1.3.

Julia 1.4

Interpolating values via `$` is available as of Julia 1.4.

Julia 1.9

A threadpool may be specified as of Julia 1.9.

Examples

```
julia> t() = println("Hello from ", Threads.threadid());

julia> tasks = fetch.([Threads.@spawn t() for i in 1:4]);
Hello from 1
Hello from 1
Hello from 3
Hello from 4
```

[source](#)

`Base.Threads.threadid` – Function.

```
| Threads.threadid() -> Int
```

Get the ID number of the current thread of execution. The master thread has ID 1.

Examples

```
julia> Threads.threadid()
1

julia> Threads.@threads for i in 1:4
    println(Threads.threadid())
end
4
2
5
4
```

Note

The thread that a task runs on may change if the task yields, which is known as [Task Migration](#). For this reason in most cases it is not safe to use `threadid()` to index into, say, a vector of buffer or stateful objects.

[source](#)

`Base.Threads.maxthreadid` – Function.

```
| Threads.maxthreadid() -> Int
```

Get a lower bound on the number of threads (across all thread pools) available to the Julia process, with atomic-acquire semantics. The result will always be greater than or equal to `threadid()` as well as `threadid(task)` for any task you were able to observe before calling `maxthreadid`.

[source](#)

`Base.Threads.nthreads` – Function.

```
| Threads.nthreads(:default | :interactive) -> Int
```

Get the current number of threads within the specified thread pool. The threads in `:interactive` have id numbers `1:nthreads(:interactive)`, and the threads in `:default` have id numbers in `nthreads(:interactive) .+ (1:nthreads(:default))`.

See also `BLAS.get_num_threads` and `BLAS.set_num_threads` in the [LinearAlgebra](#) standard library, and `nprocs()` in the [Distributed](#) standard library and `Threads.maxthreadid()`.

[source](#)

`Base.Threads.threadpool` – Function.

```
| Threads.threadpool(tid = threadid()) -> Symbol
```

Returns the specified thread's threadpool; either `:default`, `:interactive`, or `:foreign`.

[source](#)

`Base.Threads.nthreadpools` – Function.

```
| Threads.nthreadpools() -> Int
```

Returns the number of threadpools currently configured.

[source](#)

`Base.Threads.threadpoolsize` – Function.

```
| Threads.threadpoolsize(pool::Symbol = :default) -> Int
```

Get the number of threads available to the default thread pool (or to the specified thread pool).

See also: `BLAS.get_num_threads` and `BLAS.set_num_threads` in the [LinearAlgebra](#) standard library, and `nprocs()` in the [Distributed](#) standard library.

[source](#)

Base.Threads.ngcthreads – Function.

```
| Threads.ngcthreads() -> Int
```

Returns the number of GC threads currently configured. This includes both mark threads and concurrent sweep threads.

[source](#)

See also [Multi-Threading](#).

48.1 Atomic operations

atomic – Keyword.

Unsafe pointer operations are compatible with loading and storing pointers declared with `_Atomic` and `std::atomic` type in C11 and C++23 respectively. An error may be thrown if there is not support for atomically loading the Julia type `T`.

See also: [unsafe_load](#), [unsafe_modify!](#), [unsafe_replace!](#), [unsafe_store!](#), [unsafe_swap!](#)

[source](#)

Base.@atomic – Macro.

```
| @atomic var
| @atomic order ex
```

Mark `var` or `ex` as being performed atomically, if `ex` is a supported expression. If no order is specified it defaults to `:sequentially_consistent`.

```
| @atomic a.b.x = new
| @atomic a.b.x += addend
| @atomic :release a.b.x = new
| @atomic :acquire_release a.b.x += addend
```

Perform the store operation expressed on the right atomically and return the new value.

With `=`, this operation translates to a `setproperty!(a.b, :x, new)` call. With any operator also, this operation translates to a `modifyproperty!(a.b, :x, +, addend)[2]` call.

```
| @atomic a.b.x max arg2
| @atomic a.b.x + arg2
| @atomic max(a.b.x, arg2)
| @atomic :acquire_release max(a.b.x, arg2)
| @atomic :acquire_release a.b.x + arg2
| @atomic :acquire_release a.b.x max arg2
```

Perform the binary operation expressed on the right atomically. Store the result into the field in the first argument and return the values (old, new).

This operation translates to a `modifyproperty!(a.b, :x, func, arg2)` call.

See [Per-field atomics](#) section in the manual for more details.

Examples

```

julia> mutable struct Atomic{T}; @atomic x::T; end

julia> a = Atomic(1)
Atomic{Int64}{1}

julia> @atomic a.x # fetch field x of a, with sequential consistency
1

julia> @atomic :sequentially_consistent a.x = 2 # set field x of a, with sequential
↪ consistency
2

julia> @atomic a.x += 1 # increment field x of a, with sequential consistency
3

julia> @atomic a.x + 1 # increment field x of a, with sequential consistency
3 => 4

julia> @atomic a.x # fetch field x of a, with sequential consistency
4

julia> @atomic max(a.x, 10) # change field x of a to the max value, with sequential
↪ consistency
4 => 10

julia> @atomic a.x max 5 # again change field x of a to the max value, with sequential
↪ consistency
10 => 10

```

Julia 1.7

This functionality requires at least Julia 1.7.

source

Base.@atomicswap – Macro.

```

@atomicswap a.b.x = new
@atomicswap :sequentially_consistent a.b.x = new

```

Stores new into a.b.x and returns the old value of a.b.x.

This operation translates to a `swapproperty!(a.b, :x, new)` call.

See [Per-field atomics](#) section in the manual for more details.

Examples

```

julia> mutable struct Atomic{T}; @atomic x::T; end

julia> a = Atomic(1)
Atomic{Int64}{1}

julia> @atomicswap a.x = 2+2 # replace field x of a with 4, with sequential consistency
1

```

```
julia> @atomic a.x # fetch field x of a, with sequential consistency
4
```

Julia 1.7

This functionality requires at least Julia 1.7.

[source](#)

Base.@atomicreplace – Macro.

```
@atomicreplace a.b.x expected => desired
@atomicreplace :sequentially_consistent a.b.x expected => desired
@atomicreplace :sequentially_consistent :monotonic a.b.x expected => desired
```

Perform the conditional replacement expressed by the pair atomically, returning the values (old, success::Bool). Where success indicates whether the replacement was completed.

This operation translates to a replaceproperty!(a.b, :x, expected, desired) call.

See [Per-field atomics](#) section in the manual for more details.

Examples

```
julia> mutable struct Atomic{T}; @atomic x::T; end

julia> a = Atomic{1}
Atomic{Int64}{1}

julia> @atomicreplace a.x 1 => 2 # replace field x of a with 2 if it was 1, with sequential
↔ consistency
(old = 1, success = true)

julia> @atomic a.x # fetch field x of a, with sequential consistency
2

julia> @atomicreplace a.x 1 => 2 # replace field x of a with 2 if it was 1, with sequential
↔ consistency
(old = 2, success = false)

julia> xchg = 2 => 0; # replace field x of a with 0 if it was 2, with sequential consistency

julia> @atomicreplace a.x xchg
(old = 2, success = true)

julia> @atomic a.x # fetch field x of a, with sequential consistency
0
```

Julia 1.7

This functionality requires at least Julia 1.7.

[source](#)

Note

The following APIs are fairly primitive, and will likely be exposed through an `unsafe_*`-like wrapper.

```
Core.Intrinsics.atomic_pointerref(pointer::Ptr{T}, order::Symbol) --> T
Core.Intrinsics.atomic_pointerset(pointer::Ptr{T}, new::T, order::Symbol) --> pointer
Core.Intrinsics.atomic_pointerswap(pointer::Ptr{T}, new::T, order::Symbol) --> old
Core.Intrinsics.atomic_pointermodify(pointer::Ptr{T}, function::(old::T,arg::S)->T, arg::S, order::Symbol) --> old
Core.Intrinsics.atomic_pointerreplace(pointer::Ptr{T}, expected::Any, new::T, success_order::Symbol, failure_order::Symbol) --> (old, cmp)
```

Warning

The following APIs are deprecated, though support for them is likely to remain for several releases.

`Base.Threads.Atomic` – Type.

```
| Threads.Atomic{T}
```

Holds a reference to an object of type `T`, ensuring that it is only accessed atomically, i.e. in a thread-safe manner.

Only certain "simple" types can be used atomically, namely the primitive boolean, integer, and float-point types. These are `Bool`, `Int8...Int128`, `UInt8...UInt128`, and `Float16...Float64`.

New atomic objects can be created from a non-atomic values; if none is specified, the atomic object is initialized with zero.

Atomic objects can be accessed using the `[]` notation:

Examples

```
julia> x = Threads.Atomic{Int}(3)
Base.Threads.Atomic{Int64}(3)

julia> x[] = 1
1

julia> x[]
1
```

Atomic operations use an `atomic_` prefix, such as `atomic_add!`, `atomic_xchg!`, etc.

[source](#)

`Base.Threads.atomic_cas!` – Function.

```
| Threads.atomic_cas!(x::Atomic{T}, cmp::T, newval::T) where T
```

Atomically compare-and-set x

Atomically compares the value in x with cmp. If equal, write newval to x. Otherwise, leaves x unmodified. Returns the old value in x. By comparing the returned value to cmp (via ==) one knows whether x was modified and now holds the new value newval.

For further details, see LLVM's cmpxchg instruction.

This function can be used to implement transactional semantics. Before the transaction, one records the value in x. After the transaction, the new value is stored only if x has not been modified in the mean time.

Examples

```
julia> x = Threads.Atomic{Int}(3)
Base.Threads.Atomic{Int64}(3)

julia> Threads.atomic_cas!(x, 4, 2);

julia> x
Base.Threads.Atomic{Int64}(3)

julia> Threads.atomic_cas!(x, 3, 2);

julia> x
Base.Threads.Atomic{Int64}(2)
```

[source](#)

Base.Threads.atomic_xchg! – Function.

```
| Threads.atomic_xchg!(x::Atomic{T}, newval::T) where T
```

Atomically exchange the value in x

Atomically exchanges the value in x with newval. Returns the **old** value.

For further details, see LLVM's atomicrmw xchg instruction.

Examples

```
julia> x = Threads.Atomic{Int}(3)
Base.Threads.Atomic{Int64}(3)

julia> Threads.atomic_xchg!(x, 2)
3

julia> x[]
2
```

[source](#)

Base.Threads.atomic_add! – Function.

```
| Threads.atomic_add!(x::Atomic{T}, val::T) where T <: ArithmeticTypes
```

Atomically add `val` to `x`

Performs `x[] += val` atomically. Returns the **old** value. Not defined for `Atomic{Bool}`.

For further details, see LLVM's `atomicrmw add` instruction.

Examples

```
julia> x = Threads.Atomic{Int}(3)
Base.Threads.Atomic{Int64}(3)

julia> Threads.atomic_add!(x, 2)
3

julia> x[]
5
```

[source](#)

`Base.Threads.atomic_sub!` – Function.

```
Threads.atomic_sub!(x::Atomic{T}, val::T) where T <: ArithmeticTypes
```

Atomically subtract `val` from `x`

Performs `x[] -= val` atomically. Returns the **old** value. Not defined for `Atomic{Bool}`.

For further details, see LLVM's `atomicrmw sub` instruction.

Examples

```
julia> x = Threads.Atomic{Int}(3)
Base.Threads.Atomic{Int64}(3)

julia> Threads.atomic_sub!(x, 2)
3

julia> x[]
1
```

[source](#)

`Base.Threads.atomic_and!` – Function.

```
Threads.atomic_and!(x::Atomic{T}, val::T) where T
```

Atomically bitwise-and `x` with `val`

Performs `x[] &= val` atomically. Returns the **old** value.

For further details, see LLVM's `atomicrmw and` instruction.

Examples

```
julia> x = Threads.Atomic{Int}(3)
Base.Threads.Atomic{Int64}(3)
```

```
julia> Threads.atomic_and!(x, 2)
3

julia> x[]
2
```

[source](#)

Base.Threads.atomic_nand! – Function.

```
Threads.atomic_nand!(x::Atomic{T}, val::T) where T
```

Atomically bitwise-nand (not-and) x with val

Performs $x[] = \sim(x[] \& \text{val})$ atomically. Returns the **old** value.

For further details, see LLVM's `atomicrmw_nand` instruction.

Examples

```
julia> x = Threads.Atomic{Int}(3)
Base.Threads.Atomic{Int64}(3)

julia> Threads.atomic_nand!(x, 2)
3

julia> x[]
-3
```

[source](#)

Base.Threads.atomic_or! – Function.

```
Threads.atomic_or!(x::Atomic{T}, val::T) where T
```

Atomically bitwise-or x with val

Performs $x[] |= \text{val}$ atomically. Returns the **old** value.

For further details, see LLVM's `atomicrmw_or` instruction.

Examples

```
julia> x = Threads.Atomic{Int}(5)
Base.Threads.Atomic{Int64}(5)

julia> Threads.atomic_or!(x, 7)
5

julia> x[]
7
```

[source](#)

Base.Threads.atomic_xor! – Function.

```
| Threads.atomic_xor!(x::Atomic{T}, val::T) where T
```

Atomically bitwise-xor (exclusive-or) x with val

Performs `x[] -= val` atomically. Returns the **old** value.

For further details, see LLVM's `atomicrmw xor` instruction.

Examples

```
julia> x = Threads.Atomic{Int}(5)
Base.Threads.Atomic{Int64}(5)

julia> Threads.atomic_xor!(x, 7)
5

julia> x[]
2
```

[source](#)

`Base.Threads.atomic_max!` – Function.

```
| Threads.atomic_max!(x::Atomic{T}, val::T) where T
```

Atomically store the maximum of x and val in x

Performs `x[] = max(x[], val)` atomically. Returns the **old** value.

For further details, see LLVM's `atomicrmw max` instruction.

Examples

```
julia> x = Threads.Atomic{Int}(5)
Base.Threads.Atomic{Int64}(5)

julia> Threads.atomic_max!(x, 7)
5

julia> x[]
7
```

[source](#)

`Base.Threads.atomic_min!` – Function.

```
| Threads.atomic_min!(x::Atomic{T}, val::T) where T
```

Atomically store the minimum of x and val in x

Performs `x[] = min(x[], val)` atomically. Returns the **old** value.

For further details, see LLVM's `atomicrmw min` instruction.

Examples

```
julia> x = Threads.Atomic{Int}(7)
Base.Threads.Atomic{Int64}(7)

julia> Threads.atomic_min!(x, 5)
7

julia> x[]
5
```

[source](#)

Base.Threads.atomic_fence – Function.

```
| Threads.atomic_fence()
```

Insert a sequential-consistency memory fence

Inserts a memory fence with sequentially-consistent ordering semantics. There are algorithms where this is needed, i.e. where an acquire/release ordering is insufficient.

This is likely a very expensive operation. Given that all other atomic operations in Julia already have acquire/release semantics, explicit fences should not be necessary in most cases.

For further details, see LLVM's fence instruction.

[source](#)

48.2 ccall using a libuv threadpool (Experimental)

Base.@threadcall – Macro.

```
| @threadcall((cfunc, clib), rettype, (argtypes...), argvals...)
```

The @threadcall macro is called in the same way as `ccall` but does the work in a different thread. This is useful when you want to call a blocking C function without causing the current julia thread to become blocked. Concurrency is limited by size of the libuv thread pool, which defaults to 4 threads but can be increased by setting the `UV_THREADPOOL_SIZE` environment variable and restarting the julia process.

Note that the called function should never call back into Julia.

[source](#)

48.3 Low-level synchronization primitives

These building blocks are used to create the regular synchronization objects.

Base.Threads.SpinLock – Type.

```
| SpinLock()
```

Create a non-reentrant, test-and-test-and-set spin lock. Recursive use will result in a deadlock. This kind of lock should only be used around code that takes little time to execute and does not block (e.g. perform I/O). In general, [ReentrantLock](#) should be used instead.

Each `lock` must be matched with an `unlock`. If `!islocked(lck::SpinLock)` holds, `trylock(lck)` succeeds unless there are other tasks attempting to hold the lock "at the same time."

Test-and-test-and-set spin locks are quickest up to about 30ish contending threads. If you have more contention than that, different synchronization approaches should be considered.

[source](#)

Chapter 49

Constants

Core.nothing – Constant.

| `nothing`

The singleton instance of type `Nothing`, used by convention when there is no value to return (as in a C void function) or when a variable or field holds no value.

See also: `isnothing`, `something`, `missing`.

[source](#)

Base.PROGRAM_FILE – Constant.

| `PROGRAM_FILE`

A string containing the script name passed to Julia from the command line. Note that the script name remains unchanged from within included files. Alternatively see `@__FILE__`.

[source](#)

Base.ARGS – Constant.

| `ARGS`

An array of the command line arguments passed to Julia, as strings.

[source](#)

Base.C_NULL – Constant.

| `C_NULL`

The C null pointer constant, sometimes used when calling external code.

[source](#)

Base.VERSION – Constant.

| `VERSION`

A [VersionNumber](#) object describing which version of Julia is in use. See also [Version Number Literals](#).

[source](#)

`Base.DEPOT_PATH` – Constant.

| `DEPOT_PATH`

A stack of "depot" locations where the package manager, as well as Julia's code loading mechanisms, look for package registries, installed packages, named environments, repo clones, cached compiled package images, and configuration files. By default it includes:

1. `~/.julia` where `~` is the user home as appropriate on the system;
2. an architecture-specific shared system directory, e.g. `/usr/local/share/julia`;
3. an architecture-independent shared system directory, e.g. `/usr/share/julia`.

So `DEPOT_PATH` might be:

```
| [joinpath(homedir(), ".julia"), "/usr/local/share/julia", "/usr/share/julia"]
```

The first entry is the "user depot" and should be writable by and owned by the current user. The user depot is where: registries are cloned, new package versions are installed, named environments are created and updated, package repos are cloned, newly compiled package image files are saved, log files are written, development packages are checked out by default, and global configuration data is saved. Later entries in the depot path are treated as read-only and are appropriate for registries, packages, etc. installed and managed by system administrators.

`DEPOT_PATH` is populated based on the [JULIA_DEPOT_PATH](#) environment variable if set.

DEPOT_PATH contents

Each entry in `DEPOT_PATH` is a path to a directory which contains subdirectories used by Julia for various purposes. Here is an overview of some of the subdirectories that may exist in a depot:

- `artifacts`: Contains content that packages use for which `Pkg` manages the installation of.
- `clones`: Contains full clones of package repos. Maintained by `Pkg.jl` and used as a cache.
- `config`: Contains julia-level configuration such as a `startup.jl`
- `compiled`: Contains precompiled `*.ji` files for packages. Maintained by Julia.
- `dev`: Default directory for `Pkg.develop`. Maintained by `Pkg.jl` and the user.
- `environments`: Default package environments. For instance the global environment for a specific julia version. Maintained by `Pkg.jl`.
- `logs`: Contains logs of `Pkg` and REPL operations. Maintained by `Pkg.jl` and Julia.
- `packages`: Contains packages, some of which were explicitly installed and some which are implicit dependencies. Maintained by `Pkg.jl`.
- `registries`: Contains package registries. By default only `General`. Maintained by `Pkg.jl`.
- `scratchspaces`: Contains content that a package itself installs via the [Scratch.jl](#) package. `Pkg.gc()` will delete content that is known to be unused.

Note

Packages that want to store content should use the `scratchspaces` subdirectory via `Scratch.jl` instead of creating new subdirectories in the depot root.

See also [JULIA_DEPOT_PATH](#), and [Code Loading](#).

[source](#)

`Base.LOAD_PATH` – Constant.

| `LOAD_PATH`

An array of paths for using and import statements to consider as project environments or package directories when loading code. It is populated based on the `JULIA_LOAD_PATH` environment variable if set; otherwise it defaults to `["@@", "@v#.#", "@stdlib"]`. Entries starting with `@` have special meanings:

- `@` refers to the "current active environment", the initial value of which is initially determined by the `JULIA_PROJECT` environment variable or the `--project` command-line option.
- `@stdlib` expands to the absolute path of the current Julia installation's standard library directory.
- `@name` refers to a named environment, which are stored in depots (see [JULIA_DEPOT_PATH](#)) under the `environments` subdirectory. The user's named environments are stored in `~/.julia/environments` so `@name` would refer to the environment in `~/.julia/environments/name` if it exists and contains a `Project.toml` file. If `name` contains `#` characters, then they are replaced with the major, minor and patch components of the Julia version number. For example, if you are running Julia 1.2 then `@v#.#` expands to `@v1.2` and will look for an environment by that name, typically at `~/.julia/environments/v1.2`.

The fully expanded value of `LOAD_PATH` that is searched for projects and packages can be seen by calling the `Base.load_path()` function.

See also [JULIA_LOAD_PATH](#), [JULIA_PROJECT](#), [JULIA_DEPOT_PATH](#), and [Code Loading](#).

[source](#)

`Base.Sys.BINDIR` – Constant.

| `Sys.BINDIR::String`

A string containing the full path to the directory containing the `julia` executable.

[source](#)

`Base.Sys.CPU_THREADS` – Constant.

| `Sys.CPU_THREADS::Int`

The number of logical CPU cores available in the system, i.e. the number of threads that the CPU can run concurrently. Note that this is not necessarily the number of CPU cores, for example, in the presence of [hyper-threading](#).

See `Hwloc.jl` or `Cpuid.jl` for extended information, including number of physical cores.

[source](#)

`Base.Sys.WORD_SIZE` – Constant.

| `Sys.WORD_SIZE :: Int`

Standard word size on the current machine, in bits.

[source](#)

`Base.Sys.KERNEL` – Constant.

| `Sys.KERNEL :: Symbol`

A symbol representing the name of the operating system, as returned by `uname` of the build configuration.

[source](#)

`Base.Sys.ARCH` – Constant.

| `Sys.ARCH :: Symbol`

A symbol representing the architecture of the build configuration.

[source](#)

`Base.Sys.MACHINE` – Constant.

| `Sys.MACHINE :: String`

A string containing the build triple.

[source](#)

See also:

- [stdin](#)
- [stdout](#)
- [stderr](#)
- [ENV](#)
- [ENDIAN_BOM](#)

Chapter 50

Filesystem

Base.Filesystem.pwd – Function.

```
| pwd() -> String
```

Get the current working directory.

See also: [cd](#), [tempdir](#).

Examples

```
julia> pwd()  
"/home/JuliaUser"  
  
julia> cd("/home/JuliaUser/Projects/julia")  
  
julia> pwd()  
"/home/JuliaUser/Projects/julia"
```

[source](#)

Base.Filesystem.cd – Method.

```
| cd(dir::AbstractString=homedir())
```

Set the current working directory.

See also: [pwd](#), [mkdir](#), [mkpath](#), [mktempdir](#).

Examples

```
julia> cd("/home/JuliaUser/Projects/julia")  
  
julia> pwd()  
"/home/JuliaUser/Projects/julia"  
  
julia> cd()  
  
julia> pwd()  
"/home/JuliaUser"
```

source

Base.Filesystem.cd – Method.

```
| cd(f::Function, dir::AbstractString=homedir())
```

Temporarily change the current working directory to `dir`, apply function `f` and finally return to the original directory.

Examples

```
julia> pwd()
"/home/JuliaUser"

julia> cd(readdir, "/home/JuliaUser/Projects/julia")
34-element Array{String,1}:
 ".circleci"
 ".freebsdci.sh"
 ".git"
 ".gitattributes"
 ".github"

 ".test"
 ".ui"
 ".usr"
 ".usr-staging"

julia> pwd()
"/home/JuliaUser"
```

source

Base.Filesystem.readdir – Function.

```
| readdir(dir::AbstractString=pwd();
    join::Bool = false,
    sort::Bool = true,
) -> Vector{String}
```

Return the names in the directory `dir` or the current working directory if not given. When `join` is false, `readdir` returns just the names in the directory as is; when `join` is true, it returns `joinpath(dir, name)` for each name so that the returned strings are full paths. If you want to get absolute paths back, call `readdir` with an absolute directory path and `join` set to true.

By default, `readdir` sorts the list of names it returns. If you want to skip sorting the names and get them in the order that the file system lists them, you can use `readdir(dir, sort=false)` to opt out of sorting.

See also: [walkdir](#).

Julia 1.4

The `join` and `sort` keyword arguments require at least Julia 1.4.

Examples

```
julia> cd("/home/JuliaUser/dev/julia")

julia> readdir()
30-element Array{String,1}:
 ".appveyor.yml"
 ".git"
 ".gitattributes"

 "ui"
 "usr"
 "usr-staging"

julia> readdir(join=true)
30-element Array{String,1}:
 "/home/JuliaUser/dev/julia/.appveyor.yml"
 "/home/JuliaUser/dev/julia/.git"
 "/home/JuliaUser/dev/julia/.gitattributes"

 "/home/JuliaUser/dev/julia/ui"
 "/home/JuliaUser/dev/julia/usr"
 "/home/JuliaUser/dev/julia/usr-staging"

julia> readdir("base")
145-element Array{String,1}:
 ".gitignore"
 "Base.jl"
 "Enums.jl"

 "version_git.sh"
 "views.jl"
 "weakkeydict.jl"

julia> readdir("base", join=true)
145-element Array{String,1}:
 "base/.gitignore"
 "base/Base.jl"
 "base/Enums.jl"

 "base/version_git.sh"
 "base/views.jl"
 "base/weakkeydict.jl"

julia> readdir(abspath("base"), join=true)
145-element Array{String,1}:
 "/home/JuliaUser/dev/julia/base/.gitignore"
 "/home/JuliaUser/dev/julia/base/Base.jl"
 "/home/JuliaUser/dev/julia/base/Enums.jl"

 "/home/JuliaUser/dev/julia/base/version_git.sh"
 "/home/JuliaUser/dev/julia/base/views.jl"
 "/home/JuliaUser/dev/julia/base/weakkeydict.jl"
```

[source](#)

Base.Filesystem.walkdir – Function.

```
walkdir(dir; topdown=true, follow_symlinks=false, onerror=throw)
```

Return an iterator that walks the directory tree of a directory. The iterator returns a tuple containing (rootpath, dirs, files). The directory tree can be traversed top-down or bottom-up. If walkdir or stat encounters a IOError it will rethrow the error by default. A custom error handling function can be provided through onerror keyword argument. onerror is called with a IOError as argument.

See also: [readdir](#).

Examples

```
for (root, dirs, files) in walkdir(".")
    println("Directories in $root")
    for dir in dirs
        println(joinpath(root, dir)) # path to directories
    end
    println("Files in $root")
    for file in files
        println(joinpath(root, file)) # path to files
    end
end
```

```
julia> mkpath("my/test/dir");

julia> itr = walkdir("my");

julia> (root, dirs, files) = first(itr)
("my", ["test"], String[])

julia> (root, dirs, files) = first(itr)
("my/test", ["dir"], String[])

julia> (root, dirs, files) = first(itr)
("my/test/dir", String[], String[])
```

[source](#)

Base.Filesystem.mkdir – Function.

```
mkdir(path::AbstractString; mode::Unsigned = 0o777)
```

Make a new directory with name path and permissions mode. mode defaults to 0o777, modified by the current file creation mask. This function never creates more than one directory. If the directory already exists, or some intermediate directories do not exist, this function throws an error. See [mkpath](#) for a function which creates all required intermediate directories. Return path.

Examples

```
julia> mkdir("testingdir")
"testingdir"

julia> cd("testingdir")
```

```
julia> pwd()
"/home/JuliaUser/testingdir"
```

[source](#)

Base.Filesystem.mkpath – Function.

```
mkpath(path::AbstractString; mode::Unsigned = 0o777)
```

Create all intermediate directories in the path as required. Directories are created with the permissions mode which defaults to 0o777 and is modified by the current file creation mask. Unlike [mkdir](#), mkpath does not error if path (or parts of it) already exists. However, an error will be thrown if path (or parts of it) points to an existing file. Return path.

If path includes a filename you will probably want to use `mkpath(dirname(path))` to avoid creating a directory using the filename.

Examples

```
julia> cd(mktempdir())

julia> mkpath("my/test/dir") # creates three directories
"my/test/dir"

julia> readdir()
1-element Array{String,1}:
 "my"

julia> cd("my")

julia> readdir()
1-element Array{String,1}:
 "test"

julia> readdir("test")
1-element Array{String,1}:
 "dir"

julia> mkpath("intermediate_dir/actually_a_directory.txt") # creates two directories
"intermediate_dir/actually_a_directory.txt"

julia> isdir("intermediate_dir/actually_a_directory.txt")
true
```

[source](#)

Base.Filesystem.hardlink – Function.

```
hardlink(src::AbstractString, dst::AbstractString)
```

Creates a hard link to an existing source file `src` with the name `dst`. The destination, `dst`, must not exist.

See also: [symlink](#).

Julia 1.8

This method was added in Julia 1.8.

source

`Base.Filesystem.symlink` – Function.

```
| symlink(target::AbstractString, link::AbstractString; dir_target = false)
```

Creates a symbolic link to `target` with the name `link`.

On Windows, symlinks must be explicitly declared as referring to a directory or not. If `target` already exists, by default the type of `link` will be auto-detected, however if `target` does not exist, this function defaults to creating a file symlink unless `dir_target` is set to `true`. Note that if the user sets `dir_target` but `target` exists and is a file, a directory symlink will still be created, but dereferencing the symlink will fail, just as if the user creates a file symlink (by calling `symlink()` with `dir_target` set to `false` before the directory is created) and tries to dereference it to a directory.

Additionally, there are two methods of making a link on Windows; symbolic links and junction points. Junction points are slightly more efficient, but do not support relative paths, so if a relative directory symlink is requested (as denoted by `isabspath(target)` returning `false`) a symlink will be used, else a junction point will be used. Best practice for creating symlinks on Windows is to create them only after the files/directories they reference are already created.

See also: [hardlink](#).

Note

This function raises an error under operating systems that do not support soft symbolic links, such as Windows XP.

Julia 1.6

The `dir_target` keyword argument was added in Julia 1.6. Prior to this, symlinks to non-existent paths on windows would always be file symlinks, and relative symlinks to directories were not supported.

source

`Base.Filesystem.readlink` – Function.

```
| readlink(path::AbstractString) -> String
```

Return the target location a symbolic link path points to.

source

`Base.Filesystem.chmod` – Function.

```
| chmod(path::AbstractString, mode::Integer; recursive::Bool=false)
```

Change the permissions mode of `path` to `mode`. Only integer modes (e.g. `0o777`) are currently supported. If `recursive=true` and the path is a directory all permissions in that directory will be recursively changed. Return `path`.

Note

Prior to Julia 1.6, this did not correctly manipulate filesystem ACLs on Windows, therefore it would only set read-only bits on files. It now is able to manipulate ACLs.

[source](#)

`Base.Filesystem.chown` – Function.

```
| chown(path::AbstractString, owner::Integer, group::Integer=-1)
```

Change the owner and/or group of path to owner and/or group. If the value entered for owner or group is -1 the corresponding ID will not change. Only integer owners and groups are currently supported. Return path.

[source](#)

`Base.Libc.RawFD` – Type.

```
| RawFD
```

Primitive type which wraps the native OS file descriptor. RawFDs can be passed to methods like [stat](#) to discover information about the underlying file, and can also be used to open streams, with the RawFD describing the OS file backing the stream.

[source](#)

`Base.stat` – Function.

```
| stat(file)
```

Return a structure whose fields contain information about the file. The fields of the structure are:

| Name | Description |
|---------|--|
| desc | The path or OS file descriptor |
| size | The size (in bytes) of the file |
| device | ID of the device that contains the file |
| inode | The inode number of the file |
| mode | The protection mode of the file |
| nlink | The number of hard links to the file |
| uid | The user id of the owner of the file |
| gid | The group id of the file owner |
| rdev | If this file refers to a device, the ID of the device it refers to |
| blksize | The file-system preferred block size for the file |
| blocks | The number of such blocks allocated |
| mtime | Unix timestamp of when the file was last modified |
| ctime | Unix timestamp of when the file's metadata was changed |

[source](#)

`Base.Filesystem.diskstat` – Function.

```
| diskstat(path=pwd())
```

Returns statistics in bytes about the disk that contains the file or directory pointed at by path. If no argument is passed, statistics about the disk that contains the current working directory are returned.

Julia 1.8

This method was added in Julia 1.8.

[source](#)

`Base.Filesystem.lstat` – Function.

```
| lstat(file)
```

Like [stat](#), but for symbolic links gets the info for the link itself rather than the file it refers to. This function must be called on a file path rather than a file object or a file descriptor.

[source](#)

`Base.Filesystem.ctime` – Function.

```
| ctime(file)
```

Equivalent to `stat(file).ctime`.

[source](#)

`Base.Filesystem.mtime` – Function.

```
| mtime(file)
```

Equivalent to `stat(file).mtime`.

[source](#)

`Base.Filesystem.filemode` – Function.

```
| filemode(file)
```

Equivalent to `stat(file).mode`.

[source](#)

`Base.filesize` – Function.

```
| filesize(path...)
```

Equivalent to `stat(file).size`.

[source](#)

`Base.Filesystem.uperm` – Function.

```
| uperm(file)
```

Get the permissions of the owner of the file as a bitfield of

For allowed arguments, see [stat](#).

[source](#)

| Value | Description |
|-------|--------------------|
| 01 | Execute Permission |
| 02 | Write Permission |
| 04 | Read Permission |

Base.Filesystem.gperm – Function.

```
| gperm(file)
```

Like `uperm` but gets the permissions of the group owning the file.

[source](#)

Base.Filesystem.operm – Function.

```
| operm(file)
```

Like `uperm` but gets the permissions for people who neither own the file nor are a member of the group owning the file

[source](#)

Base.Filesystem.cp – Function.

```
| cp(src::AbstractString, dst::AbstractString; force::Bool=false, follow_symlinks::Bool=false)
```

Copy the file, link, or directory from `src` to `dst`. `force=true` will first remove an existing `dst`.

If `follow_symlinks=false`, and `src` is a symbolic link, `dst` will be created as a symbolic link. If `follow_symlinks=true` and `src` is a symbolic link, `dst` will be a copy of the file or directory `src` refers to. Return `dst`.

Note

The `cp` function is different from the `cp` command. The `cp` function always operates on the assumption that `dst` is a file, while the command does different things depending on whether `dst` is a directory or a file. Using `force=true` when `dst` is a directory will result in loss of all the contents present in the `dst` directory, and `dst` will become a file that has the contents of `src` instead.

[source](#)

Base.download – Function.

```
| download(url::AbstractString, [path::AbstractString = tempname()]) -> path
```

Download a file from the given `url`, saving it to the location `path`, or if not specified, a temporary path. Returns the path of the downloaded file.

Note

Since Julia 1.6, this function is deprecated and is just a thin wrapper around `Downloads.download`. In new code, you should use that function directly instead of calling this.

source

Base.Filesystem.mv – Function.

```
mv(src::AbstractString, dst::AbstractString; force::Bool=false)
```

Move the file, link, or directory from src to dst. force=true will first remove an existing dst. Return dst.

Examples

```
julia> write("hello.txt", "world");

julia> mv("hello.txt", "goodbye.txt")
"goodbye.txt"

julia> "hello.txt" in readdir()
false

julia> readline("goodbye.txt")
"world"

julia> write("hello.txt", "world2");

julia> mv("hello.txt", "goodbye.txt")
ERROR: ArgumentError: 'goodbye.txt' exists. `force=true` is required to remove 'goodbye.txt'
↳ before moving.
Stacktrace:
 [1] #checkfor_mv_cp_ptree#10(::Bool, ::Function, ::String, ::String, ::String) at
↳ ./file.jl:293
[...]

julia> mv("hello.txt", "goodbye.txt", force=true)
"goodbye.txt"

julia> rm("goodbye.txt");
```

source

Base.Filesystem.rm – Function.

```
rm(path::AbstractString; force::Bool=false, recursive::Bool=false)
```

Delete the file, link, or empty directory at the given path. If force=true is passed, a non-existing path is not treated as error. If recursive=true is passed and the path is a directory, then all contents are removed recursively.

Examples

```
julia> mkpath("my/test/dir");

julia> rm("my", recursive=true)

julia> rm("this_file_does_not_exist", force=true)
```

```
julia> rm("this_file_does_not_exist")
ERROR: IOError: unlink("this_file_does_not_exist"): no such file or directory (ENOENT)
Stacktrace:
[...]
```

[source](#)

`Base.Filesystem.touch` – Function.

```
Base.touch(::Pidfile.LockMonitor)
```

Update the `mtime` on the lock, to indicate it is still fresh.

See also the `refresh` keyword in the `mkpidlock` constructor.

```
touch(path::AbstractString)
touch(fd::File)
```

Update the last-modified timestamp on a file to the current time.

If the file does not exist a new file is created.

Return path.

Examples

```
julia> write("my_little_file", 2);

julia> mtime("my_little_file")
1.5273815391135583e9

julia> touch("my_little_file");

julia> mtime("my_little_file")
1.527381559163435e9
```

We can see the `mtime` has been modified by `touch`.

[source](#)

`Base.Filesystem.tempname` – Function.

```
tempname(parent=tempdir(); cleanup=true) -> String
```

Generate a temporary file path. This function only returns a path; no file is created. The path is likely to be unique, but this cannot be guaranteed due to the very remote possibility of two simultaneous calls to `tempname` generating the same file name. The name is guaranteed to differ from all files already existing at the time of the call to `tempname`.

When called with no arguments, the temporary name will be an absolute path to a temporary name in the system temporary directory as given by `tempdir()`. If a parent directory argument is given, the temporary path will be in that directory instead.

The `cleanup` option controls whether the process attempts to delete the returned path automatically when the process exits. Note that the `tempname` function does not create any file or directory at the returned location, so there is nothing to cleanup unless you create a file or directory there. If you do and `clean` is `true` it will be deleted upon process termination.

Julia 1.4

The `parent` and `cleanup` arguments were added in 1.4. Prior to Julia 1.4 the path `tempname` would never be cleaned up at process termination.

Warning

This can lead to security holes if another process obtains the same file name and creates the file before you are able to. Open the file with `JL_0_EXCL` if this is a concern. Using `mktemp()` is also recommended instead.

[source](#)

`Base.Filesystem.tempdir` – Function.

```
| tempdir()
```

Gets the path of the temporary directory. On Windows, `tempdir()` uses the first environment variable found in the ordered list `TMP`, `TEMP`, `USERPROFILE`. On all other operating systems, `tempdir()` uses the first environment variable found in the ordered list `TMPDIR`, `TMP`, `TEMP`, and `TEMPDIR`. If none of these are found, the path `"/tmp"` is used.

[source](#)

`Base.Filesystem.mktemp` – Method.

```
| mktemp(parent=tempdir(); cleanup=true) -> (path, io)
```

Return `(path, io)`, where `path` is the path of a new temporary file in `parent` and `io` is an open file object for this path. The `cleanup` option controls whether the temporary file is automatically deleted when the process exits.

Julia 1.3

The `cleanup` keyword argument was added in Julia 1.3. Relatedly, starting from 1.3, Julia will remove the temporary paths created by `mktemp` when the Julia process exits, unless `cleanup` is explicitly set to `false`.

[source](#)

`Base.Filesystem.mktemp` – Method.

```
| mktemp(f::Function, parent=tempdir())
```

Apply the function `f` to the result of `mktemp(parent)` and remove the temporary file upon completion.

See also: `mktempdir`.

[source](#)

`Base.Filesystem.mktempdir` – Method.

```
| mktempdir(parent=tempdir(); prefix="jl_", cleanup=true) -> path
```

Create a temporary directory in the `parent` directory with a name constructed from the given `prefix` and a random suffix, and return its path. Additionally, on some platforms, any trailing `'X'` characters in `prefix` may be replaced with random characters. If `parent` does not exist, throw an error. The `cleanup` option controls whether the temporary directory is automatically deleted when the process exits.

Julia 1.2

The `prefix` keyword argument was added in Julia 1.2.

Julia 1.3

The `cleanup` keyword argument was added in Julia 1.3. Relatedly, starting from 1.3, Julia will remove the temporary paths created by `mktempdir` when the Julia process exits, unless `cleanup` is explicitly set to `false`.

See also: [mktemp](#), [mkdir](#).

[source](#)

`Base.Filesystem.mktempdir` – Method.

```
| mktempdir(f::Function, parent=tempdir(); prefix="jl_")
```

Apply the function `f` to the result of `mktempdir(parent; prefix)` and remove the temporary directory all of its contents upon completion.

See also: [mktemp](#), [mkdir](#).

Julia 1.2

The `prefix` keyword argument was added in Julia 1.2.

[source](#)

`Base.Filesystem.isblockdev` – Function.

```
| isblockdev(path) -> Bool
```

Return true if `path` is a block device, false otherwise.

[source](#)

`Base.Filesystem.ischardev` – Function.

```
| ischardev(path) -> Bool
```

Return true if `path` is a character device, false otherwise.

[source](#)

`Base.Filesystem.isdir` – Function.

```
| isdir(path) -> Bool
```

Return true if `path` is a directory, false otherwise.

Examples

```
| julia> isdir(homedir())
true

| julia> isdir("not/a/directory")
false
```

See also [isfile](#) and [ispath](#).

[source](#)

`Base.Filesystem.isfifo` – Function.

```
| isfifo(path) -> Bool
```

Return true if path is a FIFO, false otherwise.

[source](#)

`Base.Filesystem.isfile` – Function.

```
| isfile(path) -> Bool
```

Return true if path is a regular file, false otherwise.

Examples

```
julia> isfile(homedir())
false

julia> filename = "test_file.txt";

julia> write(filename, "Hello world!");

julia> isfile(filename)
true

julia> rm(filename);

julia> isfile(filename)
false
```

See also [isdir](#) and [ispath](#).

[source](#)

`Base.Filesystem.islink` – Function.

```
| islink(path) -> Bool
```

Return true if path is a symbolic link, false otherwise.

[source](#)

`Base.Filesystem.ismount` – Function.

```
| ismount(path) -> Bool
```

Return true if path is a mount point, false otherwise.

[source](#)

`Base.Filesystem.ispath` – Function.

```
| ispath(path) -> Bool
```

Return true if a valid filesystem entity exists at path, otherwise returns false. This is the generalization of [isfile](#), [isdir](#) etc.

[source](#)

Base.Filesystem.issetgid – Function.

```
| issetgid(path) -> Bool
```

Return true if path has the setgid flag set, false otherwise.

[source](#)

Base.Filesystem.issetuid – Function.

```
| issetuid(path) -> Bool
```

Return true if path has the setuid flag set, false otherwise.

[source](#)

Base.Filesystem.issocket – Function.

```
| issocket(path) -> Bool
```

Return true if path is a socket, false otherwise.

[source](#)

Base.Filesystem.issticky – Function.

```
| issticky(path) -> Bool
```

Return true if path has the sticky bit set, false otherwise.

[source](#)

Base.Filesystem.homedir – Function.

```
| homedir() -> String
```

Return the current user's home directory.

Note

`homedir` determines the home directory via `libuv's uv_os_homedir`. For details (for example on how to specify the home directory via environment variables), see the [uv_os_homedir documentation](#).

[source](#)

Base.Filesystem.dirname – Function.

```
| dirname(path::AbstractString) -> String
```

Get the directory part of a path. Trailing characters ('/' or '\') in the path are counted as part of the path.

Examples

```
julia> dirname("/home/myuser")
"/home"

julia> dirname("/home/myuser/")
"/home/myuser"
```

See also [basename](#).

[source](#)

`Base.Filesystem.basename` – Function.

```
basename(path::AbstractString) -> String
```

Get the file name part of a path.

Note

This function differs slightly from the Unix `basename` program, where trailing slashes are ignored, i.e. `$ basename /foo/bar/` returns `bar`, whereas `basename` in Julia returns an empty string `""`.

Examples

```
julia> basename("/home/myuser/example.jl")
"example.jl"

julia> basename("/home/myuser/")
""
```

See also [dirname](#).

[source](#)

`Base.Filesystem.isabspath` – Function.

```
isabspath(path::AbstractString) -> Bool
```

Determine whether a path is absolute (begins at the root directory).

Examples

```
julia> isabspath("/home")
true

julia> isabspath("home")
false
```

[source](#)

Base.Filesystem.isdirpath – Function.

```
| isdirpath(path::AbstractString) -> Bool
```

Determine whether a path refers to a directory (for example, ends with a path separator).

Examples

```
| julia> isdirpath("/home")
false

| julia> isdirpath("/home/")
true
```

[source](#)

Base.Filesystem.joinpath – Function.

```
| joinpath(parts::AbstractString...) -> String
| joinpath(parts::Vector{AbstractString}) -> String
| joinpath(parts::Tuple{AbstractString}) -> String
```

Join path components into a full path. If some argument is an absolute path or (on Windows) has a drive specification that doesn't match the drive computed for the join of the preceding paths, then prior components are dropped.

Note on Windows since there is a current directory for each drive, `joinpath("c:", "foo")` represents a path relative to the current directory on drive "c:" so this is equal to "c:foo", not "c:\foo". Furthermore, `joinpath` treats this as a non-absolute path and ignores the drive letter casing, hence `joinpath("C:\A", "c:b") = "C:\A\b"`.

Examples

```
| julia> joinpath("/home/myuser", "example.jl")
"/home/myuser/example.jl"

| julia> joinpath(["/home/myuser", "example.jl"])
"/home/myuser/example.jl"
```

[source](#)

Base.Filesystem.abspath – Function.

```
| abspath(path::AbstractString) -> String
```

Convert a path to an absolute path by adding the current directory if necessary. Also normalizes the path as in [normpath](#).

Example

If you are in a directory called `JuliaExample` and the data you are using is two levels up relative to the `JuliaExample` directory, you could write:

```
abspath(".././data")
```

Which gives a path like `"/home/JuliaUser/data/"`.

See also [joinpath](#), [pwd](#), [expanduser](#).

[source](#)

```
| abspath(path::AbstractString, paths::AbstractString...) -> String
```

Convert a set of paths to an absolute path by joining them together and adding the current directory if necessary. Equivalent to `abspath(joinpath(path, paths...))`.

[source](#)

`Base.Filesystem.normpath` – Function.

```
| normpath(path::AbstractString) -> String
```

Normalize a path, removing "." and ".." entries and changing "/" to the canonical path separator for the system.

Examples

```
| julia> normpath("/home/myuser/./example.jl")
"/home/example.jl"

| julia> normpath("Documents/Julia") == joinpath("Documents", "Julia")
true
```

[source](#)

```
| normpath(path::AbstractString, paths::AbstractString...) -> String
```

Convert a set of paths to a normalized path by joining them together and removing "." and ".." entries. Equivalent to `normpath(joinpath(path, paths...))`.

[source](#)

`Base.Filesystem.realpath` – Function.

```
| realpath(path::AbstractString) -> String
```

Canonicalize a path by expanding symbolic links and removing "." and ".." entries. On case-insensitive case-preserving filesystems (typically Mac and Windows), the filesystem's stored case for the path is returned.

(This function throws an exception if path does not exist in the filesystem.)

[source](#)

`Base.Filesystem.relpath` – Function.

```
| relpath(path::AbstractString, startpath::AbstractString = ".") -> String
```

Return a relative filepath to path either from the current directory or from an optional start directory. This is a path computation: the filesystem is not accessed to confirm the existence or nature of path or startpath.

On Windows, case sensitivity is applied to every part of the path except drive letters. If path and startpath refer to different drives, the absolute path of path is returned.

[source](#)

Base.Filesystem.expanduser – Function.

```
| expanduser(path::AbstractString) -> AbstractString
```

On Unix systems, replace a tilde character at the start of a path with the current user's home directory.

See also: [contractuser](#).

[source](#)

Base.Filesystem.contractuser – Function.

```
| contractuser(path::AbstractString) -> AbstractString
```

On Unix systems, if the path starts with `homedir()`, replace it with a tilde character.

See also: [expanduser](#).

[source](#)

Base.Filesystem.samefile – Function.

```
| samefile(path_a::AbstractString, path_b::AbstractString)
```

Check if the paths `path_a` and `path_b` refer to the same existing file or directory.

[source](#)

Base.Filesystem.splitdir – Function.

```
| splitdir(path::AbstractString) -> (AbstractString, AbstractString)
```

Split a path into a tuple of the directory name and file name.

Examples

```
| julia> splitdir("/home/myuser")  
| ("/home", "myuser")
```

[source](#)

Base.Filesystem.splitdrive – Function.

```
| splitdrive(path::AbstractString) -> (AbstractString, AbstractString)
```

On Windows, split a path into the drive letter part and the path part. On Unix systems, the first component is always the empty string.

[source](#)

Base.Filesystem.splitext – Function.

```
| splitext(path::AbstractString) -> (String, String)
```

If the last component of a path contains one or more dots, split the path into everything before the last dot and everything including and after the dot. Otherwise, return a tuple of the argument unmodified and the empty string. "splitext" is short for "split extension".

Examples

```
julia> splitext("/home/myuser/example.jl")
("/home/myuser/example", ".jl")

julia> splitext("/home/myuser/example.tar.gz")
("/home/myuser/example.tar", ".gz")

julia> splitext("/home/my.user/example")
("/home/my.user/example", "")
```

[source](#)

`Base.Filesystem.splitpath` – Function.

```
splitpath(path::AbstractString) -> Vector{String}
```

Split a file path into all its path components. This is the opposite of `joinpath`. Returns an array of substrings, one for each directory or file in the path, including the root directory if present.

Julia 1.1

This function requires at least Julia 1.1.

Examples

```
julia> splitpath("/home/myuser/example.jl")
4-element Vector{String}:
 "/"
 "home"
 "myuser"
 "example.jl"
```

[source](#)

Chapter 51

I/O and Network

51.1 General I/O

`Base.stdout` – Constant.

```
| stdout::IO
```

Global variable referring to the standard out stream.

[source](#)

`Base.stderr` – Constant.

```
| stderr::IO
```

Global variable referring to the standard error stream.

[source](#)

`Base.stdin` – Constant.

```
| stdin::IO
```

Global variable referring to the standard input stream.

[source](#)

`Base.open` – Function.

```
| open(f::Function, args...; kwargs...)
```

Apply the function `f` to the result of `open(args...; kwargs...)` and close the resulting file descriptor upon completion.

Examples

```
julia> write("myfile.txt", "Hello world!");

julia> open(io->read(io, String), "myfile.txt")
"Hello world!"

julia> rm("myfile.txt")
```

source

```
| open(filename::AbstractString; lock = true, keywords...) -> IOStream
```

Open a file in a mode specified by five boolean keyword arguments:

| Keyword | Description | Default |
|----------|------------------------|-----------------------------------|
| read | open for reading | !write |
| write | open for writing | truncate append |
| create | create if non-existent | !read & write truncate append |
| truncate | truncate to zero size | !read & write |
| append | seek to end | false |

The default when no keywords are passed is to open files for reading only. Returns a stream for accessing the opened file.

The lock keyword argument controls whether operations will be locked for safe multi-threaded access.

Julia 1.5

The lock argument is available as of Julia 1.5.

source

```
| open(filename::AbstractString, [mode::AbstractString]; lock = true) -> IOStream
```

Alternate syntax for open, where a string-based mode specifier is used instead of the five booleans. The values of mode correspond to those from fopen(3) or Perl open, and are equivalent to setting the following boolean groups:

| Mode | Description | Keywords |
|------|-------------------------------|------------------------------|
| r | read | none |
| w | write, create, truncate | write = true |
| a | write, create, append | append = true |
| r+ | read, write | read = true, write = true |
| w+ | read, write, create, truncate | truncate = true, read = true |
| a+ | read, write, create, append | append = true, read = true |

The lock keyword argument controls whether operations will be locked for safe multi-threaded access.

Examples

```
| julia> io = open("myfile.txt", "w");
|
| julia> write(io, "Hello world!");
|
| julia> close(io);
|
| julia> io = open("myfile.txt", "r");
|
| julia> read(io, String)
| "Hello world!"
```

```

julia> write(io, "This file is read only")
ERROR: ArgumentError: write failed, IOStream is not writeable
[...]

julia> close(io)

julia> io = open("myfile.txt", "a");

julia> write(io, "This stream is not read only")
28

julia> close(io)

julia> rm("myfile.txt")

```

Julia 1.5

The lock argument is available as of Julia 1.5.

source

```
open(fd::OS_HANDLE) -> IO
```

Take a raw file descriptor wrap it in a Julia-aware IO type, and take ownership of the fd handle. Call `open(Libc.dup(fd))` to avoid the ownership capture of the original handle.

Warning

Do not call this on a handle that's already owned by some other part of the system.

source

```
open(command, mode::AbstractString, stdio=devnull)
```

Run command asynchronously. Like `open(command, stdio; read, write)` except specifying the read and write flags via a mode string instead of keyword arguments. Possible mode strings are:

| Mode | Description | Keywords |
|------|-------------|---------------------------|
| r | read | none |
| w | write | write = true |
| r+ | read, write | read = true, write = true |
| w+ | read, write | read = true, write = true |

source

```
open(command, stdio=devnull; write::Bool = false, read::Bool = !write)
```

Start running command asynchronously, and return a `process::IO` object. If `read` is true, then reads from the process come from the process's standard output and `stdio` optionally specifies the process's standard input stream. If `write` is true, then writes go to the process's standard input and `stdio` optionally specifies the process's standard output stream. The process's standard error stream is connected to the current global `stderr`.

source

```
| open(f::Function, command, args...; kwargs...)
```

Similar to `open(command, args...; kwargs...)`, but calls `f(stream)` on the resulting process stream, then closes the input stream and waits for the process to complete. Return the value returned by `f` on success. Throw an error if the process failed, or if the process attempts to print anything to stdout.

[source](#)

Base.IOStream – Type.

```
| IOStream
```

A buffered IO stream wrapping an OS file descriptor. Mostly used to represent files returned by [open](#).

[source](#)

Base.IOBuffer – Type.

```
| IOBuffer([data::AbstractVector{UInt8}]; keywords...) -> IOBuffer
```

Create an in-memory I/O stream, which may optionally operate on a pre-existing array.

It may take optional keyword arguments:

- `read, write, append`: restricts operations to the buffer; see `open` for details.
- `truncate`: truncates the buffer size to zero length.
- `maxsize`: specifies a size beyond which the buffer may not be grown.
- `sizehint`: suggests a capacity of the buffer (data must implement `sizehint!(data, size)`).

When data is not given, the buffer will be both readable and writable by default.

Examples

```
julia> io = IOBuffer();

julia> write(io, "JuliaLang is a GitHub organization.", " It has many members.")
56

julia> String(take!(io))
"JuliaLang is a GitHub organization. It has many members."

julia> io = IOBuffer(b"JuliaLang is a GitHub organization.")
IOBuffer{data=UInt8[], readable=true, writable=false, seekable=true, append=false,
↪ size=35, maxsize=Inf, ptr=1, mark=-1}

julia> read(io, String)
"JuliaLang is a GitHub organization."

julia> write(io, "This isn't writable.")
ERROR: ArgumentError: ensureroom failed, IOBuffer is not writeable

julia> io = IOBuffer{UInt8[], read=true, write=true, maxsize=34}
IOBuffer{data=UInt8[], readable=true, writable=true, seekable=true, append=false, size=0,
↪ maxsize=34, ptr=1, mark=-1}
```

```
julia> write(io, "JuliaLang is a GitHub organization.")
34

julia> String(take!(io))
"JuliaLang is a GitHub organization"

julia> length(read(IOBuffer(b"data", read=true, truncate=false)))
4

julia> length(read(IOBuffer(b"data", read=true, truncate=true)))
0
```

source

```
IOBuffer(string::String)
```

Create a read-only IOBuffer on the data underlying the given string.

Examples

```
julia> io = IOBuffer("Haho");

julia> String(take!(io))
"Haho"

julia> String(take!(io))
"Haho"
```

source

Base.take! – Method.

```
take!(b::IOBuffer)
```

Obtain the contents of an IOBuffer as an array. Afterwards, the IOBuffer is reset to its initial state.

Examples

```
julia> io = IOBuffer();

julia> write(io, "JuliaLang is a GitHub organization.", " It has many members.")
56

julia> String(take!(io))
"JuliaLang is a GitHub organization. It has many members."
```

source

Base.fdio – Function.

```
fdio([name::AbstractString, ]fd::Integer[, own::Bool=false]) -> IOStream
```

Create an `IStream` object from an integer file descriptor. If `own` is `true`, closing this object will close the underlying descriptor. By default, an `IStream` is closed when it is garbage collected. `name` allows you to associate the descriptor with a named file.

[source](#)

`Base.flush` – Function.

```
| flush(stream)
```

Commit all currently buffered writes to the given stream.

[source](#)

`Base.close` – Function.

```
| close(stream)
```

Close an I/O stream. Performs a `flush` first.

[source](#)

`Base.closewrite` – Function.

```
| closewrite(stream)
```

Shutdown the write half of a full-duplex I/O stream. Performs a `flush` first. Notify the other end that no more data will be written to the underlying file. This is not supported by all IO types.

Examples

```
julia> io = Base.BufferStream(); # this never blocks, so we can read and write on the same
↔ Task

julia> write(io, "request");

julia> # calling `read(io)` here would block forever

julia> closewrite(io);

julia> read(io, String)
"request"
```

[source](#)

`Base.write` – Function.

```
| write(io::IO, x)
```

Write the canonical binary representation of a value to the given I/O stream or file. Return the number of bytes written into the stream. See also `print` to write a text representation (with an encoding that may depend upon `io`).

The endianness of the written value depends on the endianness of the host system. Convert to/from a fixed endianness when writing/reading (e.g. using `htol` and `ltoh`) to get results that are consistent across platforms.

You can write multiple values with the same `write` call. i.e. the following are equivalent:

```
write(io, x, y...)
write(io, x) + write(io, y...)
```

Examples

Consistent serialization:

```
julia> fname = tempname(); # random temporary filename

julia> open(fname, "w") do f
    # Make sure we write 64bit integer in little-endian byte order
    write(f, htol{Int64}(42))
end
8

julia> open(fname, "r") do f
    # Convert back to host byte order and host integer type
    Int(ltoh(read(f, Int64)))
end
42
```

Merging write calls:

```
julia> io = IOBuffer();

julia> write(io, "JuliaLang is a GitHub organization.", " It has many members.")
56

julia> String(take!(io))
"JuliaLang is a GitHub organization. It has many members."

julia> write(io, "Sometimes those members") + write(io, " write documentation.")
44

julia> String(take!(io))
"Sometimes those members write documentation."
```

User-defined plain-data types without write methods can be written when wrapped in a Ref:

```
julia> struct MyStruct; x::Float64; end

julia> io = IOBuffer()
IOBuffer{data=UInt8{...}, readable=true, writable=true, seekable=true, append=false, size=0,
↪ maxsize=Inf, ptr=1, mark=-1}

julia> write(io, Ref{MyStruct}(42.0))
8

julia> seekstart(io); read!(io, Ref{MyStruct}(NaN))
Base.RefValue{MyStruct}(MyStruct{42.0})
```

[source](#)

Base.read – Function.

```
| read(io::IO, T)
```

Read a single value of type `T` from `io`, in canonical binary representation.

Note that Julia does not convert the endianness for you. Use `ntoh` or `ltoh` for this purpose.

```
| read(io::IO, String)
```

Read the entirety of `io`, as a `String` (see also `readchomp`).

Examples

```
julia> io = IOBuffer("JuliaLang is a GitHub organization");

julia> read(io, Char)
'J': ASCII/Unicode U+004A (category Lu: Letter, uppercase)

julia> io = IOBuffer("JuliaLang is a GitHub organization");

julia> read(io, String)
"JuliaLang is a GitHub organization"
```

source

```
| read(filename::AbstractString)
```

Read the entire contents of a file as a `Vector{UInt8}`.

```
| read(filename::AbstractString, String)
```

Read the entire contents of a file as a string.

```
| read(filename::AbstractString, args...)
```

Open a file and read its contents. `args` is passed to `read`: this is equivalent to `open(io->read(io, args...), filename)`.

source

```
| read(s::IO, nb=typemax{Int})
```

Read at most `nb` bytes from `s`, returning a `Vector{UInt8}` of the bytes read.

source

```
| read(s::IOStream, nb::Integer; all=true)
```

Read at most `nb` bytes from `s`, returning a `Vector{UInt8}` of the bytes read.

If `all` is `true` (the default), this function will block repeatedly trying to read all requested bytes, until an error or end-of-file occurs. If `all` is `false`, at most one read call is performed, and the amount of data returned is device-dependent. Note that not all stream types support the `all` option.

source

```
| read(command::Cmd)
```

Run command and return the resulting output as an array of bytes.

source

```
| read(command::Cmd, String)
```

Run command and return the resulting output as a String.

source

Base.read! – Function.

```
| read!(stream::IO, array::AbstractArray)
| read!(filename::AbstractString, array::AbstractArray)
```

Read binary data from an I/O stream or file, filling in array.

source

Base.readbytes! – Function.

```
| readbytes!(stream::IO, b::AbstractVector{UInt8}, nb=length(b))
```

Read at most nb bytes from stream into b, returning the number of bytes read. The size of b will be increased if needed (i.e. if nb is greater than length(b) and enough bytes could be read), but it will never be decreased.

source

```
| readbytes!(stream::IOStream, b::AbstractVector{UInt8}, nb=length(b); all::Bool=true)
```

Read at most nb bytes from stream into b, returning the number of bytes read. The size of b will be increased if needed (i.e. if nb is greater than length(b) and enough bytes could be read), but it will never be decreased.

If all is true (the default), this function will block repeatedly trying to read all requested bytes, until an error or end-of-file occurs. If all is false, at most one read call is performed, and the amount of data returned is device-dependent. Note that not all stream types support the all option.

source

Base.unsafe_read – Function.

```
| unsafe_read(io::IO, ref, nbytes::UInt)
```

Copy nbytes from the IO stream object into ref (converted to a pointer).

It is recommended that subtypes T<:IO override the following method signature to provide more efficient implementations: unsafe_read(s::T, p::Ptr{UInt8}, n::UInt)

source

Base.unsafe_write – Function.

```
| unsafe_write(io::IO, ref, nbytes::UInt)
```

Copy `nbytes` from `ref` (converted to a pointer) into the `IO` object.

It is recommended that subtypes `T<:IO` override the following method signature to provide more efficient implementations: `unsafe_write(s::T, p::Ptr{UInt8}, n::UInt)`

[source](#)

`Base.readeach` – Function.

```
| readeach(io::IO, T)
```

Return an iterable object yielding `read(io, T)`.

See also [skipchars](#), [eachline](#), [readuntil](#).

Julia 1.6

`readeach` requires Julia 1.6 or later.

Examples

```
julia> io = IOBuffer("JuliaLang is a GitHub organization.\n It has many members.\n");

julia> for c in readeach(io, Char)
    c == '\n' && break
    print(c)
end
JuliaLang is a GitHub organization.
```

[source](#)

`Base.peek` – Function.

```
| peek(stream[, T=UInt8])
```

Read and return a value of type `T` from a stream without advancing the current position in the stream.

See also [startswith\(stream, char_or_string\)](#).

Examples

```
julia> b = IOBuffer("julia");

julia> peek(b)
0x6a

julia> position(b)
0

julia> peek(b, Char)
'j': ASCII/Unicode U+006A (category Ll: Letter, lowercase)
```

Julia 1.5

The method which accepts a type requires Julia 1.5 or later.

[source](#)

Base.position – Function.

```
| position(l::Lexer)
```

Returns the current position.

```
| position(s)
```

Get the current position of a stream.

Examples

```
julia> io = IOBuffer("JuliaLang is a GitHub organization.");  
  
julia> seek(io, 5);  
  
julia> position(io)  
5  
  
julia> skip(io, 10);  
  
julia> position(io)  
15  
  
julia> seekend(io);  
  
julia> position(io)  
35
```

[source](#)

Base.seek – Function.

```
| seek(s, pos)
```

Seek a stream to the given position.

Examples

```
julia> io = IOBuffer("JuliaLang is a GitHub organization.");  
  
julia> seek(io, 5);  
  
julia> read(io, Char)  
'L': ASCII/Unicode U+004C (category Lu: Letter, uppercase)
```

[source](#)

Base.seekstart – Function.

```
| seekstart(s)
```

Seek a stream to its beginning.

Examples

```
julia> io = IOBuffer("JuliaLang is a GitHub organization.");

julia> seek(io, 5);

julia> read(io, Char)
'L': ASCII/Unicode U+004C (category Lu: Letter, uppercase)

julia> seekstart(io);

julia> read(io, Char)
'J': ASCII/Unicode U+004A (category Lu: Letter, uppercase)
```

[source](#)

Base.seekend – Function.

```
| seekend(s)
```

Seek a stream to its end.

[source](#)

Base.skip – Function.

```
| skip(s, offset)
```

Seek a stream relative to the current position.

Examples

```
julia> io = IOBuffer("JuliaLang is a GitHub organization.");

julia> seek(io, 5);

julia> skip(io, 10);

julia> read(io, Char)
'G': ASCII/Unicode U+0047 (category Lu: Letter, uppercase)
```

[source](#)

Base.mark – Function.

```
| mark(s::IO)
```

Add a mark at the current position of stream s. Return the marked position.

See also [unmark](#), [reset](#), [ismarked](#).

[source](#)

Base.unmark – Function.

```
| unmark(s::IO)
```

Remove a mark from stream `s`. Return `true` if the stream was marked, `false` otherwise.

See also [mark](#), [reset](#), [ismarked](#).

[source](#)

`Base.reset` – Method.

```
| reset(s::IO)
```

Reset a stream `s` to a previously marked position, and remove the mark. Return the previously marked position. Throw an error if the stream is not marked.

See also [mark](#), [unmark](#), [ismarked](#).

[source](#)

`Base.ismarked` – Function.

```
| ismarked(s::IO)
```

Return `true` if stream `s` is marked.

See also [mark](#), [unmark](#), [reset](#).

[source](#)

`Base.eof` – Function.

```
| eof(stream) -> Bool
```

Test whether an I/O stream is at end-of-file. If the stream is not yet exhausted, this function will block to wait for more data if necessary, and then return `false`. Therefore it is always safe to read one byte after seeing `eof` return `false`. `eof` will return `false` as long as buffered data is still available, even if the remote end of a connection is closed.

Examples

```
julia> b = IOBuffer("my buffer");

julia> eof(b)
false

julia> seekend(b);

julia> eof(b)
true
```

[source](#)

`Base.isreadonly` – Function.

```
| isreadonly(io) -> Bool
```

Determine whether a stream is read-only.

Examples

```
julia> io = IOBuffer("JuliaLang is a GitHub organization");

julia> isreadonly(io)
true

julia> io = IOBuffer();

julia> isreadonly(io)
false
```

[source](#)

Base.iswritable - Function.

```
| iswritable(io) -> Bool
```

Return false if the specified IO object is not writable.

Examples

```
julia> open("myfile.txt", "w") do io
    print(io, "Hello world!");
    iswritable(io)
end
true

julia> open("myfile.txt", "r") do io
    iswritable(io)
end
false

julia> rm("myfile.txt")
```

[source](#)

Base.isreadable - Function.

```
| isreadable(io) -> Bool
```

Return false if the specified IO object is not readable.

Examples

```
julia> open("myfile.txt", "w") do io
    print(io, "Hello world!");
    isreadable(io)
end
false

julia> open("myfile.txt", "r") do io
    isreadable(io)
end
true

julia> rm("myfile.txt")
```

[source](#)

Base.isopen – Function.

```
| isopen(object) -> Bool
```

Determine whether an object - such as a stream or timer - is not yet closed. Once an object is closed, it will never produce a new event. However, since a closed stream may still have data to read in its buffer, use `eof` to check for the ability to read data. Use the `FileWatching` package to be notified when a stream might be writable or readable.

Examples

```
julia> io = open("my_file.txt", "w+");
julia> isopen(io)
true
julia> close(io)
julia> isopen(io)
false
```

[source](#)

Base.fd – Function.

```
| fd(stream)
```

Return the file descriptor backing the stream or file. Note that this function only applies to synchronous `File`'s and `IOStream`'s not to any of the asynchronous streams.

[source](#)

Base.redirect_stdio – Function.

```
| redirect_stdio(;stdin=stdin, stderr=stderr, stdout=stdout)
```

Redirect a subset of the streams `stdin`, `stderr`, `stdout`. Each argument must be an `IOStream`, `TTY`, `Pipe`, `socket`, or `devnull`.

Julia 1.7

`redirect_stdio` requires Julia 1.7 or later.

[source](#)

```
| redirect_stdio(f; stdin=nothing, stderr=nothing, stdout=nothing)
```

Redirect a subset of the streams `stdin`, `stderr`, `stdout`, call `f()` and restore each stream.

Possible values for each stream are:

- `nothing` indicating the stream should not be redirected.
- `path::AbstractString` redirecting the stream to the file at `path`.

- io an IOStream, TTY, Pipe, socket, or devnull.

Examples

```
julia> redirect_stdio(stdout="stdout.txt", stderr="stderr.txt") do
    print("hello stdout")
    print(stderr, "hello stderr")
end

julia> read("stdout.txt", String)
"hello stdout"

julia> read("stderr.txt", String)
"hello stderr"
```

Edge cases

It is possible to pass the same argument to stdout and stderr:

```
julia> redirect_stdio(stdout="log.txt", stderr="log.txt", stdin=devnull) do
    ...
end
```

However it is not supported to pass two distinct descriptors of the same file.

```
julia> io1 = open("same/path", "w")

julia> io2 = open("same/path", "w")

julia> redirect_stdio(f, stdout=io1, stderr=io2) # not supported
```

Also the stdin argument may not be the same descriptor as stdout or stderr.

```
julia> io = open(...)

julia> redirect_stdio(f, stdout=io, stdin=io) # not supported
```

Julia 1.7

redirect_stdio requires Julia 1.7 or later.

source

Base.redirect_stdout - Function.

```
| redirect_stdout([stream]) -> stream
```

Create a pipe to which all C and Julia level `stdout` output will be redirected. Return a stream representing the pipe ends. Data written to `stdout` may now be read from the rd end of the pipe.

Note

stream must be a compatible objects, such as an IOStream, TTY, Pipe, socket, or devnull.

See also [redirect_stdio](#).

[source](#)

`Base.redirect_stdout` – Method.

```
| redirect_stdout(f::Function, stream)
```

Run the function `f` while redirecting `stdout` to `stream`. Upon completion, `stdout` is restored to its prior setting.

[source](#)

`Base.redirect_stderr` – Function.

```
| redirect_stderr([stream]) -> stream
```

Like [redirect_stdout](#), but for `stderr`.

Note

`stream` must be a compatible objects, such as an `IStream`, `TTY`, `Pipe`, `socket`, or `devnull`.

See also [redirect_stdio](#).

[source](#)

`Base.redirect_stderr` – Method.

```
| redirect_stderr(f::Function, stream)
```

Run the function `f` while redirecting `stderr` to `stream`. Upon completion, `stderr` is restored to its prior setting.

[source](#)

`Base.redirect_stdin` – Function.

```
| redirect_stdin([stream]) -> stream
```

Like [redirect_stdout](#), but for `stdin`. Note that the direction of the stream is reversed.

Note

`stream` must be a compatible objects, such as an `IStream`, `TTY`, `Pipe`, `socket`, or `devnull`.

See also [redirect_stdio](#).

[source](#)

`Base.redirect_stdin` – Method.

```
| redirect_stdin(f::Function, stream)
```

Run the function `f` while redirecting `stdin` to `stream`. Upon completion, `stdin` is restored to its prior setting.

[source](#)

Base.readchomp – Function.

```
| readchomp(x)
```

Read the entirety of `x` as a string and remove a single trailing newline if there is one. Equivalent to `chomp(read(x, String))`.

Examples

```
julia> write("my_file.txt", "JuliaLang is a GitHub organization.\nIt has many members.\n");

julia> readchomp("my_file.txt")
"JuliaLang is a GitHub organization.\nIt has many members."

julia> rm("my_file.txt");
```

[source](#)

Base.truncate – Function.

```
| truncate(file, n)
```

Resize the file or buffer given by the first argument to exactly `n` bytes, filling previously unallocated space with `'\0'` if the file or buffer is grown.

Examples

```
julia> io = IOBuffer();

julia> write(io, "JuliaLang is a GitHub organization.")
35

julia> truncate(io, 15)
IOBuffer{data=UInt8[], readable=true, writable=true, seekable=true, append=false, size=15,
↪ maxsize=Inf, ptr=16, mark=-1}

julia> String(take!(io))
"JuliaLang is a "

julia> io = IOBuffer();

julia> write(io, "JuliaLang is a GitHub organization.");

julia> truncate(io, 40);

julia> String(take!(io))
"JuliaLang is a GitHub organization.\0\0\0\0\0"
```

[source](#)

Base.skipchars – Function.

```
| skipchars(predicate, io::IO; linecomment=nothing)
```

Advance the stream `io` such that the next-read character will be the first remaining for which predicate returns `false`. If the keyword argument `linecomment` is specified, all characters from that character until the start of the next line are ignored.

Examples

```
julia> buf = IOBuffer("    text")
IOBuffer{data=UInt8[], readable=true, writable=false, seekable=true, append=false, size=8,
↪ maxsize=Inf, ptr=1, mark=-1}

julia> skipchars(isspace, buf)
IOBuffer{data=UInt8[], readable=true, writable=false, seekable=true, append=false, size=8,
↪ maxsize=Inf, ptr=5, mark=-1}

julia> String(readavailable(buf))
"text"
```

[source](#)

`Base.countlines` – Function.

```
countlines(io::IO; eol::AbstractChar = '\n')
countlines(filename::AbstractString; eol::AbstractChar = '\n')
```

Read `io` until the end of the stream/file and count the number of lines. To specify a file pass the filename as the first argument. EOL markers other than `'\n'` are supported by passing them as the second argument. The last non-empty line of `io` is counted even if it does not end with the EOL, matching the length returned by [eachline](#) and [readlines](#).

To count lines of a `String`, `countlines(IOBuffer(str))` can be used.

Examples

```
julia> io = IOBuffer("JuliaLang is a GitHub organization.\n");

julia> countlines(io)
1

julia> io = IOBuffer("JuliaLang is a GitHub organization.");

julia> countlines(io)
1

julia> eof(io) # counting lines moves the file pointer
true

julia> io = IOBuffer("JuliaLang is a GitHub organization.");

julia> countlines(io, eol = '.')
1

julia> write("my_file.txt", "JuliaLang is a GitHub organization.\n")
36
```

```
julia> countlines("my_file.txt")
1

julia> countlines("my_file.txt", eol = 'n')
4

julia> rm("my_file.txt")
```

[source](#)

Base.PipeBuffer – Function.

```
| PipeBuffer(data::Vector{UInt8}=UInt8[]; maxsize::Integer = typemax{Int})
```

An [IOBuffer](#) that allows reading and performs writes by appending. Seeking and truncating are not supported. See [IOBuffer](#) for the available constructors. If data is given, creates a PipeBuffer to operate on a data vector, optionally specifying a size beyond which the underlying Array may not be grown.

[source](#)

Base.readavailable – Function.

```
| readavailable(stream)
```

Read available buffered data from a stream. Actual I/O is performed only if no data has already been buffered. The result is a Vector{UInt8}.

Warning

The amount of data returned is implementation-dependent; for example it can depend on the internal choice of buffer size. Other functions such as [read](#) should generally be used instead.

[source](#)

Base.IOContext – Type.

```
| IOContext
```

IOContext provides a mechanism for passing output configuration settings among [show](#) methods.

In short, it is an immutable dictionary that is a subclass of IO. It supports standard dictionary operations such as [getindex](#), and can also be used as an I/O stream.

[source](#)

Base.IOContext – Method.

```
| IOContext(io::IO, KV::Pair...)
```

Create an IOContext that wraps a given stream, adding the specified key=>value pairs to the properties of that stream (note that io can itself be an IOContext).

- use (key => value) in io to see if this particular combination is in the properties set

- use `get(io, key, default)` to retrieve the most recent value for a particular key

The following properties are in common use:

- `:compact`: Boolean specifying that values should be printed more compactly, e.g. that numbers should be printed with fewer digits. This is set when printing array elements. `:compact` output should not contain line breaks.
- `:limit`: Boolean specifying that containers should be truncated, e.g. showing ... in place of most elements.
- `:displaysize`: A `Tuple{Int,Int}` giving the size in rows and columns to use for text output. This can be used to override the display size for called functions, but to get the size of the screen use the `displaysize` function.
- `:typeinfo`: a `Type` characterizing the information already printed concerning the type of the object about to be displayed. This is mainly useful when displaying a collection of objects of the same type, so that redundant type information can be avoided (e.g. `[Float16(0)]` can be shown as `"Float16[0.0]"` instead of `"Float16[Float16(0.0)]"` : while displaying the elements of the array, the `:typeinfo` property will be set to `Float16`).
- `:color`: Boolean specifying whether ANSI color/escape codes are supported/expected. By default, this is determined by whether `io` is a compatible terminal and by any `--color` command-line flag when `julia` was launched.

Examples

```
julia> io = IOBuffer();

julia> printstyled(IOContext(io, :color => true), "string", color=:red)

julia> String(take!(io))
"\e[31mstring\e[39m"

julia> printstyled(io, "string", color=:red)

julia> String(take!(io))
"string"

julia> print(IOContext(stdout, :compact => false), 1.12341234)
1.12341234
julia> print(IOContext(stdout, :compact => true), 1.12341234)
1.12341

julia> function f(io::IO)
    if get(io, :short, false)
        print(io, "short")
    else
        print(io, "loooooong")
    end
end
f (generic function with 1 method)

julia> f(stdout)
```

```
| loooooong
| julia> f(IOContext(stdout, :short => true))
| short
```

[source](#)

Base.IOContext – Method.

```
| IOContext(io::IO, context::IOContext)
```

Create an IOContext that wraps an alternate IO but inherits the properties of context.

[source](#)

51.2 Text I/O

Base.show – Method.

```
| show([io::IO = stdout], x)
```

Write a text representation of a value `x` to the output stream `io`. New types `T` should overload `show(io::IO, x::T)`. The representation used by `show` generally includes Julia-specific formatting and type information, and should be parseable Julia code when possible.

`repr` returns the output of `show` as a string.

For a more verbose human-readable text output for objects of type `T`, define `show(io::IO, ::MIME"text/plain", ::T)` in addition. Checking the `:compact IOContext` key (often checked as `get(io, :compact, false)::Bool`) of `io` in such methods is recommended, since some containers show their elements by calling this method with `:compact => true`.

See also `print`, which writes un-decorated representations.

Examples

```
| julia> show("Hello World!")
| "Hello World!"
| julia> print("Hello World!")
| Hello World!
```

[source](#)

Base.summary – Function.

```
| summary(io::IO, x)
| str = summary(x)
```

Print to a stream `io`, or return a string `str`, giving a brief description of a value. By default returns `string(typeof(x))`, e.g. `Int64`.

For arrays, returns a string of size and type info, e.g. `10-element Array{Int64,1}`.

Examples

```
julia> summary(1)
"Int64"

julia> summary(zeros(2))
"2-element Vector{Float64}"
```

[source](#)

Base.print – Function.

```
| print([io::IO], xs...)
```

Write to `io` (or to the default output stream `stdout` if `io` is not given) a canonical (un-decorated) text representation. The representation used by `print` includes minimal formatting and tries to avoid Julia-specific details.

`print` falls back to calling `show`, so most types should just define `show`. Define `print` if your type has a separate "plain" representation. For example, `show` displays strings with quotes, and `print` displays strings without quotes.

See also [println](#), [string](#), [printstyled](#).

Examples

```
julia> print("Hello World!")
Hello World!

julia> io = IOBuffer();

julia> print(io, "Hello", ' ', :World!)

julia> String(take!(io))
"Hello World!"
```

[source](#)

Base.println – Function.

```
| println([io::IO], xs...)
```

Print (using [print](#)) `xs` to `io` followed by a newline. If `io` is not supplied, prints to the default output stream `stdout`.

See also [printstyled](#) to add colors etc.

Examples

```
julia> println("Hello, world")
Hello, world

julia> io = IOBuffer();

julia> println(io, "Hello", ' ', " world.")

julia> String(take!(io))
"Hello, world.\n"
```

source

Base.printstyled – Function.

```
| printstyled([io], xs...; bold::Bool=false, italic::Bool=false, underline::Bool=false,  
| ↪ blink::Bool=false, reverse::Bool=false, hidden::Bool=false,  
| ↪ color::Union{Symbol,Int}=:normal)
```

Print xs in a color specified as a symbol or integer, optionally in bold.

Keyword color may take any of the values :normal, :italic, :default, :bold, :black, :blink, :blue, :cyan, :green, :hidden, :light_black, :light_blue, :light_cyan, :light_green, :light_magenta, :light_red, :light_white, :light_yellow, :magenta, :nothing, :red, :reverse, :underline, :white, or :yellow or an integer between 0 and 255 inclusive. Note that not all terminals support 256 colors.

Keywords bold=true, italic=true, underline=true, blink=true are self-explanatory. Keyword reverse=true prints with foreground and background colors exchanged, and hidden=true should be invisible in the terminal but can still be copied. These properties can be used in any combination.

See also [print](#), [println](#), [show](#).

Note

Not all terminals support italic output. Some terminals interpret italic as reverse or blink.

Julia 1.7

Keywords except color and bold were added in Julia 1.7.

Julia 1.10

Support for italic output was added in Julia 1.10.

source

Base.sprint – Function.

```
| sprint(f::Function, args...; context=nothing, sizehint=0)
```

Call the given function with an I/O stream and the supplied extra arguments. Everything written to this I/O stream is returned as a string. context can be an [IOContext](#) whose properties will be used, a Pair specifying a property and its value, or a tuple of Pair specifying multiple properties and their values. sizehint suggests the capacity of the buffer (in bytes).

The optional keyword argument context can be set to a :key=>value pair, a tuple of :key=>value pairs, or an IO or [IOContext](#) object whose attributes are used for the I/O stream passed to f. The optional sizehint is a suggested size (in bytes) to allocate for the buffer used to write the string.

Julia 1.7

Passing a tuple to keyword context requires Julia 1.7 or later.

Examples

```
| julia> sprint(show, 66.66666; context=:compact => true)  
| "66.6667"  
  
| julia> sprint(showerror, BoundsError{[1], 100})  
| "BoundsError: attempt to access 1-element Vector{Int64} at index [100]"
```

[source](#)

`Base.showerror` – Function.

```
| showerror(io, e)
```

Show a descriptive representation of an exception object `e`. This method is used to display the exception after a call to `throw`.

Examples

```
julia> struct MyException <: Exception
        msg::String
    end

julia> function Base.showerror(io::IO, err::MyException)
    print(io, "MyException: ")
    print(io, err.msg)
end

julia> err = MyException("test exception")
MyException("test exception")

julia> sprint(showerror, err)
"MyException: test exception"

julia> throw(MyException("test exception"))
ERROR: MyException: test exception
```

[source](#)

`Base.dump` – Function.

```
| dump(x; maxdepth=8)
```

Show every part of the representation of a value. The depth of the output is truncated at `maxdepth`.

Examples

```
julia> struct MyStruct
        x
        y
    end

julia> x = MyStruct(1, (2,3));

julia> dump(x)
MyStruct
 x: Int64 1
 y: Tuple{Int64, Int64}
   1: Int64 2
   2: Int64 3

julia> dump(x; maxdepth = 1)
```

```
MyStruct
  x: Int64 1
  y: Tuple{Int64, Int64}
```

source

Base.Meta.@dump – Macro.

```
@dump expr
```

Show every part of the representation of the given expression. Equivalent to `dump(:(expr))`.

source

Base.readline – Function.

```
readline(io::IO=stdin; keep::Bool=false)
readline(filename::AbstractString; keep::Bool=false)
```

Read a single line of text from the given I/O stream or file (defaults to `stdin`). When reading from a file, the text is assumed to be encoded in UTF-8. Lines in the input end with `'\n'` or `"\r\n"` or the end of an input stream. When `keep` is `false` (as it is by default), these trailing newline characters are removed from the line before it is returned. When `keep` is `true`, they are returned as part of the line.

Examples

```
julia> write("my_file.txt", "JuliaLang is a GitHub organization.\nIt has many members.\n");

julia> readline("my_file.txt")
"JuliaLang is a GitHub organization."

julia> readline("my_file.txt", keep=true)
"JuliaLang is a GitHub organization.\n"

julia> rm("my_file.txt")

julia> print("Enter your name: ")
Enter your name:

julia> your_name = readline()
Logan
"Logan"
```

source

Base.readuntil – Function.

```
readuntil(stream::IO, delim; keep::Bool = false)
readuntil(filename::AbstractString, delim; keep::Bool = false)
```

Read a string from an I/O stream or a file, up to the given delimiter. The delimiter can be a `UInt8`, `AbstractChar`, string, or vector. Keyword argument `keep` controls whether the delimiter is included in the result. The text is assumed to be encoded in UTF-8.

Examples

```
julia> write("my_file.txt", "JuliaLang is a GitHub organization.\nIt has many members.\n");

julia> readuntil("my_file.txt", 'L')
"Julia"

julia> readuntil("my_file.txt", '.', keep = true)
"JuliaLang is a GitHub organization."

julia> rm("my_file.txt")
```

[source](#)

`Base.readlines` – Function.

```
readlines(io::IO=stdin; keep::Bool=false)
readlines(filename::AbstractString; keep::Bool=false)
```

Read all lines of an I/O stream or a file as a vector of strings. Behavior is equivalent to saving the result of reading `readline` repeatedly with the same arguments and saving the resulting lines as a vector of strings. See also `eachline` to iterate over the lines without reading them all at once.

Examples

```
julia> write("my_file.txt", "JuliaLang is a GitHub organization.\nIt has many members.\n");

julia> readlines("my_file.txt")
2-element Vector{String}:
"JuliaLang is a GitHub organization."
"It has many members."

julia> readlines("my_file.txt", keep=true)
2-element Vector{String}:
"JuliaLang is a GitHub organization.\n"
"It has many members.\n"

julia> rm("my_file.txt")
```

[source](#)

`Base.eachline` – Function.

```
eachline(io::IO=stdin; keep::Bool=false)
eachline(filename::AbstractString; keep::Bool=false)
```

Create an iterable `EachLine` object that will yield each line from an I/O stream or a file. Iteration calls `readline` on the stream argument repeatedly with `keep` passed through, determining whether trailing end-of-line characters are retained. When called with a file name, the file is opened once at the beginning of iteration and closed at the end. If iteration is interrupted, the file will be closed when the `EachLine` object is garbage collected.

To iterate over each line of a `String`, `eachline(IOBuffer(str))` can be used.

`Iterators.reverse` can be used on an `EachLine` object to read the lines in reverse order (for files, buffers, and other I/O streams supporting `seek`), and `first` or `last` can be used to extract the initial or final lines, respectively.

Examples

```
julia> write("my_file.txt", "JuliaLang is a GitHub organization.\n It has many members.\n");

julia> for line in eachline("my_file.txt")
    print(line)
end
JuliaLang is a GitHub organization. It has many members.

julia> rm("my_file.txt");
```

Julia 1.8

Julia 1.8 is required to use `Iterators.reverse` or `last` with `eachline` iterators.

[source](#)

`Base.displaysize` - Function.

```
| displaysize([io::IO]) -> (lines, columns)
```

Return the nominal size of the screen that may be used for rendering output to this IO object. If no input is provided, the environment variables `LINES` and `COLUMNS` are read. If those are not set, a default size of (24, 80) is returned.

Examples

```
julia> withenv("LINES" => 30, "COLUMNS" => 100) do
    displaysize()
end
(30, 100)
```

To get your TTY size,

```
julia> displaysize(stdout)
(34, 147)
```

[source](#)

51.3 Multimedia I/O

Just as text output is performed by `print` and user-defined types can indicate their textual representation by overloading `show`, Julia provides a standardized mechanism for rich multimedia output (such as images, formatted text, or even audio and video), consisting of three parts:

- A function `display(x)` to request the richest available multimedia display of a Julia object `x` (with a plain-text fallback).
- Overloading `show` allows one to indicate arbitrary multimedia representations (keyed by standard MIME types) of user-defined types.
- Multimedia-capable display backends may be registered by subclassing a generic `AbstractDisplay` type and pushing them onto a stack of display backends via `pushdisplay`.

The base Julia runtime provides only plain-text display, but richer displays may be enabled by loading external modules or by using graphical Julia environments (such as the IPython-based IJulia notebook).

`Base.Multimedia.AbstractDisplay` – Type.

```
| AbstractDisplay
```

Abstract supertype for rich display output devices. `TextDisplay` is a subtype of this.

[source](#)

`Base.Multimedia.display` – Function.

```
| display(x)
| display(d::AbstractDisplay, x)
| display(mime, x)
| display(d::AbstractDisplay, mime, x)
```

Display `x` using the topmost applicable display in the display stack, typically using the richest supported multimedia output for `x`, with plain-text `stdout` output as a fallback. The `display(d, x)` variant attempts to display `x` on the given display `d` only, throwing a `MethodError` if `d` cannot display objects of this type.

In general, you cannot assume that display output goes to `stdout` (unlike `print(x)` or `show(x)`). For example, `display(x)` may open up a separate window with an image. `display(x)` means "show `x` in the best way you can for the current output device(s)." If you want REPL-like text output that is guaranteed to go to `stdout`, use `show(stdout, "text/plain", x)` instead.

There are also two variants with a `mime` argument (a MIME type string, such as "image/png"), which attempt to display `x` using the requested MIME type only, throwing a `MethodError` if this type is not supported by either the display(s) or by `x`. With these variants, one can also supply the "raw" data in the requested MIME type by passing `x::AbstractString` (for MIME types with text-based storage, such as `text/html` or `application/postscript`) or `x::Vector{UInt8}` (for binary MIME types).

To customize how instances of a type are displayed, overload `show` rather than `display`, as explained in the manual section on [custom pretty-printing](#).

[source](#)

`Base.Multimedia.redisplay` – Function.

```
| redisplay(x)
| redisplay(d::AbstractDisplay, x)
| redisplay(mime, x)
| redisplay(d::AbstractDisplay, mime, x)
```

By default, the `redisplay` functions simply call `display`. However, some display backends may override `redisplay` to modify an existing display of `x` (if any). Using `redisplay` is also a hint to the backend that `x` may be redisplayed several times, and the backend may choose to defer the display until (for example) the next interactive prompt.

[source](#)

`Base.Multimedia.displayable` – Function.

```
| displayable(mime) -> Bool
| displayable(d::AbstractDisplay, mime) -> Bool
```

Return a boolean value indicating whether the given mime type (string) is displayable by any of the displays in the current display stack, or specifically by the display `d` in the second variant.

[source](#)

`Base.show` – Method.

```
| show(io::IO, mime, x)
```

The `display` functions ultimately call `show` in order to write an object `x` as a given mime type to a given I/O stream `io` (usually a memory buffer), if possible. In order to provide a rich multimedia representation of a user-defined type `T`, it is only necessary to define a new `show` method for `T`, via: `show(io, ::MIME"mime", x::T) = ...`, where `mime` is a MIME-type string and the function body calls `write` (or similar) to write that representation of `x` to `io`. (Note that the `MIME""` notation only supports literal strings; to construct MIME types in a more flexible manner use `MIME{Symbol{""}}.`)

For example, if you define a `MyImage` type and know how to write it to a PNG file, you could define a function `show(io, ::MIME"image/png", x::MyImage) = ...` to allow your images to be displayed on any PNG-capable `AbstractDisplay` (such as `IJulia`). As usual, be sure to `import Base.show` in order to add new methods to the built-in Julia function `show`.

Technically, the `MIME"mime"` macro defines a singleton type for the given mime string, which allows us to exploit Julia's dispatch mechanisms in determining how to display objects of any given type.

The default MIME type is `MIME"text/plain"`. There is a fallback definition for text/plain output that calls `show` with 2 arguments, so it is not always necessary to add a method for that case. If a type benefits from custom human-readable output though, `show(::IO, ::MIME"text/plain", ::T)` should be defined. For example, the `Day` type uses `1 day` as the output for the text/plain MIME type, and `Day(1)` as the output of 2-argument `show`.

Examples

```
julia> struct Day
           n::Int
       end

julia> Base.show(io::IO, ::MIME"text/plain", d::Day) = print(io, d.n, " day")

julia> Day(1)
1 day
```

Container types generally implement 3-argument `show` by calling `show(io, MIME"text/plain"(), x)` for elements `x`, with `:compact => true` set in an `IOContext` passed as the first argument.

[source](#)

`Base.Multimedia.showable` – Function.

```
| showable(mime, x)
```

Return a boolean value indicating whether or not the object `x` can be written as the given mime type.

(By default, this is determined automatically by the existence of the corresponding `show` method for `typeof(x)`. Some types provide custom `showable` methods; for example, if the available MIME formats depend on the value of `x`.)

Examples

```
julia> showable(MIME("text/plain"), rand(5))
true

julia> showable("image/png", rand(5))
false
```

[source](#)

Base.repr – Method.

```
repr(mime, x; context=nothing)
```

Return an AbstractString or Vector{UInt8} containing the representation of *x* in the requested mime type, as written by `show(io, mime, x)` (throwing a `MethodError` if no appropriate show is available). An AbstractString is returned for MIME types with textual representations (such as "text/html" or "application/postscript"), whereas binary data is returned as Vector{UInt8}. (The function `istextmime(mime)` returns whether or not Julia treats a given mime type as text.)

The optional keyword argument `context` can be set to `:key=>value` pair or an `IO` or `IOContext` object whose attributes are used for the I/O stream passed to `show`.

As a special case, if *x* is an AbstractString (for textual MIME types) or a Vector{UInt8} (for binary MIME types), the `repr` function assumes that *x* is already in the requested mime format and simply returns *x*. This special case does not apply to the "text/plain" MIME type. This is useful so that raw data can be passed to `display(m::MIME, x)`.

In particular, `repr("text/plain", x)` is typically a "pretty-printed" version of *x* designed for human consumption. See also `repr(x)` to instead return a string corresponding to `show(x)` that may be closer to how the value of *x* would be entered in Julia.

Examples

```
julia> A = [1 2; 3 4];

julia> repr("text/plain", A)
"2x2 Matrix{Int64}:
 1  2
 3  4"
```

[source](#)

Base.Multimedia.MIME – Type.

```
MIME
```

A type representing a standard internet data format. "MIME" stands for "Multipurpose Internet Mail Extensions", since the standard was originally used to describe multimedia attachments to email messages.

A MIME object can be passed as the second argument to `show` to request output in that format.

Examples

```
julia> show(stdout, MIME("text/plain"), "hi")
"hi"
```

[source](#)

Base.Multimedia.@MIME_str – Macro.

```
| @MIME_str
```

A convenience macro for writing `MIME` types, typically used when adding methods to `show`. For example the syntax `show(io::IO, ::MIME"text/html", x::MyType) = ...` could be used to define how to write an HTML representation of `MyType`.

source

As mentioned above, one can also define new display backends. For example, a module that can display PNG images in a window can register this capability with Julia, so that calling `display(x)` on types with PNG representations will automatically display the image using the module's window.

In order to define a new display backend, one should first create a subtype `D` of the abstract class `AbstractDisplay`. Then, for each MIME type (`mime` string) that can be displayed on `D`, one should define a function `display(d::D, ::MIME"mime", x) = ...` that displays `x` as that MIME type, usually by calling `show(io, mime, x)` or `repr(io, mime, x)`. A `MethodError` should be thrown if `x` cannot be displayed as that MIME type; this is automatic if one calls `show` or `repr`. Finally, one should define a function `display(d::D, x)` that queries `showable(mime, x)` for the mime types supported by `D` and displays the "best" one; a `MethodError` should be thrown if no supported MIME types are found for `x`. Similarly, some subtypes may wish to override `redisplay(d::D, ...)`. (Again, one should import `Base.display` to add new methods to `display`.) The return values of these functions are up to the implementation (since in some cases it may be useful to return a display "handle" of some type). The display functions for `D` can then be called directly, but they can also be invoked automatically from `display(x)` simply by pushing a new display onto the display-backend stack with:

Base.Multimedia.pushdisplay – Function.

```
| pushdisplay(d::AbstractDisplay)
```

Pushes a new display `d` on top of the global display-backend stack. Calling `display(x)` or `display(mime, x)` will display `x` on the topmost compatible backend in the stack (i.e., the topmost backend that does not throw a `MethodError`).

source

Base.Multimedia.popdisplay – Function.

```
| popdisplay()
| popdisplay(d::AbstractDisplay)
```

Pop the topmost backend off of the display-backend stack, or the topmost copy of `d` in the second variant.

source

Base.Multimedia.TextDisplay – Type.

```
| TextDisplay(io::IO)
```

Return a `TextDisplay <: AbstractDisplay`, which displays any object as the text/plain MIME type (by default), writing the text representation to the given I/O stream. (This is how objects are printed in the Julia REPL.)

source

Base.Multimedia.istextmime – Function.

```
| istextmime(m::MIME)
```

Determine whether a MIME type is text data. MIME types are assumed to be binary data except for a set of types known to be text data (possibly Unicode).

Examples

```
| julia> istextmime(MIME("text/plain"))
| true
|
| julia> istextmime(MIME("image/png"))
| false
```

[source](#)

51.4 Network I/O

Base.bytesavailable – Function.

```
| bytesavailable(io)
```

Return the number of bytes available for reading before a read from this stream or buffer will block.

Examples

```
| julia> io = IOBuffer("JuliaLang is a GitHub organization");
|
| julia> bytesavailable(io)
| 34
```

[source](#)

Base.ntoh – Function.

```
| ntohs(x)
```

Convert the endianness of a value from Network byte order (big-endian) to that used by the Host.

[source](#)

Base.hton – Function.

```
| htons(x)
```

Convert the endianness of a value from that used by the Host to Network byte order (big-endian).

[source](#)

Base.ltoh – Function.

```
| ltoh(x)
```

Convert the endianness of a value from Little-endian to that used by the Host.

[source](#)

`Base.htol` – Function.

| `htol(x)`

Convert the endianness of a value from that used by the Host to Little-endian.

[source](#)

`Base.ENDIAN_BOM` – Constant.

| `ENDIAN_BOM`

The 32-bit byte-order-mark indicates the native byte order of the host machine. Little-endian machines will contain the value 0x04030201. Big-endian machines will contain the value 0x01020304.

[source](#)

Chapter 52

Punctuation

Extended documentation for mathematical symbols & functions is [here](#).

| sym-
bol | meaning |
|-------------|---|
| @ | the at-sign marks a macro invocation; optionally followed by an argument list |
| ! | an exclamation mark is a prefix operator for logical negation ("not") |
| a! | function names that end with an exclamation mark modify one or more of their arguments by convention |
| # | the number sign (or hash or pound) character begins single line comments |
| #= | when followed by an equals sign, it begins a multi-line comment (these are nestable) |
| =# | end a multi-line comment by immediately preceding the number sign with an equals sign |
| \$ | the dollar sign is used for string and expression interpolation |
| % | the percent symbol is the remainder operator |
| ^ | the caret is the exponentiation operator |
| & | single ampersand is bitwise and |
| && | double ampersands is short-circuiting boolean and |
| | single pipe character is bitwise or |
| | double pipe characters is short-circuiting boolean or |
| ⊕ | the unicode xor character is bitwise exclusive or |
| ~ | the tilde is an operator for bitwise not |
| ' | a trailing apostrophe is the adjoint (that is, the complex transpose) operator A^H |
| * | the asterisk is used for multiplication, including matrix multiplication and string concatenation |
| / | forward slash divides the argument on its left by the one on its right |
| \ | backslash operator divides the argument on its right by the one on its left, commonly used to solve matrix equations |
| () | parentheses with no arguments constructs an empty Tuple |
| (a, ...) | parentheses with comma-separated arguments constructs a tuple containing its arguments |
| (a=1, ...) | parentheses with comma-separated assignments constructs a NamedTuple |
| (x;y) | parentheses can also be used to group one or more semicolon separated expressions |
| a[] | array indexing (calling getindex or setindex!) |
| [,] | vector literal constructor (calling vect) |
| [;] | vertical concatenation (calling vcat or hvc) |
| [] | with space-separated expressions, horizontal concatenation (calling hcat or hvc) |
| T{ } | curly braces following a type list that type's parameters |
| { } | curly braces can also be used to group multiple where expressions in function declarations |
| ; | semicolons separate statements, begin a list of keyword arguments in function declarations or calls, or are used to separate array literals for vertical concatenation |
| , | commas separate function arguments or tuple or array components |
| ? | the question mark delimits the ternary conditional operator (used like: <code>conditional ? if_true : if_false</code>) |
| " " | the single double-quote character delimits String literals |
| """
""" | three double-quote characters delimits string literals that may contain " and ignore leading indentation |
| ' ' | the single-quote character delimits Char (that is, character) literals |
| ` ` | the backtick character delimits external process (Cmd) literals |
| A... | triple periods are a postfix operator that "splat" their arguments' contents into many arguments of a function call or declare a varargs function that "slurps" up many arguments into a single tuple |
| a.b | single periods access named fields in objects/modules (calling getproperty or setproperty!) |
| f.() | periods may also prefix parentheses (like <code>f.()</code>) or infix operators (like <code>.+</code>) to perform the function element-wise (calling broadcast) |
| a:b | colons (:) used as a binary infix operator construct a range from a to b (inclusive) with fixed step size 1 |
| a:s:b | colons (:) used as a ternary infix operator construct a range from a to b (inclusive) with step size s |
| : | when used by themselves, Colons represent all indices within a dimension, frequently combined with indexing |
| :: | double-colons represent a type annotation or typeassert , depending on context, frequently used when declaring function arguments |
| :() | quoted expression |
| ⚡ | Symbol |

Chapter 53

Sorting and Related Functions

Julia has an extensive, flexible API for sorting and interacting with already-sorted arrays of values. By default, Julia picks reasonable algorithms and sorts in ascending order:

```
julia> sort([2,3,1])
3-element Vector{Int64}:
 1
 2
 3
```

You can sort in reverse order as well:

```
julia> sort([2,3,1], rev=true)
3-element Vector{Int64}:
 3
 2
 1
```

`sort` constructs a sorted copy leaving its input unchanged. Use the "bang" version of the sort function to mutate an existing array:

```
julia> a = [2,3,1];

julia> sort!(a);

julia> a
3-element Vector{Int64}:
 1
 2
 3
```

Instead of directly sorting an array, you can compute a permutation of the array's indices that puts the array into sorted order:

```
julia> v = randn(5)
5-element Array{Float64,1}:
 0.297288
 0.382396
-0.597634
-0.0104452
-0.839027

julia> p = sortperm(v)
5-element Array{Int64,1}:
 5
 3
 4
 1
 2

julia> v[p]
5-element Array{Float64,1}:
-0.839027
-0.597634
-0.0104452
 0.297288
 0.382396
```

Arrays can be sorted according to an arbitrary transformation of their values:

```
julia> sort(v, by=abs)
5-element Array{Float64,1}:
-0.0104452
 0.297288
 0.382396
-0.597634
-0.839027
```

Or in reverse order by a transformation:

```
julia> sort(v, by=abs, rev=true)
5-element Array{Float64,1}:
-0.839027
-0.597634
 0.382396
 0.297288
-0.0104452
```

If needed, the sorting algorithm can be chosen:

```
julia> sort(v, alg=InsertionSort)
5-element Array{Float64,1}:
-0.839027
-0.597634
-0.0104452
```

```
0.297288
0.382396
```

All the sorting and order related functions rely on a "less than" relation defining a [strict weak order](#) on the values to be manipulated. The `isless` function is invoked by default, but the relation can be specified via the `lt` keyword, a function that takes two array elements and returns `true` if and only if the first argument is "less than" the second. See [sort!](#) and [Alternate Orderings](#) for more information.

53.1 Sorting Functions

`Base.sort!` – Function.

```
sort!(v; alg::Algorithm=defalg(v), lt=isless, by=identity, rev::Bool=false,
↳ order::Ordering=Forward)
```

Sort the vector `v` in place. A stable algorithm is used by default: the ordering of elements that compare equal is preserved. A specific algorithm can be selected via the `alg` keyword (see [Sorting Algorithms](#) for available algorithms).

Elements are first transformed with the function `by` and then compared according to either the function `lt` or the ordering order. Finally, the resulting order is reversed if `rev=true` (this preserves forward stability: elements that compare equal are not reversed). The current implementation applies the `by` transformation before each comparison rather than once per element.

Passing an `lt` other than `isless` along with an order other than `Base.Order.Forward` or `Base.Order.Reverse` is not permitted, otherwise all options are independent and can be used together in all possible combinations. Note that order can also include a "by" transformation, in which case it is applied after that defined with the `by` keyword. For more information on order values see the documentation on [Alternate Orderings](#).

Relations between two elements are defined as follows (with "less" and "greater" exchanged when `rev=true`):

- `x` is less than `y` if `lt(by(x), by(y))` (or `Base.Order.lt(order, by(x), by(y))`) yields `true`.
- `x` is greater than `y` if `y` is less than `x`.
- `x` and `y` are equivalent if neither is less than the other ("incomparable" is sometimes used as a synonym for "equivalent").

The result of `sort!` is sorted in the sense that every element is greater than or equivalent to the previous one.

The `lt` function must define a strict weak order, that is, it must be

- irreflexive: `lt(x, x)` always yields `false`,
- asymmetric: if `lt(x, y)` yields `true` then `lt(y, x)` yields `false`,
- transitive: `lt(x, y) && lt(y, z)` implies `lt(x, z)`,
- transitive in equivalence: `!lt(x, y) && !lt(y, x)` and `!lt(y, z) && !lt(z, y)` together imply `!lt(x, z) && !lt(z, x)`. In words: if `x` and `y` are equivalent and `y` and `z` are equivalent then `x` and `z` must be equivalent.

For example `<` is a valid `lt` function for `Int` values but `≤` is not: it violates irreflexivity. For `Float64` values even `<` is invalid as it violates the fourth condition: `1.0` and `NaN` are equivalent and so are `NaN` and `2.0` but `1.0` and `2.0` are not equivalent.

See also [sort](#), [sortperm](#), [sortslices](#), [partialsort!](#), [partialsortperm](#), [issorted](#), [searchsorted](#), [insorted](#), [Base.Order.ord](#).

Examples

```
julia> v = [3, 1, 2]; sort!(v); v
3-element Vector{Int64}:
 1
 2
 3

julia> v = [3, 1, 2]; sort!(v, rev = true); v
3-element Vector{Int64}:
 3
 2
 1

julia> v = [(1, "c"), (3, "a"), (2, "b")]; sort!(v, by = x -> x[1]); v
3-element Vector{Tuple{Int64, String}}:
(1, "c")
(2, "b")
(3, "a")

julia> v = [(1, "c"), (3, "a"), (2, "b")]; sort!(v, by = x -> x[2]); v
3-element Vector{Tuple{Int64, String}}:
(3, "a")
(2, "b")
(1, "c")

julia> sort(0:3, by=x->x-2, order=Base.Order.By(abs)) # same as sort(0:3, by=abs(x->x-2))
4-element Vector{Int64}:
 2
 1
 3
 0

julia> sort([2, NaN, 1, NaN, 3]) # correct sort with default lt=isless
5-element Vector{Float64}:
 1.0
 2.0
 3.0
 NaN
 NaN

julia> sort([2, NaN, 1, NaN, 3], lt=≤) # wrong sort due to invalid lt. This behavior is
↪ undefined.
5-element Vector{Float64}:
 2.0
 NaN
 1.0
```

```
NaN
 3.0
```

source

```
sort!(A; dims::Integer, alg::Algorithm=defalg(A), lt=isless, by=identity, rev::Bool=false,
      order::Ordering=Forward)
```

Sort the multidimensional array `A` along dimension `dims`. See the one-dimensional version of [sort!](#) for a description of possible keyword arguments.

To sort slices of an array, refer to [sortslices](#).

Julia 1.1

This function requires at least Julia 1.1.

Examples

```
julia> A = [4 3; 1 2]
2×2 Matrix{Int64}:
 4  3
 1  2

julia> sort!(A, dims = 1); A
2×2 Matrix{Int64}:
 1  2
 4  3

julia> sort!(A, dims = 2); A
2×2 Matrix{Int64}:
 1  2
 3  4
```

source

`Base.sort` – Function.

```
sort(v; alg::Algorithm=defalg(v), lt=isless, by=identity, rev::Bool=false,
     ↪ order::Ordering=Forward)
```

Variant of [sort!](#) that returns a sorted copy of `v` leaving `v` itself unmodified.

Examples

```
julia> v = [3, 1, 2];

julia> sort(v)
3-element Vector{Int64}:
 1
 2
 3

julia> v
3-element Vector{Int64}:
 3
 1
 2
```

```
3
1
2
```

[source](#)

```
sort(A; dims::Integer, alg::Algorithm=defalg(A), lt=isless, by=identity, rev::Bool=false,
      order::Ordering=Forward)
```

Sort a multidimensional array A along the given dimension. See [sort!](#) for a description of possible keyword arguments.

To sort slices of an array, refer to [sortslices](#).

Examples

```
julia> A = [4 3; 1 2]
2×2 Matrix{Int64}:
 4  3
 1  2

julia> sort(A, dims = 1)
2×2 Matrix{Int64}:
 1  2
 4  3

julia> sort(A, dims = 2)
2×2 Matrix{Int64}:
 3  4
 1  2
```

[source](#)

Base.sortperm - Function.

```
sortperm(A; alg::Algorithm=DEFAULT_UNSTABLE, lt=isless, by=identity, rev::Bool=false,
         ↪ order::Ordering=Forward, [dims::Integer])
```

Return a permutation vector or array I that puts A[I] in sorted order along the given dimension. If A has more than one dimension, then the dims keyword argument must be specified. The order is specified using the same keywords as [sort!](#). The permutation is guaranteed to be stable even if the sorting algorithm is unstable: the indices of equal elements will appear in ascending order.

See also [sortperm!](#), [partialsortperm](#), [invperm](#), [indexin](#). To sort slices of an array, refer to [sortslices](#).

Julia 1.9

The method accepting dims requires at least Julia 1.9.

Examples

```
julia> v = [3, 1, 2];

julia> p = sortperm(v)
3-element Vector{Int64}:
```

```

2
3
1

julia> v[p]
3-element Vector{Int64}:
 1
 2
 3

julia> A = [8 7; 5 6]
2×2 Matrix{Int64}:
 8  7
 5  6

julia> sortperm(A, dims = 1)
2×2 Matrix{Int64}:
 2  4
 1  3

julia> sortperm(A, dims = 2)
2×2 Matrix{Int64}:
 3  1
 2  4

```

[source](#)

Base.Sort.InsertionSort – Constant.

| [InsertionSort](#)

Use the insertion sort algorithm.

Insertion sort traverses the collection one element at a time, inserting each element into its correct, sorted position in the output vector.

Characteristics:

- stable: preserves the ordering of elements that compare equal

(e.g. "a" and "A" in a sort of letters that ignores case).

- in-place in memory.
- quadratic performance in the number of elements to be sorted:

it is well-suited to small collections but should not be used for large ones.

[source](#)

Base.Sort.MergeSort – Constant.

| [MergeSort](#)

Indicate that a sorting function should use the merge sort algorithm. Merge sort divides the collection into subcollections and repeatedly merges them, sorting each subcollection at each step, until the entire collection has been recombined in sorted form.

Characteristics:

- stable: preserves the ordering of elements that compare equal (e.g. "a" and "A" in a sort of letters that ignores case).
- not in-place in memory.
- divide-and-conquer sort strategy.
- good performance for large collections but typically not quite as fast as [QuickSort](#).

[source](#)

Base.Sort.QuickSort – Constant.

| [QuickSort](#)

Indicate that a sorting function should use the quick sort algorithm, which is not stable.

Characteristics:

- not stable: does not preserve the ordering of elements that compare equal (e.g. "a" and "A" in a sort of letters that ignores case).
- in-place in memory.
- divide-and-conquer: sort strategy similar to [MergeSort](#).
- good performance for large collections.

[source](#)

Base.Sort.PartialQuickSort – Type.

| [PartialQuickSort](#){T <: Union{Integer,OrdinalRange}}

Indicate that a sorting function should use the partial quick sort algorithm. `PartialQuickSort(k)` is like `QuickSort`, but is only required to find and sort the elements that would end up in `v[k]` were `v` fully sorted.

Characteristics:

- not stable: does not preserve the ordering of elements that compare equal (e.g. "a" and "A" in a sort of letters that ignores case).
- in-place in memory.
- divide-and-conquer: sort strategy similar to [MergeSort](#).

Note that `PartialQuickSort(k)` does not necessarily sort the whole array. For example,

```

julia> x = rand(100);

julia> k = 50:100;

julia> s1 = sort(x; alg=QuickSort);

julia> s2 = sort(x; alg=PartialQuickSort(k));

julia> map(issorted, (s1, s2))
(true, false)

julia> map(x->issorted(x[k]), (s1, s2))
(true, true)

julia> s1[k] == s2[k]
true

```

[source](#)

Base.Sort.sortperm! – Function.

```

sortperm!(ix, A; alg::Algorithm=DEFAULT_UNSTABLE, lt=isless, by=identity, rev::Bool=false,
↪ order::Ordering=Forward, [dims::Integer])

```

Like [sortperm](#), but accepts a preallocated index vector or array `ix` with the same axes as `A`. `ix` is initialized to contain the values `LinearIndices(A)`.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Julia 1.9

The method accepting `dims` requires at least Julia 1.9.

Examples

```

julia> v = [3, 1, 2]; p = zeros{Int, 3};

julia> sortperm!(p, v); p
3-element Vector{Int64}:
 2
 3
 1

julia> v[p]
3-element Vector{Int64}:
 1
 2
 3

julia> A = [8 7; 5 6]; p = zeros{Int, 2, 2};

```

```
julia> sortperm!(p, A; dims=1); p
2×2 Matrix{Int64}:
 2  4
 1  3

julia> sortperm!(p, A; dims=2); p
2×2 Matrix{Int64}:
 3  1
 2  4
```

[source](#)

Base.sortslices – Function.

```
sortslices(A; dims, alg::Algorithm=DEFAULT_UNSTABLE, lt=isless, by=identity, rev::Bool=false,
↪ order::Ordering=Forward)
```

Sort slices of an array A. The required keyword argument `dims` must be either an integer or a tuple of integers. It specifies the dimension(s) over which the slices are sorted.

E.g., if A is a matrix, `dims=1` will sort rows, `dims=2` will sort columns. Note that the default comparison function on one dimensional slices sorts lexicographically.

For the remaining keyword arguments, see the documentation of [sort!](#).

Examples

```
julia> sortslices([7 3 5; -1 6 4; 9 -2 8], dims=1) # Sort rows
3×3 Matrix{Int64}:
 -1  6  4
  7  3  5
  9 -2  8

julia> sortslices([7 3 5; -1 6 4; 9 -2 8], dims=1, lt=(x,y)->isless(x[2],y[2]))
3×3 Matrix{Int64}:
  9 -2  8
  7  3  5
 -1  6  4

julia> sortslices([7 3 5; -1 6 4; 9 -2 8], dims=1, rev=true)
3×3 Matrix{Int64}:
  9 -2  8
  7  3  5
 -1  6  4

julia> sortslices([7 3 5; 6 -1 -4; 9 -2 8], dims=2) # Sort columns
3×3 Matrix{Int64}:
  3  5  7
 -1 -4  6
 -2  8  9

julia> sortslices([7 3 5; 6 -1 -4; 9 -2 8], dims=2, alg=InsertionSort,
↪ lt=(x,y)->isless(x[2],y[2]))
3×3 Matrix{Int64}:
  5  3  7
```

```

-4 -1 6
 8 -2 9

julia> sortsllices([7 3 5; 6 -1 -4; 9 -2 8], dims=2, rev=true)
3×3 Matrix{Int64}:
 7  5  3
 6 -4 -1
 9  8 -2

```

Higher dimensions

`sortsllices` extends naturally to higher dimensions. E.g., if `A` is a `2x2x2` array, `sortsllices(A, dims=3)` will sort slices within the 3rd dimension, passing the `2x2` slices `A[:, :, 1]` and `A[:, :, 2]` to the comparison function. Note that while there is no default order on higher-dimensional slices, you may use the `by` or `lt` keyword argument to specify such an order.

If `dims` is a tuple, the order of the dimensions in `dims` is relevant and specifies the linear order of the slices. E.g., if `A` is three dimensional and `dims` is `(1, 2)`, the orderings of the first two dimensions are re-arranged such that the slices (of the remaining third dimension) are sorted. If `dims` is `(2, 1)` instead, the same slices will be taken, but the result order will be row-major instead.

Higher dimensional examples

```

julia> A = permutedims(reshape([4 3; 2 1; 'A' 'B'; 'C' 'D'], (2, 2, 2)), (1, 3, 2))
2×2×2 Array{Any, 3}:
[:, :, 1] =
 4  3
 2  1

[:, :, 2] =
 'A' 'B'
 'C' 'D'

julia> sortsllices(A, dims=(1,2))
2×2×2 Array{Any, 3}:
[:, :, 1] =
 1  3
 2  4

[:, :, 2] =
 'D' 'B'
 'C' 'A'

julia> sortsllices(A, dims=(2,1))
2×2×2 Array{Any, 3}:
[:, :, 1] =
 1  2
 3  4

[:, :, 2] =
 'D' 'C'
 'B' 'A'

julia> sortsllices(reshape([5; 4; 3; 2; 1], (1,1,5)), dims=3, by=x->x[1,1])
1×1×5 Array{Int64, 3}:

```

```
[:, :, 1] =
1

[:, :, 2] =
2

[:, :, 3] =
3

[:, :, 4] =
4

[:, :, 5] =
5
```

[source](#)

53.2 Order-Related Functions

`Base.issorted` – Function.

```
issorted(v, lt=isless, by=identity, rev::Bool=false, order::Ordering=Forward)
```

Test whether a collection is in sorted order. The keywords modify what order is considered sorted, as described in the [sort!](#) documentation.

Examples

```
julia> issorted([1, 2, 3])
true

julia> issorted([(1, "b"), (2, "a")], by = x -> x[1])
true

julia> issorted([(1, "b"), (2, "a")], by = x -> x[2])
false

julia> issorted([(1, "b"), (2, "a")], by = x -> x[2], rev=true)
true

julia> issorted([1, 2, -2, 3], by=abs)
true
```

[source](#)

`Base.Sort.searchsorted` – Function.

```
searchsorted(v, x; by=identity, lt=isless, rev=false)
```

Return the range of indices in `v` where values are equivalent to `x`, or an empty range located at the insertion point if `v` does not contain values equivalent to `x`. The vector `v` must be sorted according to the order defined by the keywords. Refer to [sort!](#) for the meaning of the keywords and the definition of equivalence. Note that the `by` function is applied to the searched value `x` as well as the values in `v`.

The range is generally found using binary search, but there are optimized implementations for some inputs.

See also: [searchsortedfirst](#), [sort!](#), [insorted](#), [findall](#).

Examples

```
julia> searchsorted([1, 2, 4, 5, 5, 7], 4) # single match
3:3

julia> searchsorted([1, 2, 4, 5, 5, 7], 5) # multiple matches
4:5

julia> searchsorted([1, 2, 4, 5, 5, 7], 3) # no match, insert in the middle
3:2

julia> searchsorted([1, 2, 4, 5, 5, 7], 9) # no match, insert at end
7:6

julia> searchsorted([1, 2, 4, 5, 5, 7], 0) # no match, insert at start
1:0

julia> searchsorted([1=>"one", 2=>"two", 2=>"two", 4=>"four"], 2=>"two", by=first) # compare
↪ the keys of the pairs
2:3
```

[source](#)

`Base.Sort.searchsortedfirst` - Function.

```
searchsortedfirst(v, x; by=identity, lt=isless, rev=false)
```

Return the index of the first value in `v` greater than or equivalent to `x`. If `x` is greater than all values in `v`, return `lastindex(v) + 1`.

The vector `v` must be sorted according to the order defined by the keywords. `insert!`ing `x` at the returned index will maintain the sorted order. Refer to [sort!](#) for the meaning of the keywords and the definition of "greater than" and equivalence. Note that the `by` function is applied to the searched value `x` as well as the values in `v`.

The index is generally found using binary search, but there are optimized implementations for some inputs.

See also: [searchsortedlast](#), [searchsorted](#), [findfirst](#).

Examples

```
julia> searchsortedfirst([1, 2, 4, 5, 5, 7], 4) # single match
3

julia> searchsortedfirst([1, 2, 4, 5, 5, 7], 5) # multiple matches
4

julia> searchsortedfirst([1, 2, 4, 5, 5, 7], 3) # no match, insert in the middle
3
```

```
julia> searchsortedfirst([1, 2, 4, 5, 5, 7], 9) # no match, insert at end
7

julia> searchsortedfirst([1, 2, 4, 5, 5, 7], 0) # no match, insert at start
1

julia> searchsortedfirst([1=>"one", 2=>"two", 4=>"four"], 3=>"three", by=first) # compare the
↪ keys of the pairs
3
```

[source](#)

Base.Sort.searchsortedlast - Function.

```
searchsortedlast(v, x; by=identity, lt=isless, rev=false)
```

Return the index of the last value in *v* less than or equivalent to *x*. If *x* is less than all values in *v* the function returns `firstindex(v) - 1`.

The vector *v* must be sorted according to the order defined by the keywords. Refer to [sort!](#) for the meaning of the keywords and the definition of "less than" and equivalence. Note that the *by* function is applied to the searched value *x* as well as the values in *v*.

The index is generally found using binary search, but there are optimized implementations for some inputs

Examples

```
julia> searchsortedlast([1, 2, 4, 5, 5, 7], 4) # single match
3

julia> searchsortedlast([1, 2, 4, 5, 5, 7], 5) # multiple matches
5

julia> searchsortedlast([1, 2, 4, 5, 5, 7], 3) # no match, insert in the middle
2

julia> searchsortedlast([1, 2, 4, 5, 5, 7], 9) # no match, insert at end
6

julia> searchsortedlast([1, 2, 4, 5, 5, 7], 0) # no match, insert at start
0

julia> searchsortedlast([1=>"one", 2=>"two", 4=>"four"], 3=>"three", by=first) # compare the
↪ keys of the pairs
2
```

[source](#)

Base.Sort.insorted - Function.

```
insorted(x, v; by=identity, lt=isless, rev=false) -> Bool
```

Determine whether a vector `v` contains any value equivalent to `x`. The vector `v` must be sorted according to the order defined by the keywords. Refer to [sort!](#) for the meaning of the keywords and the definition of equivalence. Note that the `by` function is applied to the searched value `x` as well as the values in `v`.

The check is generally done using binary search, but there are optimized implementations for some inputs.

See also [in](#).

Examples

```
julia> insorted(4, [1, 2, 4, 5, 5, 7]) # single match
true

julia> insorted(5, [1, 2, 4, 5, 5, 7]) # multiple matches
true

julia> insorted(3, [1, 2, 4, 5, 5, 7]) # no match
false

julia> insorted(9, [1, 2, 4, 5, 5, 7]) # no match
false

julia> insorted(0, [1, 2, 4, 5, 5, 7]) # no match
false

julia> insorted(2=>"TWO", [1=>"one", 2=>"two", 4=>"four"], by=first) # compare the keys of
↪ the pairs
true
```

Julia 1.6

`insorted` was added in Julia 1.6.

source

`Base.Sort.partialsort!` – Function.

```
partialsort!(v, k; by=identity, lt=isless, rev=false)
```

Partially sort the vector `v` in place so that the value at index `k` (or range of adjacent values if `k` is a range) occurs at the position where it would appear if the array were fully sorted. If `k` is a single index, that value is returned; if `k` is a range, an array of values at those indices is returned. Note that `partialsort!` may not fully sort the input array.

For the keyword arguments, see the documentation of [sort!](#).

Examples

```
julia> a = [1, 2, 4, 3, 4]
5-element Vector{Int64}:
 1
 2
 4
 4
```

```

3
4

julia> partialsort!(a, 4)
4

julia> a
5-element Vector{Int64}:
 1
 2
 3
 4
 4

julia> a = [1, 2, 4, 3, 4]
5-element Vector{Int64}:
 1
 2
 4
 3
 4

julia> partialsort!(a, 4, rev=true)
2

julia> a
5-element Vector{Int64}:
 4
 4
 3
 2
 1

```

[source](#)

Base.Sort.partialsort – Function.

```
| partialsort(v, k, by=identity, lt=isless, rev=false)
```

Variant of `partialsort!` that copies `v` before partially sorting it, thereby returning the same thing as `partialsort!` but leaving `v` unmodified.

[source](#)

Base.Sort.partialsortperm – Function.

```
| partialsortperm(v, k; by=identity, lt=isless, rev=false)
```

Return a partial permutation `I` of the vector `v`, so that `v[I]` returns values of a fully sorted version of `v` at index `k`. If `k` is a range, a vector of indices is returned; if `k` is an integer, a single index is returned. The order is specified using the same keywords as `sort!`. The permutation is stable: the indices of equal elements will appear in ascending order.

This function is equivalent to, but more efficient than, calling `sortperm(...)[k]`.

Examples

```

julia> v = [3, 1, 2, 1];

julia> v[partialsortperm(v, 1)]
1

julia> p = partialsortperm(v, 1:3)
3-element view(::Vector{Int64}, 1:3) with eltype Int64:
 2
 4
 3

julia> v[p]
3-element Vector{Int64}:
 1
 1
 2

```

[source](#)

Base.Sort.partialsortperm! – Function.

```
partialsortperm!(ix, v, k; by=identity, lt=isless, rev=false)
```

Like `partialsortperm`, but accepts a preallocated index vector `ix` the same size as `v`, which is used to store (a permutation of) the indices of `v`.

`ix` is initialized to contain the indices of `v`.

(Typically, the indices of `v` will be `1:length(v)`, although if `v` has an alternative array type with non-one-based indices, such as an `OffsetArray`, `ix` must share those same indices)

Upon return, `ix` is guaranteed to have the indices `k` in their sorted positions, such that

```

partialsortperm!(ix, v, k);
v[ix[k]] == partialsort(v, k)

```

The return value is the `k`th element of `ix` if `k` is an integer, or view into `ix` if `k` is a range.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

Examples

```

julia> v = [3, 1, 2, 1];

julia> ix = Vector{Int}(undef, 4);

julia> partialsortperm!(ix, v, 1)
2

julia> ix = [1:4;];

```

```
julia> partialsortperm!(ix, v, 2:3)
2-element view(::Vector{Int64}, 2:3) with eltype Int64:
 4
 3
```

[source](#)

53.3 Sorting Algorithms

There are currently four sorting algorithms publicly available in base Julia:

- [InsertionSort](#)
- [QuickSort](#)
- [PartialQuickSort\(k\)](#)
- [MergeSort](#)

By default, the sort family of functions uses stable sorting algorithms that are fast on most inputs. The exact algorithm choice is an implementation detail to allow for future performance improvements. Currently, a hybrid of RadixSort, ScratchQuickSort, InsertionSort, and CountingSort is used based on input type, size, and composition. Implementation details are subject to change but currently available in the extended help of `??Base.DEFAULT_STABLE` and the docstrings of internal sorting algorithms listed there.

You can explicitly specify your preferred algorithm with the `alg` keyword (e.g. `sort!(v, alg=PartialQuickSort(10:20))`) or reconfigure the default sorting algorithm for custom types by adding a specialized method to the `Base.Sort.defalg` function. For example, [InlineStrings.jl](#) defines the following method:

```
Base.Sort.defalg(::AbstractArray{<:Union{SmallInlineStrings, Missing}}) = InlineStringSort
```

Julia 1.9

The default sorting algorithm (returned by `Base.Sort.defalg`) is guaranteed to be stable since Julia 1.9. Previous versions had unstable edge cases when sorting numeric arrays.

53.4 Alternate Orderings

By default, `sort`, `searchsorted`, and related functions use `isless` to compare two elements in order to determine which should come first. The [Base.Order.Ordering](#) abstract type provides a mechanism for defining alternate orderings on the same set of elements: when calling a sorting function like `sort!`, an instance of `Ordering` can be provided with the keyword argument `order`.

Instances of `Ordering` define an order through the [Base.Order.lt](#) function, which works as a generalization of `isless`. This function's behavior on custom Orderings must satisfy all the conditions of a [strict weak order](#). See [sort!](#) for details and examples of valid and invalid `lt` functions.

`Base.Order.Ordering` – Type.

```
| Base.Order.Ordering
```

Abstract type which represents a total order on some set of elements.

Use [Base.Order.lt](#) to compare two elements according to the ordering.

[source](#)

[Base.Order.lt](#) – Function.

```
| lt(o::Ordering, a, b)
```

Test whether a is less than b according to the ordering o.

[source](#)

[Base.Order.ord](#) – Function.

```
| ord(lt, by, rev::Union{Bool, Nothing}, order::Ordering=Forward)
```

Construct an [Ordering](#) object from the same arguments used by [sort!](#). Elements are first transformed by the function by (which may be [identity](#)) and are then compared according to either the function lt or an existing ordering order. lt should be [isless](#) or a function that obeys the same rules as the lt parameter of [sort!](#). Finally, the resulting order is reversed if rev=true.

Passing an lt other than [isless](#) along with an order other than [Base.Order.Forward](#) or [Base.Order.Reverse](#) is not permitted, otherwise all options are independent and can be used together in all possible combinations.

[source](#)

[Base.Order.Forward](#) – Constant.

```
| Base.Order.Forward
```

Default ordering according to [isless](#).

[source](#)

[Base.Order.ReverseOrdering](#) – Type.

```
| ReverseOrdering(fwd::Ordering=Forward)
```

A wrapper which reverses an ordering.

For a given Ordering o, the following holds for all a, b:

```
| lt(ReverseOrdering(o), a, b) == lt(o, b, a)
```

[source](#)

[Base.Order.Reverse](#) – Constant.

```
| Base.Order.Reverse
```

Reverse ordering according to [isless](#).

[source](#)

`Base.Order.By` – Type.

```
| By(by, order::Ordering=Forward)
```

Ordering which applies order to elements after they have been transformed by the function `by`.

[source](#)

`Base.Order.Lt` – Type.

```
| Lt(lt)
```

Ordering that calls `lt(a, b)` to compare elements. `lt` must obey the same rules as the `lt` parameter of `sort!`.

[source](#)

`Base.Order.Perm` – Type.

```
| Perm(order::Ordering, data::AbstractVector)
```

Ordering on the indices of data where `i` is less than `j` if `data[i]` is less than `data[j]` according to order. In the case that `data[i]` and `data[j]` are equal, `i` and `j` are compared by numeric value.

[source](#)

Chapter 54

Iteration utilities

Base.Iterators.Stateful – Type.

```
| Stateful(itr)
```

There are several different ways to think about this iterator wrapper:

1. It provides a mutable wrapper around an iterator and its iteration state.
2. It turns an iterator-like abstraction into a Channel-like abstraction.
3. It's an iterator that mutates to become its own rest iterator whenever an item is produced.

Stateful provides the regular iterator interface. Like other mutable iterators (e.g. [Base.Channel](#)), if iteration is stopped early (e.g. by a [break](#) in a [for](#) loop), iteration can be resumed from the same spot by continuing to iterate over the same iterator object (in contrast, an immutable iterator would restart from the beginning).

Examples

```
julia> a = Iterators.Stateful("abcdef");

julia> isempty(a)
false

julia> popfirst!(a)
'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)

julia> collect(Iterators.take(a, 3))
3-element Vector{Char}:
 'b': ASCII/Unicode U+0062 (category Ll: Letter, lowercase)
 'c': ASCII/Unicode U+0063 (category Ll: Letter, lowercase)
 'd': ASCII/Unicode U+0064 (category Ll: Letter, lowercase)

julia> collect(a)
2-element Vector{Char}:
 'e': ASCII/Unicode U+0065 (category Ll: Letter, lowercase)
 'f': ASCII/Unicode U+0066 (category Ll: Letter, lowercase)

julia> Iterators.reset!(a); popfirst!(a)
```

```
'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)

julia> Iterators.reset!(a, "hello"); popfirst!(a)
'h': ASCII/Unicode U+0068 (category Ll: Letter, lowercase)

julia> a = Iterators.Stateful([1,1,1,2,3,4]);

julia> for x in a; x == 1 || break; end

julia> peek(a)
3

julia> sum(a) # Sum the remaining elements
7
```

[source](#)

`Base.Iterators.zip` – Function.

```
zip(iters...)
```

Run multiple iterators at the same time, until any of them is exhausted. The value type of the `zip` iterator is a tuple of values of its subiterators.

Note

`zip` orders the calls to its subiterators in such a way that stateful iterators will not advance when another iterator finishes in the current iteration.

Note

`zip()` with no arguments yields an infinite iterator of empty tuples.

See also: [enumerate](#), [Base.splat](#).

Examples

```
julia> a = 1:5
1:5

julia> b = ["e", "d", "b", "c", "a"]
5-element Vector{String}:
 "e"
 "d"
 "b"
 "c"
 "a"

julia> c = zip(a,b)
zip{1:5, ["e", "d", "b", "c", "a"]})

julia> length(c)
5

julia> first(c)
(1, "e")
```

source

`Base.Iterators.enumerate` – Function.

```
| enumerate(iter)
```

An iterator that yields `(i, x)` where `i` is a counter starting at 1, and `x` is the `i`th value from the given iterator. It's useful when you need not only the values `x` over which you are iterating, but also the number of iterations so far.

Note that `i` may not be valid for indexing `iter`, or may index a different element. This will happen if `iter` has indices that do not start at 1, and may happen for strings, dictionaries, etc. See the `pairs(IndexLinear(), iter)` method if you want to ensure that `i` is an index.

Examples

```
julia> a = ["a", "b", "c"];

julia> for (index, value) in enumerate(a)
    println("$index $value")
end
1 a
2 b
3 c

julia> str = "naïve";

julia> for (i, val) in enumerate(str)
    print("i = ", i, ", val = ", val, ", ")
    try @show(str[i]) catch e println(e) end
end
i = 1, val = n, str[i] = 'n'
i = 2, val = a, str[i] = 'a'
i = 3, val = i, str[i] = 'i'
i = 4, val = v, StringIndexError("naïve", 4)
i = 5, val = e, str[i] = 'v'
```

source

`Base.Iterators.rest` – Function.

```
| rest(iter, state)
```

An iterator that yields the same elements as `iter`, but starting at the given state.

See also: [Iterators.drop](#), [Iterators.peel](#), [Base.rest](#).

Examples

```
julia> collect(Iterators.rest([1,2,3,4], 2))
3-element Vector{Int64}:
 2
 3
 4
```

[source](#)

`Base.Iterators.countfrom` – Function.

```
| countfrom(start=1, step=1)
```

An iterator that counts forever, starting at `start` and incrementing by `step`.

Examples

```
julia> for v in Iterators.countfrom(5, 2)
        v > 10 && break
        println(v)
    end
5
7
9
```

[source](#)

`Base.Iterators.take` – Function.

```
| take(iter, n)
```

An iterator that generates at most the first `n` elements of `iter`.

See also: [drop](#), [peel](#), [first](#), [Base.take!](#).

Examples

```
julia> a = 1:2:11
1:2:11

julia> collect(a)
6-element Vector{Int64}:
 1
 3
 5
 7
 9
11

julia> collect(Iterators.take(a,3))
3-element Vector{Int64}:
 1
 3
 5
```

[source](#)

`Base.Iterators.takewhile` – Function.

```
| takewhile(pred, iter)
```

An iterator that generates element from `iter` as long as predicate `pred` is true, afterwards, drops every element.

Julia 1.4

This function requires at least Julia 1.4.

Examples

```
julia> s = collect(1:5)
5-element Vector{Int64}:
 1
 2
 3
 4
 5

julia> collect(Iterators.takewhile(<(3),s))
2-element Vector{Int64}:
 1
 2
```

[source](#)

`Base.Iterators.drop` – Function.

```
| drop(iter, n)
```

An iterator that generates all but the first `n` elements of `iter`.

Examples

```
julia> a = 1:2:11
1:2:11

julia> collect(a)
6-element Vector{Int64}:
 1
 3
 5
 7
 9
11

julia> collect(Iterators.drop(a,4))
2-element Vector{Int64}:
 9
11
```

[source](#)

`Base.Iterators.dropwhile` – Function.

```
| dropwhile(pred, iter)
```

An iterator that drops element from `iter` as long as predicate `pred` is true, afterwards, returns every element.

Julia 1.4

This function requires at least Julia 1.4.

Examples

```
julia> s = collect(1:5)
5-element Vector{Int64}:
 1
 2
 3
 4
 5

julia> collect(Iterators.dropwhile(<(3),s))
3-element Vector{Int64}:
 3
 4
 5
```

[source](#)

`Base.Iterators.cycle` – Function.

```
| cycle(iter)
```

An iterator that cycles through `iter` forever. If `iter` is empty, so is `cycle(iter)`.

See also: [Iterators.repeated](#), [Base.repeat](#).

Examples

```
julia> for (i, v) in enumerate(Iterators.cycle("hello"))
    print(v)
    i > 10 && break
end
hellohelloh
```

[source](#)

`Base.Iterators.repeated` – Function.

```
| repeated(x[, n::Int])
```

An iterator that generates the value `x` forever. If `n` is specified, generates `x` that many times (equivalent to `take(repeated(x), n)`).

See also: [Iterators.cycle](#), [Base.repeat](#).

Examples

```
julia> a = Iterators.repeated([1 2], 4);

julia> collect(a)
4-element Vector{Matrix{Int64}}:
```

```
[1 2]
[1 2]
[1 2]
[1 2]
```

[source](#)

`Base.Iterators.product` – Function.

```
product(iters...)
```

Return an iterator over the product of several iterators. Each generated element is a tuple whose *i*th element comes from the *i*th argument iterator. The first iterator changes the fastest.

See also: [zip](#), [Iterators.flatten](#).

Examples

```
julia> collect(Iterators.product(1:2, 3:5))
2×3 Matrix{Tuple{Int64, Int64}}:
(1, 3) (1, 4) (1, 5)
(2, 3) (2, 4) (2, 5)

julia> ans == [(x,y) for x in 1:2, y in 3:5] # collects a generator involving
↪ Iterators.product
true
```

[source](#)

`Base.Iterators.flatten` – Function.

```
flatten(iter)
```

Given an iterator that yields iterators, return an iterator that yields the elements of those iterators. Put differently, the elements of the argument iterator are concatenated.

Examples

```
julia> collect(Iterators.flatten((1:2, 8:9)))
4-element Vector{Int64}:
 1
 2
 8
 9

julia> [(x,y) for x in 0:1 for y in 'a':'c'] # collects generators involving
↪ Iterators.flatten
6-element Vector{Tuple{Int64, Char}}:
(0, 'a')
(0, 'b')
(0, 'c')
(1, 'a')
(1, 'b')
(1, 'c')
```

[source](#)

`Base.Iterators.flatmap` – Function.

```
| Iterators.flatmap(f, iterators...)
```

Equivalent to `flatten(map(f, iterators...))`.

See also [Iterators.flatten](#), [Iterators.map](#).

Julia 1.9

This function was added in Julia 1.9.

Examples

```
julia> Iterators.flatmap(n -> -n:2:n, 1:3) |> collect
9-element Vector{Int64}:
-1
 1
-2
 0
 2
-3
-1
 1
 3

julia> stack(n -> -n:2:n, 1:3)
ERROR: DimensionMismatch: stack expects uniform slices, got axes(x) == (1:3,) while first had
↪ (1:2,)
[...]

julia> Iterators.flatmap(n -> (-n, 10n), 1:2) |> collect
4-element Vector{Int64}:
-1
10
-2
20

julia> ans == vec(stack(n -> (-n, 10n), 1:2))
true
```

[source](#)

`Base.Iterators.partition` – Function.

```
| partition(collection, n)
```

Iterate over a collection `n` elements at a time.

Examples

```
julia> collect(Iterators.partition([1,2,3,4,5], 2))
3-element Vector{SubArray{Int64, 1, Vector{Int64}, Tuple{UnitRange{Int64}}, true}}:
```

```
[1, 2]
[3, 4]
[5]
```

[source](#)

`Base.Iterators.map` – Function.

```
| Iterators.map(f, iterators...)
```

Create a lazy mapping. This is another syntax for writing `(f(args...) for args in zip(iterators...))`.

Julia 1.6

This function requires at least Julia 1.6.

Examples

```
julia> collect(Iterators.map(x -> x^2, 1:3))
3-element Vector{Int64}:
 1
 4
 9
```

[source](#)

`Base.Iterators.filter` – Function.

```
| Iterators.filter(flt, itr)
```

Given a predicate function `flt` and an iterable object `itr`, return an iterable object which upon iteration yields the elements `x` of `itr` that satisfy `flt(x)`. The order of the original iterator is preserved.

This function is lazy; that is, it is guaranteed to return in (1) time and use (1) additional space, and `flt` will not be called by an invocation of `filter`. Calls to `flt` will be made when iterating over the returned iterable object. These calls are not cached and repeated calls will be made when reiterating.

See [Base.filter](#) for an eager implementation of filtering for arrays.

Examples

```
julia> f = Iterators.filter(isodd, [1, 2, 3, 4, 5])
Base.Iterators.Filter{typeof(isodd), Vector{Int64}}(isodd, [1, 2, 3, 4, 5])

julia> foreach(println, f)
1
3
5

julia> [x for x in [1, 2, 3, 4, 5] if isodd(x)] # collects a generator over Iterators.filter
3-element Vector{Int64}:
 1
 3
 5
```

[source](#)

`Base.Iterators.accumulate` – Function.

```
| Iterators.accumulate(f, itr; [init])
```

Given a 2-argument function `f` and an iterator `itr`, return a new iterator that successively applies `f` to the previous value and the next element of `itr`.

This is effectively a lazy version of [Base.accumulate](#).

Julia 1.5

Keyword argument `init` is added in Julia 1.5.

Examples

```
julia> a = Iterators.accumulate(+, [1,2,3,4]);

julia> foreach(println, a)
1
3
6
10

julia> b = Iterators.accumulate(/, (2, 5, 2, 5); init = 100);

julia> collect(b)
4-element Vector{Float64}:
 50.0
 10.0
  5.0
  1.0
```

[source](#)

`Base.Iterators.reverse` – Function.

```
| Iterators.reverse(itr)
```

Given an iterator `itr`, then `reverse(itr)` is an iterator over the same collection but in the reverse order. This iterator is "lazy" in that it does not make a copy of the collection in order to reverse it; see [Base.reverse](#) for an eager implementation.

(By default, this returns an `Iterators.Reverse` object wrapping `itr`, which is iterable if the corresponding `iterate` methods are defined, but some `itr` types may implement more specialized `Iterators.reverse` behaviors.)

Not all iterator types `T` support reverse-order iteration. If `T` doesn't, then iterating over `Iterators.reverse(itr::T)` will throw a [MethodError](#) because of the missing `iterate` methods for `Iterators.Reverse{T}`. (To implement these methods, the original iterator `itr::T` can be obtained from an `r::Iterators.Reverse{T}` object by `r itr`; more generally, one can use `Iterators.reverse(r)`.)

Examples

```
julia> foreach(println, Iterators.reverse(1:5))
5
4
3
2
1
```

[source](#)

`Base.Iterators.only` – Function.

```
| only(x)
```

Return the one and only element of collection `x`, or throw an [ArgumentError](#) if the collection has zero or multiple elements.

See also [first](#), [last](#).

Julia 1.4

This method requires at least Julia 1.4.

Examples

```
julia> only(["a"])
"a"

julia> only("a")
'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)

julia> only(())
ERROR: ArgumentError: Tuple contains 0 elements, must contain exactly 1 element
Stacktrace:
[...]

julia> only(('a', 'b'))
ERROR: ArgumentError: Tuple contains 2 elements, must contain exactly 1 element
Stacktrace:
[...]
```

[source](#)

`Base.Iterators.peel` – Function.

```
| peel(iter)
```

Returns the first element and an iterator over the remaining elements.

If the iterator is empty return nothing (like `iterate`).

Julia 1.7

Prior versions throw a `BoundsError` if the iterator is empty.

See also: [Iterators.drop](#), [Iterators.take](#).

Examples

```
julia> (a, rest) = Iterators.peel("abc");  
  
julia> a  
'a': ASCII/Unicode U+0061 (category Ll: Letter, lowercase)  
  
julia> collect(rest)  
2-element Vector{Char}:  
 'b': ASCII/Unicode U+0062 (category Ll: Letter, lowercase)  
 'c': ASCII/Unicode U+0063 (category Ll: Letter, lowercase)
```

[source](#)

Chapter 55

Reflection and introspection

Julia provides a variety of runtime reflection capabilities.

55.1 Module bindings

The exported names for a Module are available using `names(m::Module)`, which will return an array of `Symbol` elements representing the exported bindings. `names(m::Module, all = true)` returns symbols for all bindings in `m`, regardless of export status.

55.2 DataType fields

The names of `DataType` fields may be interrogated using `fieldnames`. For example, given the following type, `fieldnames(Point)` returns a tuple of `Symbols` representing the field names:

```
julia> struct Point
           x::Int
           y
       end

julia> fieldnames(Point)
(:x, :y)
```

The type of each field in a `Point` object is stored in the `types` field of the `Point` variable itself:

```
julia> Point.types
svec{Int64, Any}
```

While `x` is annotated as an `Int`, `y` was unannotated in the type definition, therefore `y` defaults to the `Any` type.

Types are themselves represented as a structure called `DataType`:

```
julia> typeof(Point)
DataType
```

Note that `fieldnames(DataType)` gives the names for each field of `DataType` itself, and one of these fields is the `types` field observed in the example above.

55.3 Subtypes

The direct subtypes of any `DataType` may be listed using `subtypes`. For example, the abstract `DataType` `AbstractFloat` has four (concrete) subtypes:

```
julia> subtypes(AbstractFloat)
4-element Vector{Any}:
  BigFloat
  Float16
  Float32
  Float64
```

Any abstract subtype will also be included in this list, but further subtypes thereof will not; recursive application of `subtypes` may be used to inspect the full type tree.

55.4 DataType layout

The internal representation of a `DataType` is critically important when interfacing with C code and several functions are available to inspect these details. `isbitstype(T::DataType)` returns true if `T` is stored with C-compatible alignment. `fieldoffset(T::DataType, i::Integer)` returns the (byte) offset for field `i` relative to the start of the type.

55.5 Function methods

The methods of any generic function may be listed using `methods`. The method dispatch table may be searched for methods accepting a given type using `methodswith`.

55.6 Expansion and lowering

As discussed in the [Metaprogramming](#) section, the `macroexpand` function gives the unquoted and interpolated expression (`Expr`) form for a given macro. To use `macroexpand`, quote the expression block itself (otherwise, the macro will be evaluated and the result will be passed instead!). For example:

```
julia> macroexpand(@__MODULE__, :(@edit println("")) )
:(InteractiveUtils.edit(println, (Base.typesof(""))))
```

The functions `Base.Meta.show_sexpr` and `dump` are used to display S-expr style views and depth-nested detail views for any expression.

Finally, the `Meta.lower` function gives the lowered form of any expression and is of particular interest for understanding how language constructs map to primitive operations such as assignments, branches, and calls:

```
julia> Meta.lower(@__MODULE__, :( [1+2, sin(0.5)] ))
:($(Expr(:thunk, CodeInfo(
  @ none within `top-level scope`
  1 - %1 = 1 + 2
  |   %2 = sin(0.5)
  |   %3 = Base.vect(%1, %2)
  └─   return %3
))))
```

55.7 Intermediate and compiled representations

Inspecting the lowered form for functions requires selection of the specific method to display, because generic functions may have many methods with different type signatures. For this purpose, method-specific code-lowering is available using `code_lowered`, and the type-inferred form is available using `code_typed`. `code_warntype` adds highlighting to the output of `code_typed`.

Closer to the machine, the LLVM intermediate representation of a function may be printed using `code_llvm`, and finally the compiled machine code is available using `code_native` (this will trigger JIT compilation/code generation for any function which has not previously been called).

For convenience, there are macro versions of the above functions which take standard function calls and expand argument types automatically:

```
julia> @code_llvm +(1,1)
; @ int.jl:87 within `+`
; Function Attrs: sspstrong uwtable
define i64 @"julia+_476"(i64 signext %0, i64 signext %1) #0 {
top:
    %2 = add i64 %1, %0
    ret i64 %2
}
```

For more information see `@code_lowered`, `@code_typed`, `@code_warntype`, `@code_llvm`, and `@code_native`.

Printing of debug information

The aforementioned functions and macros take the keyword argument `debuginfo` that controls the level debug information printed.

```
julia> @code_typed debuginfo=:source +(1,1)
CodeInfo(
  @ int.jl:53 within `+`
  1 - %1 = Base.add_int(x, y)::Int64
  └─      return %1
) => Int64
```

Possible values for `debuginfo` are: `:none`, `:source`, and `:default`. Per default debug information is not printed, but that can be changed by setting `Base.IRShow.default_debuginfo[] = :source`.

Chapter 56

C Interface

Base.@ccall – Macro.

```
@ccall library.function_name(argvalue1::argtype1, ...)::returntype
@ccall function_name(argvalue1::argtype1, ...)::returntype
@ccall $function_pointer(argvalue1::argtype1, ...)::returntype
```

Call a function in a C-exported shared library, specified by `library.function_name`, where `library` is a string constant or literal. The library may be omitted, in which case the `function_name` is resolved in the current process. Alternatively, `@ccall` may also be used to call a function pointer `$function_pointer`, such as one returned by `dlsym`.

Each `argvalue` to `@ccall` is converted to the corresponding `argtype`, by automatic insertion of calls to `unsafe_convert(argtype, cconvert(argtype, argvalue))`. (See also the documentation for [unsafe_convert](#) and [cconvert](#) for further details.) In most cases, this simply results in a call to `convert(argtype, argvalue)`.

Examples

```
@ccall strlen(s::Cstring)::Csize_t
```

This calls the C standard library function:

```
size_t strlen(char *)
```

with a Julia variable named `s`. See also `ccall`.

Varargs are supported with the following convention:

```
@ccall printf("%s = %d"::Cstring ; "foo"::Cstring, foo::Cint)::Cint
```

The semicolon is used to separate required arguments (of which there must be at least one) from variadic arguments.

Example using an external library:

```
# C signature of g_uri_escape_string:
# char *g_uri_escape_string(const char *unescape, const char *reserved_chars_allowed,
    gboolean allow_utf8);

const glib = "libglib-2.0"
@ccall glib.g_uri_escape_string(my_uri::Cstring, "://"::Cstring, true::Cint)::Cstring
```

The string literal could also be used directly before the function name, if desired `"libglib-2.0".g_uri_escape_string(...`

[source](#)

`ccall` – Keyword.

```
| ccall((function_name, library), returntype, (argtype1, ...), argvalue1, ...)
| ccall(function_name, returntype, (argtype1, ...), argvalue1, ...)
| ccall(function_pointer, returntype, (argtype1, ...), argvalue1, ...)
```

Call a function in a C-exported shared library, specified by the tuple `(function_name, library)`, where each component is either a string or symbol. Instead of specifying a library, one can also use a `function_name` symbol or string, which is resolved in the current process. Alternatively, `ccall` may also be used to call a function pointer `function_pointer`, such as one returned by `dlsym`.

Note that the argument type tuple must be a literal tuple, and not a tuple-valued variable or expression.

Each `argvalue` to the `ccall` will be converted to the corresponding `argtype`, by automatic insertion of calls to `unsafe_convert(argtype, cconvert(argtype, argvalue))`. (See also the documentation for [unsafe_convert](#) and [cconvert](#) for further details.) In most cases, this simply results in a call to `convert(argtype, argvalue)`.

[source](#)

`Core.Intrinsics.cglobal` – Function.

```
| cglobal((symbol, library) [, type=Cvoid])
```

Obtain a pointer to a global variable in a C-exported shared library, specified exactly as in [ccall](#). Returns a `Ptr{Type}`, defaulting to `Ptr{Cvoid}` if no `Type` argument is supplied. The values can be read or written by [unsafe_load](#) or [unsafe_store!](#), respectively.

[source](#)

`Base.@cfunction` – Macro.

```
| @cfunction(callable, ReturnType, (ArgumentTypes...)) -> Ptr{Cvoid}
| @cfunction($callable, ReturnType, (ArgumentTypes...)) -> CFunction
```

Generate a C-callable function pointer from the Julia function `callable` for the given type signature. To pass the return value to a `ccall`, use the argument type `Ptr{Cvoid}` in the signature.

Note that the argument type tuple must be a literal tuple, and not a tuple-valued variable or expression (although it can include a splat expression). And that these arguments will be evaluated in global scope during compile-time (not deferred until runtime). Adding a `'$'` in front of the function argument changes this to instead create a runtime closure over the local variable `callable` (this is not supported on all architectures).

See [manual section on ccall and cfunction usage](#).

Examples

```
| julia> function foo(x::Int, y::Int)
|         return x + y
|     end
|
| julia> @cfunction(foo, Int, (Int, Int))
| Ptr{Cvoid} @0x000000001b82fcd0
```

[source](#)

Base.CFunction – Type.

| CFunction struct

Garbage-collection handle for the return value from `@cfunction` when the first argument is annotated with `'$'`. Like all `cfunction` handles, it should be passed to `ccall` as a `Ptr{Cvoid}`, and will be converted automatically at the call site to the appropriate type.

See [@cfunction](#).

[source](#)

Base.unsafe_convert – Function.

| unsafe_convert(T, x)

Convert `x` to a C argument of type `T` where the input `x` must be the return value of `cconvert(T, ...)`.

In cases where [convert](#) would need to take a Julia object and turn it into a `Ptr`, this function should be used to define and perform that conversion.

Be careful to ensure that a Julia reference to `x` exists as long as the result of this function will be used. Accordingly, the argument `x` to this function should never be an expression, only a variable name or field reference. For example, `x=a.b.c` is acceptable, but `x=[a,b,c]` is not.

The `unsafe` prefix on this function indicates that using the result of this function after the `x` argument to this function is no longer accessible to the program may cause undefined behavior, including program corruption or segfaults, at any later time.

See also [cconvert](#)

[source](#)

Base.cconvert – Function.

| cconvert(T,x)

Convert `x` to a value to be passed to C code as type `T`, typically by calling `convert(T, x)`.

In cases where `x` cannot be safely converted to `T`, unlike [convert](#), `cconvert` may return an object of a type different from `T`, which however is suitable for [unsafe_convert](#) to handle. The result of this function should be kept valid (for the GC) until the result of [unsafe_convert](#) is not needed anymore. This can be used to allocate memory that will be accessed by the `ccall`. If multiple objects need to be allocated, a tuple of the objects can be used as return value.

Neither `convert` nor `cconvert` should take a Julia object and turn it into a `Ptr`.

[source](#)

Base.unsafe_load – Function.

```
unsafe_load(p::Ptr{T}, i::Integer=1)
unsafe_load(p::Ptr{T}, order::Symbol)
unsafe_load(p::Ptr{T}, i::Integer, order::Symbol)
```

Load a value of type `T` from the address of the `i`th element (1-indexed) starting at `p`. This is equivalent to the C expression `p[i-1]`. Optionally, an atomic memory ordering can be provided.

The unsafe prefix on this function indicates that no validation is performed on the pointer `p` to ensure that it is valid. Like C, the programmer is responsible for ensuring that referenced memory is not freed or garbage collected while invoking this function. Incorrect usage may segfault your program or return garbage answers. Unlike C, dereferencing memory region allocated as different type may be valid provided that the types are compatible.

Julia 1.10

The `order` argument is available as of Julia 1.10.

See also: [atomic](#)

[source](#)

`Base.unsafe_store!` – Function.

```
unsafe_store!(p::Ptr{T}, x, i::Integer=1)
unsafe_store!(p::Ptr{T}, x, order::Symbol)
unsafe_store!(p::Ptr{T}, x, i::Integer, order::Symbol)
```

Store a value of type `T` to the address of the `i`th element (1-indexed) starting at `p`. This is equivalent to the C expression `p[i-1] = x`. Optionally, an atomic memory ordering can be provided.

The unsafe prefix on this function indicates that no validation is performed on the pointer `p` to ensure that it is valid. Like C, the programmer is responsible for ensuring that referenced memory is not freed or garbage collected while invoking this function. Incorrect usage may segfault your program. Unlike C, storing memory region allocated as different type may be valid provided that the types are compatible.

Julia 1.10

The `order` argument is available as of Julia 1.10.

See also: [atomic](#)

[source](#)

`Base.unsafe_modify!` – Function.

```
unsafe_modify!(p::Ptr{T}, op, x, [order::Symbol]) -> Pair
```

These atomically perform the operations to get and set a memory address after applying the function `op`. If supported by the hardware (for example, atomic increment), this may be optimized to the appropriate hardware instruction, otherwise its execution will be similar to:

```
y = unsafe_load(p)
z = op(y, x)
unsafe_store!(p, z)
return y => z
```

The unsafe prefix on this function indicates that no validation is performed on the pointer `p` to ensure that it is valid. Like C, the programmer is responsible for ensuring that referenced memory is not freed or garbage collected while invoking this function. Incorrect usage may segfault your program.

Julia 1.10

This function requires at least Julia 1.10.

See also: [modifyproperty!](#), [atomic](#)

[source](#)

`Base.unsafe_replace!` – Function.

```
unsafe_replace!(p::Ptr{T}, expected, desired,
                [success_order::Symbol[, fail_order::Symbol=success_order]]) -> (; old,
                ↪ success::Bool)
```

These atomically perform the operations to get and conditionally set a memory address to a given value. If supported by the hardware, this may be optimized to the appropriate hardware instruction, otherwise its execution will be similar to:

```
y = unsafe_load(p, fail_order)
ok = y === expected
if ok
    unsafe_store!(p, desired, success_order)
end
return (; old = y, success = ok)
```

The unsafe prefix on this function indicates that no validation is performed on the pointer `p` to ensure that it is valid. Like C, the programmer is responsible for ensuring that referenced memory is not freed or garbage collected while invoking this function. Incorrect usage may segfault your program.

Julia 1.10

This function requires at least Julia 1.10.

See also: [replaceproperty!](#), [atomic](#)

[source](#)

`Base.unsafe_swap!` – Function.

```
unsafe_swap!(p::Ptr{T}, x, [order::Symbol])
```

These atomically perform the operations to simultaneously get and set a memory address. If supported by the hardware, this may be optimized to the appropriate hardware instruction, otherwise its execution will be similar to:

```
y = unsafe_load(p)
unsafe_store!(p, x)
return y
```

The unsafe prefix on this function indicates that no validation is performed on the pointer `p` to ensure that it is valid. Like C, the programmer is responsible for ensuring that referenced memory is not freed or garbage collected while invoking this function. Incorrect usage may segfault your program.

Julia 1.10

This function requires at least Julia 1.10.

See also: [swapproperty!](#), [atomic](#)

[source](#)

`Base.unsafe_copyto!` – Method.

```
| unsafe_copyto!(dest::Ptr{T}, src::Ptr{T}, N)
```

Copy N elements from a source pointer to a destination, with no checking. The size of an element is determined by the type of the pointers.

The unsafe prefix on this function indicates that no validation is performed on the pointers `dest` and `src` to ensure that they are valid. Incorrect usage may corrupt or segfault your program, in the same manner as C.

[source](#)

`Base.unsafe_copyto!` – Method.

```
| unsafe_copyto!(dest::Array, do, src::Array, so, N)
```

Copy N elements from a source array to a destination, starting at the linear index `so` in the source and `do` in the destination (1-indexed).

The unsafe prefix on this function indicates that no validation is performed to ensure that N is inbounds on either array. Incorrect usage may corrupt or segfault your program, in the same manner as C.

Warning

Behavior can be unexpected when any mutated argument shares memory with any other argument.

[source](#)

`Base.copyto!` – Function.

```
| copyto!(dest::AbstractMatrix, src::UniformScaling)
```

Copies a [UniformScaling](#) onto a matrix.

Julia 1.1

In Julia 1.0 this method only supported a square destination matrix. Julia 1.1. added support for a rectangular matrix.

```
| copyto!(dest, do, src, so, N)
```

Copy N elements from collection `src` starting at the linear index `so`, to array `dest` starting at the index `do`. Return `dest`.

[source](#)

```
| copyto!(dest::AbstractArray, src) -> dest
```

Copy all elements from collection `src` to array `dest`, whose length must be greater than or equal to the length `n` of `src`. The first n elements of `dest` are overwritten, the other elements are left untouched.

See also [copy!](#), [copy](#).

Examples

```
julia> x = [1., 0., 3., 0., 5.];

julia> y = zeros(7);

julia> copyto!(y, x);

julia> y
7-element Vector{Float64}:
 1.0
 0.0
 3.0
 0.0
 5.0
 0.0
 0.0
```

[source](#)

```
| copyto!(dest, Rdest::CartesianIndices, src, Rsrc::CartesianIndices) -> dest
```

Copy the block of `src` in the range of `Rsrc` to the block of `dest` in the range of `Rdest`. The sizes of the two regions must match.

Examples

```
julia> A = zeros(5, 5);

julia> B = [1 2; 3 4];

julia> Ainds = CartesianIndices((2:3, 2:3));

julia> Binds = CartesianIndices(B);

julia> copyto!(A, Ainds, B, Binds)
5×5 Matrix{Float64}:
 0.0  0.0  0.0  0.0  0.0
 0.0  1.0  2.0  0.0  0.0
 0.0  3.0  4.0  0.0  0.0
 0.0  0.0  0.0  0.0  0.0
 0.0  0.0  0.0  0.0  0.0
```

[source](#)

Base.pointer – Function.

```
| pointer(array [, index])
```

Get the native address of an array or string, optionally at a given location `index`.

This function is "unsafe". Be careful to ensure that a Julia reference to array exists as long as this pointer will be used. The `GC.@preserve` macro should be used to protect the array argument from garbage collection within a given block of code.

Calling `Ref(array[, index])` is generally preferable to this function as it guarantees validity.

[source](#)

`Base.unsafe_wrap` – Method.

```
| unsafe_wrap(Array, pointer::Ptr{T}, dims; own = false)
```

Wrap a Julia Array object around the data at the address given by `pointer`, without making a copy. The pointer element type `T` determines the array element type. `dims` is either an integer (for a 1d array) or a tuple of the array dimensions. `own` optionally specifies whether Julia should take ownership of the memory, calling `free` on the pointer when the array is no longer referenced.

This function is labeled "unsafe" because it will crash if `pointer` is not a valid memory address to data of the requested length. Unlike [unsafe_load](#) and [unsafe_store!](#), the programmer is responsible also for ensuring that the underlying data is not accessed through two arrays of different element type, similar to the strict aliasing rule in C.

[source](#)

`Base.pointer_from_objref` – Function.

```
| pointer_from_objref(x)
```

Get the memory address of a Julia object as a `Ptr`. The existence of the resulting `Ptr` will not protect the object from garbage collection, so you must ensure that the object remains referenced for the whole time that the `Ptr` will be used.

This function may not be called on immutable objects, since they do not have stable memory addresses.

See also [unsafe_pointer_to_objref](#).

[source](#)

`Base.unsafe_pointer_to_objref` – Function.

```
| unsafe_pointer_to_objref(p::Ptr)
```

Convert a `Ptr` to an object reference. Assumes the pointer refers to a valid heap-allocated Julia object. If this is not the case, undefined behavior results, hence this function is considered "unsafe" and should be used with care.

See also [pointer_from_objref](#).

[source](#)

`Base.disable_sigint` – Function.

```
| disable_sigint(f::Function)
```

Disable Ctrl-C handler during execution of a function on the current task, for calling external code that may call julia code that is not interrupt safe. Intended to be called using `do` block syntax as follows:

```
| disable_sigint() do
    # interrupt-unsafe code
    ...
end
```

This is not needed on worker threads (`Threads.threadid() != 1`) since the `InterruptException` will only be delivered to the master thread. External functions that do not call julia code or julia runtime automatically disable `sigint` during their execution.

[source](#)

Base.reenable_sigint – Function.

```
| reenable_sigint(f::Function)
```

Re-enable Ctrl-C handler during execution of a function. Temporarily reverses the effect of [disable_sigint](#).

[source](#)

Base.exit_on_sigint – Function.

```
| exit_on_sigint(on::Bool)
```

Set `exit_on_sigint` flag of the julia runtime. If false, Ctrl-C (SIGINT) is capturable as [InterruptException](#) in try block. This is the default behavior in REPL, any code run via `-e` and `-E` and in Julia script run with `-i` option.

If true, [InterruptException](#) is not thrown by Ctrl-C. Running code upon such event requires [atexit](#). This is the default behavior in Julia script run without `-i` option.

Julia 1.5

Function `exit_on_sigint` requires at least Julia 1.5.

[source](#)

Base.systemerror – Function.

```
| systemerror(sysfunc[, errno::Cint=Libc.errno()])
| systemerror(sysfunc, iftrue::Bool)
```

Raises a `SystemError` for `errno` with the descriptive string `sysfunc` if `iftrue` is true

[source](#)

Base.windowerror – Function.

```
| windowerror(sysfunc[, code::UInt32=Libc.GetLastError()])
| windowerror(sysfunc, iftrue::Bool)
```

Like [systemerror](#), but for Windows API functions that use [GetLastError](#) to return an error code instead of setting `errno`.

[source](#)

Core.Ptr – Type.

```
| Ptr{T}
```

A memory address referring to data of type `T`. However, there is no guarantee that the memory is actually valid, or that it actually represents data of the specified type.

[source](#)

Core.Ref – Type.

```
| Ref{T}
```

An object that safely references data of type `T`. This type is guaranteed to point to valid, Julia-allocated memory of the correct type. The underlying data is protected from freeing by the garbage collector as long as the `Ref` itself is referenced.

In Julia, `Ref` objects are dereferenced (loaded or stored) with `[]`.

Creation of a `Ref` to a value `x` of type `T` is usually written `Ref(x)`. Additionally, for creating interior pointers to containers (such as `Array` or `Ptr`), it can be written `Ref(a, i)` for creating a reference to the `i`-th element of `a`.

`Ref{T}()` creates a reference to a value of type `T` without initialization. For a `bitstype` `T`, the value will be whatever currently resides in the memory allocated. For a non-`bitstype` `T`, the reference will be undefined and attempting to dereference it will result in an error, "UndefRefError: access to undefined reference".

To check if a `Ref` is an undefined reference, use `isassigned(ref::RefValue)`. For example, `isassigned(Ref{T}())` is `false` if `T` is not a `bitstype`. If `T` is a `bitstype`, `isassigned(Ref{T}())` will always be `true`.

When passed as a `ccall` argument (either as a `Ptr` or `Ref` type), a `Ref` object will be converted to a native pointer to the data it references. For most `T`, or when converted to a `Ptr{Cvoid}`, this is a pointer to the object data. When `T` is an `isbits` type, this value may be safely mutated, otherwise mutation is strictly undefined behavior.

As a special case, setting `T = Any` will instead cause the creation of a pointer to the reference itself when converted to a `Ptr{Any}` (a `jl_value_t const* const*` if `T` is immutable, else a `jl_value_t *const *`). When converted to a `Ptr{Cvoid}`, it will still return a pointer to the data region as for any other `T`.

A `C_NULL` instance of `Ptr` can be passed to a `ccall` `Ref` argument to initialize it.

Use in broadcasting

`Ref` is sometimes used in broadcasting in order to treat the referenced values as a scalar.

Examples

```
julia> Ref{5}
Base.RefValue{Int64}{5}

julia> isa.(Ref{[1,2,3]}, [Array, Dict, Int]) # Treat reference values as scalar during
↔ broadcasting
3-element BitVector:
 1
 0
 0

julia> Ref{Function}() # Undefined reference to a non-bitstype, Function
Base.RefValue{Function}{#undef}

julia> try
    Ref{Function}()[1] # Dereferencing an undefined reference will result in an error
catch e
    println(e)
end
UndefRefError()
```

```
julia> Ref{Int64}{}[]; # A reference to a bitstype refers to an undetermined value if not
↪ given

julia> isassigned(Ref{Int64}()) # A reference to a bitstype is always assigned
true

julia> Ref{Int64}{}[] == 0 # Explicitly give a value for a bitstype reference
true
```

[source](#)

Base.isassigned - Method.

```
| isassigned(ref::RefValue) -> Bool
```

Test whether the given [Ref](#) is associated with a value. This is always true for a [Ref](#) of a bitstype object. Return false if the reference is undefined.

Examples

```
julia> ref = Ref{Function}{}
Base.RefValue{Function}{}(undef)

julia> isassigned(ref)
false

julia> ref[] = (foobar(x) = x)
foobar (generic function with 1 method)

julia> isassigned(ref)
true

julia> isassigned(Ref{Int}{}())
true
```

[source](#)

Base.Cchar - Type.

```
| Cchar
```

Equivalent to the native char c-type.

[source](#)

Base.Cuchar - Type.

```
| Cuchar
```

Equivalent to the native unsigned char c-type ([UInt8](#)).

[source](#)

Base.Cshort - Type.

```
| Cshort
```

Equivalent to the native signed short c-type ([Int16](#)).

[source](#)

Base.Cstring – Type.

| **Cstring**

A C-style string composed of the native character type [Cchars](#). Cstrings are NUL-terminated. For C-style strings composed of the native wide character type, see [Cwstring](#). For more information about string interoperability with C, see the [manual](#).

[source](#)

Base.Cushort – Type.

| **Cushort**

Equivalent to the native unsigned short c-type ([UInt16](#)).

[source](#)

Base.Cint – Type.

| **Cint**

Equivalent to the native signed int c-type ([Int32](#)).

[source](#)

Base.Cuint – Type.

| **Cuint**

Equivalent to the native unsigned int c-type ([UInt32](#)).

[source](#)

Base.Clong – Type.

| **Clong**

Equivalent to the native signed long c-type.

[source](#)

Base.Culong – Type.

| **Culong**

Equivalent to the native unsigned long c-type.

[source](#)

Base.Clonglong – Type.

| **Clonglong**

Equivalent to the native signed long long c-type ([Int64](#)).

Chapter 57

LLVM Interface

Core.Intrinsics.llvmcall - Function.

```
llvmcall(fun_ir::String, returntype, Tuple{argtype1, ...}, argvalue1, ...)
llvmcall((mod_ir::String, entry_fn::String), returntype, Tuple{argtype1, ...}, argvalue1,
↪ ...)
llvmcall((mod_bc::Vector{UInt8}, entry_fn::String), returntype, Tuple{argtype1, ...},
↪ argvalue1, ...)
```

Call the LLVM code provided in the first argument. There are several ways to specify this first argument:

- as a literal string, representing function-level IR (similar to an LLVM define block), with arguments are available as consecutive unnamed SSA variables (%0, %1, etc.);
- as a 2-element tuple, containing a string of module IR and a string representing the name of the entry-point function to call;
- as a 2-element tuple, but with the module provided as an Vector{UInt8} with bytecode.

Note that contrary to ccall, the argument types must be specified as a tuple type, and not a tuple of types. All types, as well as the LLVM code, should be specified as literals, and not as variables or expressions (it may be necessary to use @eval to generate these literals).

See test/llvmcall.jl for usage examples.

[source](#)

Chapter 58

C Standard Library

Base.Libc.malloc – Function.

```
| malloc(size::Integer) -> Ptr{Cvoid}
```

Call malloc from the C standard library.

[source](#)

Base.Libc.calloc – Function.

```
| calloc(num::Integer, size::Integer) -> Ptr{Cvoid}
```

Call calloc from the C standard library.

[source](#)

Base.Libc.realloc – Function.

```
| realloc(addr::Ptr, size::Integer) -> Ptr{Cvoid}
```

Call realloc from the C standard library.

See warning in the documentation for [free](#) regarding only using this on memory originally obtained from [malloc](#).

[source](#)

Base.memcpy – Function.

```
| memcpy(dst::Ptr, src::Ptr, n::Integer) -> Ptr{Cvoid}
```

Call memcpy from the C standard library.

Julia 1.10

Support for memcpy requires at least Julia 1.10.

[source](#)

Base.memmove – Function.

```
| memmove(dst::Ptr, src::Ptr, n::Integer) -> Ptr{Cvoid}
```

Call memmove from the C standard library.

Julia 1.10

Support for memmove requires at least Julia 1.10.

source

Base.memset – Function.

```
| memset(dst::Ptr, val, n::Integer) -> Ptr{Cvoid}
```

Call memset from the C standard library.

Julia 1.10

Support for memset requires at least Julia 1.10.

source

Base.memcmp – Function.

```
| memcmp(a::Ptr, b::Ptr, n::Integer) -> Int
```

Call memcmp from the C standard library.

Julia 1.10

Support for memcmp requires at least Julia 1.9.

source

Base.Libc.free – Function.

```
| free(addr::Ptr)
```

Call free from the C standard library. Only use this on memory obtained from `malloc`, not on pointers retrieved from other C libraries. `Ptr` objects obtained from C libraries should be freed by the free functions defined in that library, to avoid assertion failures if multiple `libc` libraries exist on the system.

source

Base.Libc.errno – Function.

```
| errno([code])
```

Get the value of the C library's `errno`. If an argument is specified, it is used to set the value of `errno`.

The value of `errno` is only valid immediately after a `ccall` to a C library routine that sets it. Specifically, you cannot call `errno` at the next prompt in a REPL, because lots of code is executed between prompts.

source

Base.Libc.strerror – Function.

```
| strerror(n=errno())
```

Convert a system call error code to a descriptive string

[source](#)

Base.Libc.GetLastError – Function.

```
| GetLastError()
```

Call the Win32 GetLastError function [only available on Windows].

[source](#)

Base.Libc.FormatMessage – Function.

```
| FormatMessage(n=GetLastError())
```

Convert a Win32 system call error code to a descriptive string [only available on Windows].

[source](#)

Base.Libc.time – Method.

```
| time(t::TmStruct) -> Float64
```

Converts a TmStruct struct to a number of seconds since the epoch.

[source](#)

Base.Libc.strptime – Function.

```
| strftime([format], time)
```

Convert time, given as a number of seconds since the epoch or a TmStruct, to a formatted string using the given format. Supported formats are the same as those in the standard C library.

[source](#)

Base.Libc.strptime – Function.

```
|.strptime([format], timestr)
```

Parse a formatted time string into a TmStruct giving the seconds, minute, hour, date, etc. Supported formats are the same as those in the standard C library. On some platforms, timezones will not be parsed correctly. If the result of this function will be passed to time to convert it to seconds since the epoch, the isdst field should be filled in manually. Setting it to -1 will tell the C library to use the current system settings to determine the timezone.

[source](#)

Base.Libc.TmStruct – Type.

```
| TmStruct([seconds])
```

Convert a number of seconds since the epoch to broken-down format, with fields sec, min, hour, mday, month, year, wday, yday, and isdst.

[source](#)

`Base.Libc.flush_cstdio` – Function.

| `flush_cstdio()`

Flushes the C stdout and stderr streams (which may have been written to by external C code).

[source](#)

`Base.Libc.systemsleep` – Function.

| `systemsleep(s::Real)`

Suspends execution for `s` seconds. This function does not yield to Julia's scheduler and therefore blocks the Julia thread that it is running on for the duration of the sleep time.

See also [sleep](#).

[source](#)

Chapter 59

StackTraces

Base.StackTraces.StackFrame – Type.

| StackFrame

Stack information representing execution context, with the following fields:

- `func::Symbol`
The name of the function containing the execution context.
- `linfo::Union{Core.MethodInstance, Method, Module, Core.CodeInfo, Nothing}`
The MethodInstance or CodeInfo containing the execution context (if it could be found), or Module (for macro expansions)"
- `file::Symbol`
The path to the file containing the execution context.
- `line::Int`
The line number in the file containing the execution context.
- `from_c::Bool`
True if the code is from C.
- `inlined::Bool`
True if the code is from an inlined frame.
- `pointer::UInt64`
Representation of the pointer to the execution context as returned by `backtrace`.

[source](#)

Base.StackTraces.StackTrace – Type.

| StackTrace

An alias for `Vector{StackFrame}` provided for convenience; returned by calls to `stacktrace`.

[source](#)

Base.StackTraces.stacktrace – Function.

```
| stacktrace([trace::Vector{Ptr{Cvoid}},] [c_funcs::Bool=false]) -> StackTrace
```

Return a stack trace in the form of a vector of StackFrames. (By default stacktrace doesn't return C functions, but this can be enabled.) When called without specifying a trace, stacktrace first calls backtrace.

[source](#)

The following methods and types in Base.StackTrace are not exported and need to be called e.g. as StackTraces.lookup(ptr).

Base.StackTrace.lookup – Function.

```
| lookup(pointer::Ptr{Cvoid}) -> Vector{StackFrame}
```

Given a pointer to an execution context (usually generated by a call to backtrace), looks up stack frame context information. Returns an array of frame information for all functions inlined at that point, innermost function first.

[source](#)

Base.StackTrace.remove_frames! – Function.

```
| remove_frames!(stack::StackTrace, name::Symbol)
```

Takes a StackTrace (a vector of StackFrames) and a function name (a Symbol) and removes the StackFrame specified by the function name from the StackTrace (also removing all frames above the specified function). Primarily used to remove StackTraces functions from the StackTrace prior to returning it.

[source](#)

```
| remove_frames!(stack::StackTrace, m::Module)
```

Return the StackTrace with all StackFrames from the provided Module removed.

[source](#)

Chapter 60

SIMD Support

Type `VecElement{T}` is intended for building libraries of SIMD operations. Practical use of it requires using `llvmcall`. The type is defined as:

```
struct VecElement{T}
    value::T
end
```

It has a special compilation rule: a homogeneous tuple of `VecElement{T}` maps to an LLVM vector type when `T` is a primitive bits type.

At `-O3`, the compiler might automatically vectorize operations on such tuples. For example, the following program, when compiled with `julia -O3` generates two SIMD addition instructions (`addps`) on x86 systems:

```
const m128 = NTuple{4,VecElement{Float32}}

function add(a::m128, b::m128)
    (VecElement(a[1].value+b[1].value),
     VecElement(a[2].value+b[2].value),
     VecElement(a[3].value+b[3].value),
     VecElement(a[4].value+b[4].value))
end

triple(c::m128) = add(add(c,c),c)

code_native(triple,(m128,))
```

However, since the automatic vectorization cannot be relied upon, future use will mostly be via libraries that use `llvmcall`.

Part III

Standard Library

Chapter 61

ArgTools

61.1 Argument Handling

ArgTools.ArgRead – Type.

```
| ArgRead = Union{AbstractString, AbstractCmd, IO}
```

The ArgRead types is a union of the types that the `arg_read` function knows how to convert into readable IO handles. See [arg_read](#) for details.

ArgTools.ArgWrite – Type.

```
| ArgWrite = Union{AbstractString, AbstractCmd, IO}
```

The ArgWrite types is a union of the types that the `arg_write` function knows how to convert into writeable IO handles, except for `Nothing` which `arg_write` handles by generating a temporary file. See [arg_write](#) for details.

ArgTools.arg_read – Function.

```
| arg_read(f::Function, arg::ArgRead) -> f(arg_io)
```

The `arg_read` function accepts an argument `arg` that can be any of these:

- `AbstractString`: a file path to be opened for reading
- `AbstractCmd`: a command to be run, reading from its standard output
- `IO`: an open IO handle to be read from

Whether the body returns normally or throws an error, a path which is opened will be closed before returning from `arg_read` and an `IO` handle will be flushed but not closed before returning from `arg_read`.

Note: when opening a file, ArgTools will pass `lock = false` to the file `open(...)` call. Therefore, the object returned by this function should not be used from multiple threads. This restriction may be relaxed in the future, which would not break any working code.

ArgTools.arg_write – Function.

```
| arg_write(f::Function, arg::ArgWrite) -> arg  
| arg_write(f::Function, arg::Nothing) -> tempname()
```

The `arg_read` function accepts an argument `arg` that can be any of these:

- `AbstractString`: a file path to be opened for writing
- `AbstractCmd`: a command to be run, writing to its standard input
- `IO`: an open IO handle to be written to
- `Nothing`: a temporary path should be written to

If the body returns normally, a path that is opened will be closed upon completion; an IO handle argument is left open but flushed before return. If the argument is `nothing` then a temporary path is opened for writing and closed upon completion and the path is returned from `arg_write`. In all other cases, `arg` itself is returned. This is a useful pattern since you can consistently return whatever was written, whether an argument was passed or not.

If there is an error during the evaluation of the body, a path that is opened by `arg_write` for writing will be deleted, whether it's passed in as a string or a temporary path generated when `arg` is `nothing`.

Note: when opening a file, `ArgTools` will pass `lock = false` to the `file open(...)` call. Therefore, the object returned by this function should not be used from multiple threads. This restriction may be relaxed in the future, which would not break any working code.

`ArgTools.arg_isdir` - Function.

```
| arg_isdir(f::Function, arg::AbstractString) -> f(arg)
```

The `arg_isdir` function takes `arg` which must be the path to an existing directory (an error is raised otherwise) and passes that path to `f` finally returning the result of `f(arg)`. This is definitely the least useful tool offered by `ArgTools` and mostly exists for symmetry with `arg_mkdir` and to give consistent error messages.

`ArgTools.arg_mkdir` - Function.

```
| arg_mkdir(f::Function, arg::AbstractString) -> arg
| arg_mkdir(f::Function, arg::Nothing) -> mktempdir()
```

The `arg_mkdir` function takes `arg` which must either be one of:

- a path to an already existing empty directory,
- a non-existent path which can be created as a directory, or
- `nothing` in which case a temporary directory is created.

In all cases the path to the directory is returned. If an error occurs during `f(arg)`, the directory is returned to its original state: if it already existed but was empty, it will be emptied; if it did not exist it will be deleted.

61.2 Function Testing

`ArgTools.arg_readers` - Function.

```

arg_readers(arg :: AbstractString, [ type = ArgRead ]) do arg::Function
  ## pre-test setup ##
  @arg_test arg begin
    arg :: ArgRead
    ## test using `arg` ##
  end
  ## post-test cleanup ##
end

```

The `arg_readers` function takes a path to be read and a single-argument do block, which is invoked once for each test reader type that `arg_read` can handle. If the optional type argument is given then the do block is only invoked for readers that produce arguments of that type.

The `arg` passed to the do block is not the argument value itself, because some of test argument types need to be initialized and finalized for each test case. Consider an open file handle argument: once you've used it for one test, you can't use it again; you need to close it and open the file again for the next test. This function `arg` can be converted into an `ArgRead` instance using `@arg_test arg begin ... end`.

`ArgTools.arg_writers` - Function.

```

arg_writers([ type = ArgWrite ]) do path::String, arg::Function
  ## pre-test setup ##
  @arg_test arg begin
    arg :: ArgWrite
    ## test using `arg` ##
  end
  ## post-test cleanup ##
end

```

The `arg_writers` function takes a do block, which is invoked once for each test writer type that `arg_write` can handle with a temporary (non-existent) path and `arg` which can be converted into various writable argument types which write to path. If the optional type argument is given then the do block is only invoked for writers that produce arguments of that type.

The `arg` passed to the do block is not the argument value itself, because some of test argument types need to be initialized and finalized for each test case. Consider an open file handle argument: once you've used it for one test, you can't use it again; you need to close it and open the file again for the next test. This function `arg` can be converted into an `ArgWrite` instance using `@arg_test arg begin ... end`.

There is also an `arg_writers` method that takes a path name like `arg_readers`:

```

arg_writers(path::AbstractString, [ type = ArgWrite ]) do arg::Function
  ## pre-test setup ##
  @arg_test arg begin
    # here `arg` :: ArgWrite`
    ## test using `arg` ##
  end
  ## post-test cleanup ##
end

```

This method is useful if you need to specify path instead of using path name generated by `tempname()`. Since `path` is passed from outside of `arg_writers`, the path is not an argument to the do block in this form.

ArgTools.@arg_test - Macro.

```
| @arg_test arg1 arg2 ... body
```

The @arg_test macro is used to convert arg functions provided by arg_readers and arg_writers into actual argument values. When you write @arg_test arg body it is equivalent to arg(arg -> body).

Chapter 62

Artifacts

Starting with Julia 1.6, the artifacts support has moved from `Pkg.jl` to Julia itself. Until proper documentation can be added here, you can learn more about artifacts in the `Pkg.jl` manual at <https://julialang.github.io/Pkg.jl/v1/artifacts/>.

Julia 1.6

Julia's artifacts API requires at least Julia 1.6. In Julia versions 1.3 to 1.5, you can use `Pkg.Artifacts` instead.

`Artifacts.artifact_meta` – Function.

```
artifact_meta(name::String, artifacts_toml::String;  
              platform::AbstractPlatform = HostPlatform(),  
              pkg_uuid::Union{Base.UUID,Nothing}=nothing)
```

Get metadata about a given artifact (identified by name) stored within the given (Julia)`Artifacts.toml` file. If the artifact is platform-specific, use `platform` to choose the most appropriate mapping. If none is found, return `nothing`.

Julia 1.3

This function requires at least Julia 1.3.

`Artifacts.artifact_hash` – Function.

```
artifact_hash(name::String, artifacts_toml::String;  
              platform::AbstractPlatform = HostPlatform())
```

Thin wrapper around `artifact_meta()` to return the hash of the specified, platform- collapsed artifact. Returns `nothing` if no mapping can be found.

Julia 1.3

This function requires at least Julia 1.3.

`Artifacts.find_artifacts_toml` – Function.

```
find_artifacts_toml(path::String)
```

Given the path to a .jl file, (such as the one returned by `__source__.file` in a macro context), find the `(Julia)Artifacts.toml` that is contained within the containing project (if it exists), otherwise return nothing.

Julia 1.3

This function requires at least Julia 1.3.

`Artifacts.@artifact_str` - Macro.

```
| macro artifact_str(name)
```

Return the on-disk path to an artifact. Automatically looks the artifact up by name in the project's `(Julia)Artifacts.toml` file. Throws an error on if the requested artifact is not present. If run in the REPL, searches for the toml file starting in the current directory, see `find_artifacts_toml()` for more.

If the artifact is marked "lazy" and the package has using `LazyArtifacts` defined, the artifact will be downloaded on-demand with `Pkg` the first time this macro tries to compute the path. The files will then be left installed locally for later.

If `name` contains a forward or backward slash, all elements after the first slash will be taken to be path names indexing into the artifact, allowing for an easy one-liner to access a single file/directory within an artifact. Example:

```
| ffmpeg_path = @artifact"FFMPEG/bin/ffmpeg"
```

Julia 1.3

This macro requires at least Julia 1.3.

Julia 1.6

Slash-indexing requires at least Julia 1.6.

Chapter 63

Base64

Base64.Base64 – Module.

| Base64

Functionality for [base64 encoding and decoding](#), a method to represent binary data using text, common on the web.

Base64.Base64EncodePipe – Type.

| **Base64EncodePipe**(ostream)

Return a new write-only I/O stream, which converts any bytes written to it into base64-encoded ASCII bytes written to ostream. Calling [close](#) on the Base64EncodePipe stream is necessary to complete the encoding (but does not close ostream).

Examples

```
julia> io = IOBuffer();  
  
julia> iob64_encode = Base64EncodePipe(io);  
  
julia> write(iob64_encode, "Hello!")  
6  
  
julia> close(iob64_encode);  
  
julia> str = String(take!(io))  
"SGVsbG8h"  
  
julia> String(base64decode(str))  
"Hello!"
```

Base64.base64encode – Function.

```
| base64encode(writefunc, args...; context=nothing)  
| base64encode(args...; context=nothing)
```

Given a [write](#)-like function `writfunc`, which takes an I/O stream as its first argument, `base64encode(writfunc, args...)` calls `writfunc` to write `args...` to a base64-encoded string, and returns the string. `base64encode(args...)` is equivalent to `base64encode(write, args...)`: it converts its arguments into bytes using the standard [write](#) functions and returns the base64-encoded string.

The optional keyword argument `context` can be set to `:key=>value` pair or an `I0` or [I0Context](#) object whose attributes are used for the I/O stream passed to `writfunc` or `write`.

See also [base64decode](#).

`Base64.Base64DecodePipe` – Type.

```
| Base64DecodePipe(istream)
```

Return a new read-only I/O stream, which decodes base64-encoded data read from `istream`.

Examples

```
julia> io = IOBuffer();
julia> iob64_decode = Base64DecodePipe(io);
julia> write(io, "SGVsbG8h")
8
julia> seekstart(io);
julia> String(read(iob64_decode))
"Hello!"
```

`Base64.base64decode` – Function.

```
| base64decode(string)
```

Decode the base64-encoded string and returns a `Vector{UInt8}` of the decoded bytes.

See also [base64encode](#).

Examples

```
julia> b = base64decode("SGVsbG8h")
6-element Vector{UInt8}:
 0x48
 0x65
 0x6c
 0x6c
 0x6f
 0x21
julia> String(b)
"Hello!"
```

`Base64.stringmime` – Function.

```
| stringmime(mime, x; context=nothing)
```

Return an `AbstractString` containing the representation of `x` in the requested `mime` type. This is similar to `repr(mime, x)` except that binary data is base64-encoded as an ASCII string.

The optional keyword argument `context` can be set to `:key=>value` pair or an `I0` or `I0Context` object whose attributes are used for the I/O stream passed to `show`.

Chapter 64

CRC32c

Standard library module for computing the CRC-32c checksum.

CRC32c.crc32c – Function.

```
| crc32c(data, crc::UInt32=0x00000000)
```

Compute the CRC-32c checksum of the given data, which can be an `Array{UInt8}`, a contiguous subarray thereof, or a `String`. Optionally, you can pass a starting `crc` integer to be mixed in with the checksum. The `crc` parameter can be used to compute a checksum on data divided into chunks: performing `crc32c(data2, crc32c(data1))` is equivalent to the checksum of `[data1; data2]`. (Technically, a little-endian checksum is computed.)

There is also a method `crc32c(io, nb, crc)` to checksum `nb` bytes from a stream `io`, or `crc32c(io, crc)` to checksum all the remaining bytes. Hence you can do `open(crc32c, filename)` to checksum an entire file, or `crc32c(seekstart(buf))` to checksum an `IOBuffer` without calling `take!`.

For a `String`, note that the result is specific to the UTF-8 encoding (a different checksum would be obtained from a different Unicode encoding). To checksum an `a::Array` of some other bitstype, you can do `crc32c(reinterpret(UInt8,a))`, but note that the result may be endian-dependent.

CRC32c.crc32c – Method.

```
| crc32c(io::IO, [nb::Integer,] crc::UInt32=0x00000000)
```

Read up to `nb` bytes from `io` and return the CRC-32c checksum, optionally mixed with a starting `crc` integer. If `nb` is not supplied, then `io` will be read until the end of the stream.

Chapter 65

Dates

The Dates module provides two types for working with dates: `Date` and `DateTime`, representing day and millisecond precision, respectively; both are subtypes of the abstract `TimeType`. The motivation for distinct types is simple: some operations are much simpler, both in terms of code and mental reasoning, when the complexities of greater precision don't have to be dealt with. For example, since the `Date` type only resolves to the precision of a single date (i.e. no hours, minutes, or seconds), normal considerations for time zones, daylight savings/summer time, and leap seconds are unnecessary and avoided.

Both `Date` and `DateTime` are basically immutable `Int64` wrappers. The single instant field of either type is actually a `UTInstant{P}` type, which represents a continuously increasing machine timeline based on the UT second¹. The `DateTime` type is not aware of time zones (naive, in Python parlance), analogous to a `LocalDateTime` in Java 8. Additional time zone functionality can be added through the `TimeZones.jl` package, which compiles the [IANA time zone database](#). Both `Date` and `DateTime` are based on the [ISO 8601](#) standard, which follows the proleptic Gregorian calendar. One note is that the ISO 8601 standard is particular about BC/BCE dates. In general, the last day of the BC/BCE era, 1-12-31 BC/BCE, was followed by 1-1-1 AD/CE, thus no year zero exists. The ISO standard, however, states that 1 BC/BCE is year zero, so 0000-12-31 is the day before 0001-01-01, and year -0001 (yes, negative one for the year) is 2 BC/BCE, year -0002 is 3 BC/BCE, etc.

65.1 Constructors

`Date` and `DateTime` types can be constructed by integer or `Period` types, by parsing, or through adjusters (more on those later):

```
julia> DateTime(2013)
2013-01-01T00:00:00

julia> DateTime(2013, 7)
2013-07-01T00:00:00
```

¹The notion of the UT second is actually quite fundamental. There are basically two different notions of time generally accepted, one based on the physical rotation of the earth (one full rotation = 1 day), the other based on the SI second (a fixed, constant value). These are radically different! Think about it, a "UT second", as defined relative to the rotation of the earth, may have a different absolute length depending on the day! Anyway, the fact that `Date` and `DateTime` are based on UT seconds is a simplifying, yet honest assumption so that things like leap seconds and all their complexity can be avoided. This basis of time is formally called `UT` or `UT1`. Basing types on the UT second basically means that every minute has 60 seconds and every day has 24 hours and leads to more natural calculations when working with calendar dates.

```

julia> DateTime(2013,7,1)
2013-07-01T00:00:00

julia> DateTime(2013,7,1,12)
2013-07-01T12:00:00

julia> DateTime(2013,7,1,12,30)
2013-07-01T12:30:00

julia> DateTime(2013,7,1,12,30,59)
2013-07-01T12:30:59

julia> DateTime(2013,7,1,12,30,59,1)
2013-07-01T12:30:59.001

julia> Date(2013)
2013-01-01

julia> Date(2013,7)
2013-07-01

julia> Date(2013,7,1)
2013-07-01

julia> Date(Dates.Year(2013),Dates.Month(7),Dates.Day(1))
2013-07-01

julia> Date(Dates.Month(7),Dates.Year(2013))
2013-07-01

```

`Date` or `DateTime` parsing is accomplished by the use of format strings. Format strings work by the notion of defining delimited or fixed-width "slots" that contain a period to parse and passing the text to parse and format string to a `Date` or `DateTime` constructor, of the form `Date("2015-01-01", dateformat"y-m-d")` or `DateTime("20150101", dateformat"yyyymmdd")`.

Delimited slots are marked by specifying the delimiter the parser should expect between two subsequent periods; so "y-m-d" lets the parser know that between the first and second slots in a date string like "2014-07-16", it should find the - character. The y, m, and d characters let the parser know which periods to parse in each slot.

As in the case of constructors above such as `Date(2013)`, delimited `DateFormats` allow for missing parts of dates and times so long as the preceding parts are given. The other parts are given the usual default values. For example, `Date("1981-03", dateformat"y-m-d")` returns 1981-03-01, whilst `Date("31/12", dateformat"d/m/y")` gives 0001-12-31. (Note that the default year is 1 AD/CE.) An empty string, however, always throws an `ArgumentError`.

Fixed-width slots are specified by repeating the period character the number of times corresponding to the width with no delimiter between characters. So `dateformat"yyyymmdd"` would correspond to a date string like "20140716". The parser distinguishes a fixed-width slot by the absence of a delimiter, noting the transition "yyyymm" from one period character to the next.

Support for text-form month parsing is also supported through the u and U characters, for abbreviated and full-length month names, respectively. By default, only English month names are supported, so u corre-

sponds to "Jan", "Feb", "Mar", etc. And U corresponds to "January", "February", "March", etc. Similar to other name=>value mapping functions `dayname` and `monthname`, custom locales can be loaded by passing in the `locale=>Dict{String,Int}` mapping to the `MONTHTOVALUEABBR` and `MONTHTOVALUE` dicts for abbreviated and full-name month names, respectively.

The above examples used the `dateformat""` string macro. This macro creates a `DateFormat` object once when the macro is expanded and uses the same `DateFormat` object even if a code snippet is run multiple times.

```
julia> for i = 1:10^5
        Date("2015-01-01", dateformat"y-m-d")
    end
```

Or you can create the `DateFormat` object explicitly:

```
julia> df = DateFormat("y-m-d");

julia> dt = Date("2015-01-01", df)
2015-01-01

julia> dt2 = Date("2015-01-02", df)
2015-01-02
```

Alternatively, use broadcasting:

```
julia> years = ["2015", "2016"];

julia> Date.(years, DateFormat("yyyy"))
2-element Vector{Date}:
 2015-01-01
 2016-01-01
```

For convenience, you may pass the format string directly (e.g., `Date("2015-01-01", "y-m-d")`), although this form incurs performance costs if you are parsing the same format repeatedly, as it internally creates a new `DateFormat` object each time.

As well as via the constructors, a `Date` or `DateTime` can be constructed from strings using the `parse` and `tryparse` functions, but with an optional third argument of type `DateFormat` specifying the format; for example, `parse(Date, "06.23.2013", dateformat"m.d.y")`, or `tryparse(DateTime, "1999-12-31T23:59:59")` which uses the default format. The notable difference between the functions is that with `tryparse`, an error is not thrown if the string is empty or in an invalid format; instead nothing is returned.

Julia 1.9

Before Julia 1.9, empty strings could be passed to constructors and `parse` without error, returning as appropriate `DateTime(1)`, `Date(1)` or `Time(0)`. Likewise, `tryparse` did not return nothing.

A full suite of parsing and formatting tests and examples is available in [stdlib/Dates/test/io.jl](#).

65.2 Durations/Comparisons

Finding the length of time between two `Date` or `DateTime` is straightforward given their underlying representation as `UTInstant{Day}` and `UTInstant{Millisecond}`, respectively. The difference between `Date` is returned in the number of `Day`, and `DateTime` in the number of `Millisecond`. Similarly, comparing `TimeType` is a simple matter of comparing the underlying machine instants (which in turn compares the internal `Int64` values).

```
julia> dt = Date(2012,2,29)
2012-02-29

julia> dt2 = Date(2000,2,1)
2000-02-01

julia> dump(dt)
Date
  instant: Dates.UTInstant{Day}
  periods: Day
  value: Int64 734562

julia> dump(dt2)
Date
  instant: Dates.UTInstant{Day}
  periods: Day
  value: Int64 730151

julia> dt > dt2
true

julia> dt != dt2
true

julia> dt + dt2
ERROR: MethodError: no method matching +(::Date, ::Date)
[...]

julia> dt * dt2
ERROR: MethodError: no method matching *(::Date, ::Date)
[...]

julia> dt / dt2
ERROR: MethodError: no method matching /(::Date, ::Date)

julia> dt - dt2
4411 days

julia> dt2 - dt
-4411 days

julia> dt = DateTime(2012,2,29)
2012-02-29T00:00:00

julia> dt2 = DateTime(2000,2,1)
```

```
2000-02-01T00:00:00
julia> dt - dt2
381110400000 milliseconds
```

65.3 Accessor Functions

Because the `Date` and `DateTime` types are stored as single `Int64` values, date parts or fields can be retrieved through accessor functions. The lowercase accessors return the field as an integer:

```
julia> t = Date(2014, 1, 31)
2014-01-31

julia> Dates.year(t)
2014

julia> Dates.month(t)
1

julia> Dates.week(t)
5

julia> Dates.day(t)
31
```

While propercase return the same value in the corresponding `Period` type:

```
julia> Dates.Year(t)
2014 years

julia> Dates.Day(t)
31 days
```

Compound methods are provided because it is more efficient to access multiple fields at the same time than individually:

```
julia> Dates.yearmonth(t)
(2014, 1)

julia> Dates.monthday(t)
(1, 31)

julia> Dates.yearmonthday(t)
(2014, 1, 31)
```

One may also access the underlying `UTInstant` or integer value:

```
julia> dump(t)
Date
```

```
instant: Dates.UTInstant{Day}
periods: Day
value: Int64 735264

julia> t.instant
Dates.UTInstant{Day}(Day(735264))

julia> Dates.value(t)
735264
```

65.4 Query Functions

Query functions provide calendrical information about a [TimeType](#). They include information about the day of the week:

```
julia> t = Date(2014, 1, 31)
2014-01-31

julia> Dates.dayofweek(t)
5

julia> Dates.dayname(t)
"Friday"

julia> Dates.dayofweekofmonth(t) # 5th Friday of January
5
```

Month of the year:

```
julia> Dates.monthname(t)
"January"

julia> Dates.daysinmonth(t)
31
```

As well as information about the [TimeType](#)'s year and quarter:

```
julia> Dates.isleapyear(t)
false

julia> Dates.dayofyear(t)
31

julia> Dates.quarterofyear(t)
1

julia> Dates.dayofquarter(t)
31
```

The `dayname` and `monthname` methods can also take an optional `locale` keyword that can be used to return the name of the day or month of the year for other languages/locales. There are also versions of these functions returning the abbreviated names, namely `dayabbr` and `monthabbr`. First the mapping is loaded into the `LOCALES` variable:

```
julia> french_months = ["janvier", "février", "mars", "avril", "mai", "juin",
                        "juillet", "août", "septembre", "octobre", "novembre", "décembre"];

julia> french_monts_abbrev = ["janv", "févr", "mars", "avril", "mai", "juin",
                              "juil", "août", "sept", "oct", "nov", "déc"];

julia> french_days = ["lundi", "mardi", "mercredi", "jeudi", "vendredi", "samedi", "dimanche"];

julia> Dates.LOCALES["french"] = Dates.DateLocale(french_months, french_monts_abbrev,
↪ french_days, [""]);
```

The above mentioned functions can then be used to perform the queries:

```
julia> Dates.dayname(t; locale="french")
"vendredi"

julia> Dates.monthname(t; locale="french")
"janvier"

julia> Dates.monthabbr(t; locale="french")
"janv"
```

Since the abbreviated versions of the days are not loaded, trying to use the function `dayabbr` will throw an error.

```
julia> Dates.dayabbr(t; locale="french")
ERROR: BoundsError: attempt to access 1-element Vector{String} at index [5]
Stacktrace:
[...]
```

65.5 TimeType-Period Arithmetic

It's good practice when using any language/date framework to be familiar with how date-period arithmetic is handled as there are some [tricky issues](#) to deal with (though much less so for day-precision types).

The Dates module approach tries to follow the simple principle of trying to change as little as possible when doing [Period](#) arithmetic. This approach is also often known as calendrical arithmetic or what you would probably guess if someone were to ask you the same calculation in a conversation. Why all the fuss about this? Let's take a classic example: add 1 month to January 31st, 2014. What's the answer? Javascript will say [March 3](#) (assumes 31 days). PHP says [March 2](#) (assumes 30 days). The fact is, there is no right answer. In the Dates module, it gives the result of February 28th. How does it figure that out? Consider the classic 7-7-7 gambling game in casinos.

Now just imagine that instead of 7-7-7, the slots are Year-Month-Day, or in our example, 2014-01-31. When you ask to add 1 month to this date, the month slot is incremented, so now we have 2014-02-31. Then the

day number is checked if it is greater than the last valid day of the new month; if it is (as in the case above), the day number is adjusted down to the last valid day (28). What are the ramifications with this approach? Go ahead and add another month to our date, `2014-02-28 + Month(1) == 2014-03-28`. What? Were you expecting the last day of March? Nope, sorry, remember the 7-7-7 slots. As few slots as possible are going to change, so we first increment the month slot by 1, `2014-03-28`, and boom, we're done because that's a valid date. On the other hand, if we were to add 2 months to our original date, `2014-01-31`, then we end up with `2014-03-31`, as expected. The other ramification of this approach is a loss in associativity when a specific ordering is forced (i.e. adding things in different orders results in different outcomes). For example:

```
julia> (Date(2014,1,29)+Dates.Day(1)) + Dates.Month(1)
2014-02-28

julia> (Date(2014,1,29)+Dates.Month(1)) + Dates.Day(1)
2014-03-01
```

What's going on there? In the first line, we're adding 1 day to January 29th, which results in `2014-01-30`; then we add 1 month, so we get `2014-02-30`, which then adjusts down to `2014-02-28`. In the second example, we add 1 month first, where we get `2014-02-29`, which adjusts down to `2014-02-28`, and then add 1 day, which results in `2014-03-01`. One design principle that helps in this case is that, in the presence of multiple Periods, the operations will be ordered by the Periods' types, not their value or positional order; this means Year will always be added first, then Month, then Week, etc. Hence the following does result in associativity and Just Works:

```
julia> Date(2014,1,29) + Dates.Day(1) + Dates.Month(1)
2014-03-01

julia> Date(2014,1,29) + Dates.Month(1) + Dates.Day(1)
2014-03-01
```

Tricky? Perhaps. What is an innocent Dates user to do? The bottom line is to be aware that explicitly forcing a certain associativity, when dealing with months, may lead to some unexpected results, but otherwise, everything should work as expected. Thankfully, that's pretty much the extent of the odd cases in date-period arithmetic when dealing with time in UT (avoiding the "joys" of dealing with daylight savings, leap seconds, etc.).

As a bonus, all period arithmetic objects work directly with ranges:

```
julia> dr = Date(2014,1,29):Day(1):Date(2014,2,3)
Date("2014-01-29"):Day(1):Date("2014-02-03")

julia> collect(dr)
6-element Vector{Date}:
 2014-01-29
 2014-01-30
 2014-01-31
 2014-02-01
 2014-02-02
 2014-02-03
```

```
julia> dr = Date(2014,1,29):Dates.Month(1):Date(2014,07,29)
Date("2014-01-29"):Month(1):Date("2014-07-29")

julia> collect(dr)
7-element Vector{Date}:
 2014-01-29
 2014-02-28
 2014-03-29
 2014-04-29
 2014-05-29
 2014-06-29
 2014-07-29
```

65.6 Adjuster Functions

As convenient as date-period arithmetic is, often the kinds of calculations needed on dates take on a calendrical or temporal nature rather than a fixed number of periods. Holidays are a perfect example; most follow rules such as "Memorial Day = Last Monday of May", or "Thanksgiving = 4th Thursday of November". These kinds of temporal expressions deal with rules relative to the calendar, like first or last of the month, next Tuesday, or the first and third Wednesdays, etc.

The Dates module provides the adjuster API through several convenient methods that aid in simply and succinctly expressing temporal rules. The first group of adjuster methods deal with the first and last of weeks, months, quarters, and years. They each take a single `TimeType` as input and return or adjust to the first or last of the desired period relative to the input.

```
julia> Dates.firstdayofweek(Date(2014,7,16)) # Adjusts the input to the Monday of the input's
↪ week
2014-07-14

julia> Dates.lastdayofmonth(Date(2014,7,16)) # Adjusts to the last day of the input's month
2014-07-31

julia> Dates.lastdayofquarter(Date(2014,7,16)) # Adjusts to the last day of the input's quarter
2014-09-30
```

The next two higher-order methods, `tonext`, and `toprev`, generalize working with temporal expressions by taking a `DateFunction` as first argument, along with a starting `TimeType`. A `DateFunction` is just a function, usually anonymous, that takes a single `TimeType` as input and returns a `Bool`, true indicating a satisfied adjustment criterion. For example:

```
julia> istuesday = x->Dates.dayofweek(x) == Dates.Tuesday; # Returns true if the day of the week
↪ of x is Tuesday

julia> Dates.tonext(istuesday, Date(2014,7,13)) # 2014-07-13 is a Sunday
2014-07-15

julia> Dates.tonext(Date(2014,7,13), Dates.Tuesday) # Convenience method provided for day of the
↪ week adjustments
2014-07-15
```

This is useful with the do-block syntax for more complex temporal expressions:

```
julia> Dates.tonext(Date(2014,7,13)) do x
    # Return true on the 4th Thursday of November (Thanksgiving)
    Dates.dayofweek(x) == Dates.Thursday &&
    Dates.dayofweekofmonth(x) == 4 &&
    Dates.month(x) == Dates.November
end
2014-11-27
```

The `Base.filter` method can be used to obtain all valid dates/moments in a specified range:

```
# Pittsburgh street cleaning; Every 2nd Tuesday from April to November
# Date range from January 1st, 2014 to January 1st, 2015
julia> dr = Dates.Date(2014):Day(1):Dates.Date(2015);

julia> filter(dr) do x
    Dates.dayofweek(x) == Dates.Tue &&
    Dates.April <= Dates.month(x) <= Dates.Nov &&
    Dates.dayofweekofmonth(x) == 2
end
8-element Vector{Date}:
2014-04-08
2014-05-13
2014-06-10
2014-07-08
2014-08-12
2014-09-09
2014-10-14
2014-11-11
```

Additional examples and tests are available in `stdlib/Dates/test/adjusters.jl`.

65.7 Period Types

Periods are a human view of discrete, sometimes irregular durations of time. Consider 1 month; it could represent, in days, a value of 28, 29, 30, or 31 depending on the year and month context. Or a year could represent 365 or 366 days in the case of a leap year. `Period` types are simple `Int64` wrappers and are constructed by wrapping any `Int64` convertible type, i.e. `Year(1)` or `Month(3.0)`. Arithmetic between `Period` of the same type behave like integers, and limited `Period-Real` arithmetic is available. You can extract the underlying integer with `Dates.value`.

```
julia> y1 = Dates.Year(1)
1 year

julia> y2 = Dates.Year(2)
2 years

julia> y3 = Dates.Year(10)
10 years
```

```
julia> y1 + y2
3 years

julia> div(y3,y2)
5

julia> y3 - y2
8 years

julia> y3 % y2
0 years

julia> div(y3,3) # mirrors integer division
3 years

julia> Dates.value(Dates.Millisecond(10))
10
```

Representing periods or durations that are not integer multiples of the basic types can be achieved with the `Dates.CompoundPeriod` type. Compound periods may be constructed manually from simple `Period` types. Additionally, the `canonicalize` function can be used to break down a period into a `Dates.CompoundPeriod`. This is particularly useful to convert a duration, e.g., a difference of two `DateTime`, into a more convenient representation.

```
julia> cp = Dates.CompoundPeriod(Day(1),Minute(1))
1 day, 1 minute

julia> t1 = DateTime(2018,8,8,16,58,00)
2018-08-08T16:58:00

julia> t2 = DateTime(2021,6,23,10,00,00)
2021-06-23T10:00:00

julia> canonicalize(t2-t1) # creates a CompoundPeriod
149 weeks, 6 days, 17 hours, 2 minutes
```

65.8 Rounding

`Date` and `DateTime` values can be rounded to a specified resolution (e.g., 1 month or 15 minutes) with `floor`, `ceil`, or `round`:

```
julia> floor(Date(1985, 8, 16), Dates.Month)
1985-08-01

julia> ceil(DateTime(2013, 2, 13, 0, 31, 20), Dates.Minute(15))
2013-02-13T00:45:00

julia> round(DateTime(2016, 8, 6, 20, 15), Dates.Day)
2016-08-07T00:00:00
```

Unlike the numeric `round` method, which breaks ties toward the even number by default, the `TimeType.round` method uses the `RoundNearestTiesUp` rounding mode. (It's difficult to guess what breaking ties to nearest "even" `TimeType` would entail.) Further details on the available `RoundingMode`s can be found in the [API reference](#).

Rounding should generally behave as expected, but there are a few cases in which the expected behaviour is not obvious.

Rounding Epoch

In many cases, the resolution specified for rounding (e.g., `Dates.Second(30)`) divides evenly into the next largest period (in this case, `Dates.Minute(1)`). But rounding behaviour in cases in which this is not true may lead to confusion. What is the expected result of rounding a `DateTime` to the nearest 10 hours?

```
julia> round(DateTime(2016, 7, 17, 11, 55), Dates.Hour(10))
2016-07-17T12:00:00
```

That may seem confusing, given that the hour (12) is not divisible by 10. The reason that 2016-07-17T12:00:00 was chosen is that it is 17,676,660 hours after 0000-01-01T00:00:00, and 17,676,660 is divisible by 10.

As Julia `Date` and `DateTime` values are represented according to the ISO 8601 standard, 0000-01-01T00:00:00 was chosen as base (or "rounding epoch") from which to begin the count of days (and milliseconds) used in rounding calculations. (Note that this differs slightly from Julia's internal representation of `Date`s using [Rata Die notation](#); but since the ISO 8601 standard is most visible to the end user, 0000-01-01T00:00:00 was chosen as the rounding epoch instead of the 0000-12-31T00:00:00 used internally to minimize confusion.)

The only exception to the use of 0000-01-01T00:00:00 as the rounding epoch is when rounding to weeks. Rounding to the nearest week will always return a Monday (the first day of the week as specified by ISO 8601). For this reason, we use 0000-01-03T00:00:00 (the first day of the first week of year 0000, as defined by ISO 8601) as the base when rounding to a number of weeks.

Here is a related case in which the expected behaviour is not necessarily obvious: What happens when we round to the nearest `P(2)`, where `P` is a `Period` type? In some cases (specifically, when `P <: Dates.TimePeriod`) the answer is clear:

```
julia> round(DateTime(2016, 7, 17, 8, 55, 30), Dates.Hour(2))
2016-07-17T08:00:00

julia> round(DateTime(2016, 7, 17, 8, 55, 30), Dates.Minute(2))
2016-07-17T08:56:00
```

This seems obvious, because two of each of these periods still divides evenly into the next larger order period. But in the case of two months (which still divides evenly into one year), the answer may be surprising:

```
julia> round(DateTime(2016, 7, 17, 8, 55, 30), Dates.Month(2))
2016-07-01T00:00:00
```

Why round to the first day in July, even though it is month 7 (an odd number)? The key is that months are 1-indexed (the first month is assigned 1), unlike hours, minutes, seconds, and milliseconds (the first of which are assigned 0).

This means that rounding a [DateTime](#) to an even multiple of seconds, minutes, hours, or years (because the ISO 8601 specification includes a year zero) will result in a [DateTime](#) with an even value in that field, while rounding a [DateTime](#) to an even multiple of months will result in the months field having an odd value. Because both months and years may contain an irregular number of days, whether rounding to an even number of days will result in an even value in the days field is uncertain.

See the [API reference](#) for additional information on methods exported from the Dates module.

Chapter 66

API reference

66.1 Dates and Time Types

Dates.Period – Type.

| | |
|--|-------------|
| | Period |
| | Year |
| | Quarter |
| | Month |
| | Week |
| | Day |
| | Hour |
| | Minute |
| | Second |
| | Millisecond |
| | Microsecond |
| | Nanosecond |

Period types represent discrete, human representations of time.

Dates.CompoundPeriod – Type.

| | |
|--|----------------|
| | CompoundPeriod |
|--|----------------|

A CompoundPeriod is useful for expressing time periods that are not a fixed multiple of smaller periods. For example, "a year and a day" is not a fixed number of days, but can be expressed using a CompoundPeriod. In fact, a CompoundPeriod is automatically generated by addition of different period types, e.g. Year(1) + Day(1) produces a CompoundPeriod result.

Dates.Instant – Type.

| | |
|--|---------|
| | Instant |
|--|---------|

Instant types represent integer-based, machine representations of time as continuous timelines starting from an epoch.

Dates.UTInstant – Type.

| | |
|--|--------------|
| | UTInstant{T} |
|--|--------------|

The `UTInstant` represents a machine timeline based on UT time (1 day = one revolution of the earth). The `T` is a `Period` parameter that indicates the resolution or precision of the instant.

`Dates.TimeType` – Type.

| `TimeType`

`TimeType` types wrap `Instant` machine instances to provide human representations of the machine instant. `Time`, `DateTime` and `Date` are subtypes of `TimeType`.

`Dates.DateTime` – Type.

| `DateTime`

`DateTime` wraps a `UTInstant{Millisecond}` and interprets it according to the proleptic Gregorian calendar.

`Dates.Date` – Type.

| `Date`

`Date` wraps a `UTInstant{Day}` and interprets it according to the proleptic Gregorian calendar.

`Dates.Time` – Type.

| `Time`

`Time` wraps a `Nanosecond` and represents a specific moment in a 24-hour day.

`Dates.TimeZone` – Type.

| `TimeZone`

Geographic zone generally based on longitude determining what the time is at a certain location. Some time zones observe daylight savings (eg EST -> EDT). For implementations and more support, see the [TimeZones.jl](#) package

`Dates.UTC` – Type.

| `UTC`

UTC, or Coordinated Universal Time, is the [TimeZone](#) from which all others are measured. It is associated with the time at 0° longitude. It is not adjusted for daylight savings.

66.2 Dates Functions

`Dates.DateTime` – Method.

| `DateTime(y, [m, d, h, mi, s, ms]) -> DateTime`

Construct a `DateTime` type by parts. Arguments must be convertible to [Int64](#).

`Dates.Date` – Method.

```
| DateTime( periods::Period... ) -> DateTime
```

Construct a `DateTime` type by `Period` type parts. Arguments may be in any order. `DateTime` parts not provided will default to the value of `Dates.default(period)`.

`Dates.DateTime` – Method.

```
| DateTime( f::Function, y[, m, d, h, mi, s]; step=Day(1), limit=10000 ) -> DateTime
```

Create a `DateTime` through the adjuster API. The starting point will be constructed from the provided `y`, `m`, `d...` arguments, and will be adjusted until `f::Function` returns true. The step size in adjusting can be provided manually through the `step` keyword. `limit` provides a limit to the max number of iterations the adjustment API will pursue before throwing an error (in the case that `f::Function` is never satisfied).

Examples

```
julia> DateTime(dt -> second(dt) == 40, 2010, 10, 20, 10; step = Second(1))
2010-10-20T10:00:40

julia> DateTime(dt -> hour(dt) == 20, 2010, 10, 20, 10; step = Hour(1), limit = 5)
ERROR: ArgumentError: Adjustment limit reached: 5 iterations
Stacktrace:
[...]
```

`Dates.DateTime` – Method.

```
| DateTime( dt::Date ) -> DateTime
```

Convert a `Date` to a `DateTime`. The hour, minute, second, and millisecond parts of the new `DateTime` are assumed to be zero.

`Dates.DateTime` – Method.

```
| DateTime( dt::AbstractString, format::AbstractString; locale="english" ) -> DateTime
```

Construct a `DateTime` by parsing the `dt` date time string following the pattern given in the `format` string (see `DateFormat` for syntax).

Note

This method creates a `DateFormat` object each time it is called. It is recommended that you create a `DateFormat` object instead and use that as the second argument to avoid performance loss when using the same format repeatedly.

Example

```
julia> DateTime("2020-01-01", "yyyy-mm-dd")
2020-01-01T00:00:00

julia> a = ("2020-01-01", "2020-01-02");

julia> [DateTime(d, dateformat"yyyy-mm-dd") for d ∈ a] # preferred
2-element Vector{DateTime}:
 2020-01-01T00:00:00
 2020-01-02T00:00:00
```

Dates.format – Method.

```
| format(dt::TimeType, format::AbstractString; locale="english") -> AbstractString
```

Construct a string by using a TimeType object and applying the provided format. The following character codes can be used to construct the format string:

| Code | Examples | Comment |
|------|----------|---|
| y | 6 | Numeric year with a fixed width |
| Y | 1996 | Numeric year with a minimum width |
| m | 1, 12 | Numeric month with a minimum width |
| u | Jan | Month name shortened to 3-chars according to the locale |
| U | January | Full month name according to the locale keyword |
| d | 1, 31 | Day of the month with a minimum width |
| H | 0, 23 | Hour (24-hour clock) with a minimum width |
| M | 0, 59 | Minute with a minimum width |
| S | 0, 59 | Second with a minimum width |
| s | 000, 500 | Millisecond with a minimum width of 3 |
| e | Mon, Tue | Abbreviated days of the week |
| E | Monday | Full day of week name |

The number of sequential code characters indicate the width of the code. A format of yyyy-mm specifies that the code y should have a width of four while m a width of two. Codes that yield numeric digits have an associated mode: fixed-width or minimum-width. The fixed-width mode left-pads the value with zeros when it is shorter than the specified width and truncates the value when longer. Minimum-width mode works the same as fixed-width except that it does not truncate values longer than the width.

When creating a format you can use any non-code characters as a separator. For example to generate the string "1996-01-15T00:00:00" you could use format: "yyyy-mm-ddTHH:MM:SS". Note that if you need to use a code character as a literal you can use the escape character backslash. The string "1996y01m" can be produced with the format "yyyy\ymm\m".

Dates.DateFormat – Type.

```
| DateFormat(format::AbstractString, locale="english") -> DateFormat
```

Construct a date formatting object that can be used for parsing date strings or formatting a date object as a string. The following character codes can be used to construct the format string:

Characters not listed above are normally treated as delimiters between date and time slots. For example a dt string of "1996-01-15T00:00:00.0" would have a format string like "y-m-dTH:M:S.s". If you need to use a code character as a delimiter you can escape it using backslash. The date "1995y01m" would have the format "y\ym\m".

Note that 12:00AM corresponds 00:00 (midnight), and 12:00PM corresponds to 12:00 (noon). When parsing a time with a p specifier, any hour (either H or I) is interpreted as as a 12-hour clock, so the I code is mainly useful for output.

Creating a DateFormat object is expensive. Whenever possible, create it once and use it many times or try the `dateformat` string macro. Using this macro creates the DateFormat object once at macro expansion time and reuses it later. There are also several [pre-defined formatters](#), listed later.

See [DateTime](#) and [format](#) for how to use a DateFormat object to parse and write Date strings respectively.

| Code | Matches | Comment |
|---------|-----------|--|
| Y | 1996, 96 | Returns year of 1996, 0096 |
| y | 1996, 96 | Same as Y on parse but discards excess digits on format |
| m | 1, 01 | Matches 1 or 2-digit months |
| u | Jan | Matches abbreviated months according to the locale keyword |
| U | January | Matches full month names according to the locale keyword |
| d | 1, 01 | Matches 1 or 2-digit days |
| H | 00 | Matches hours (24-hour clock) |
| I | 00 | For outputting hours with 12-hour clock |
| M | 00 | Matches minutes |
| S | 00 | Matches seconds |
| s | .500 | Matches milliseconds |
| e | Mon, Tues | Matches abbreviated days of the week |
| E | Monday | Matches full name days of the week |
| p | AM | Matches AM/PM (case-insensitive) |
| yyymmdd | 19960101 | Matches fixed-width year, month, and day |

Dates.@dateformat_str – Macro.

```
| dateformat"Y-m-d H:M:S"
```

Create a [DateFormat](#) object. Similar to `DateFormat("Y-m-d H:M:S")` but creates the `DateFormat` object once during macro expansion.

See [DateFormat](#) for details about format specifiers.

Dates.DateTime – Method.

```
| DateTime(dt::AbstractString, df::DateFormat=ISODateTimeFormat) -> DateTime
```

Construct a `DateTime` by parsing the `dt` date time string following the pattern given in the [DateFormat](#) object, or `dateformat"yyyy-mm-dd\THH:MM:SS.s"` if omitted.

Similar to `DateTime(::AbstractString, ::AbstractString)` but more efficient when repeatedly parsing similarly formatted date time strings with a pre-created `DateFormat` object.

Dates.Date – Method.

```
| Date(y, [m, d]) -> Date
```

Construct a `Date` type by parts. Arguments must be convertible to [Int64](#).

Dates.Date – Method.

```
| Date(period::Period...) -> Date
```

Construct a `Date` type by `Period` type parts. Arguments may be in any order. Date parts not provided will default to the value of `Dates.default(period)`.

Dates.Date – Method.

```
| Date(f::Function, y[, m, d]; step=Day(1), limit=10000) -> Date
```

Create a `Date` through the adjuster API. The starting point will be constructed from the provided `y`, `m`, `d` arguments, and will be adjusted until `f::Function` returns `true`. The step size in adjusting can be provided manually through the `step` keyword. `limit` provides a limit to the max number of iterations the adjustment API will pursue before throwing an error (given that `f::Function` is never satisfied).

Examples

```
julia> Date(date -> week(date) == 20, 2010, 01, 01)
2010-05-17

julia> Date(date -> year(date) == 2010, 2000, 01, 01)
2010-01-01

julia> Date(date -> month(date) == 10, 2000, 01, 01; limit = 5)
ERROR: ArgumentError: Adjustment limit reached: 5 iterations
Stacktrace:
[...]
```

`Dates.Date` – Method.

```
| Date(dt::DateTime) -> Date
```

Convert a `DateTime` to a `Date`. The hour, minute, second, and millisecond parts of the `DateTime` are truncated, so only the year, month and day parts are used in construction.

`Dates.Date` – Method.

```
| Date(d::AbstractString, format::AbstractString; locale="english") -> Date
```

Construct a `Date` by parsing the `d` date string following the pattern given in the format string (see [DateFormat](#) for syntax).

Note

This method creates a `DateFormat` object each time it is called. It is recommended that you create a `DateFormat` object instead and use that as the second argument to avoid performance loss when using the same format repeatedly.

Example

```
julia> Date("2020-01-01", "yyyy-mm-dd")
2020-01-01

julia> a = ("2020-01-01", "2020-01-02");

julia> [Date(d, dateformat"yyyy-mm-dd") for d ∈ a] # preferred
2-element Vector{Date}:
 2020-01-01
 2020-01-02
```

`Dates.Date` – Method.

```
| Date(d::AbstractString, df::DateFormat=ISODateFormat) -> Date
```

Construct a Date by parsing the d date string following the pattern given in the `DateFormat` object, or `dateformat"yyyy-mm-dd"` if omitted.

Similar to `Date(::AbstractString, ::AbstractString)` but more efficient when repeatedly parsing similarly formatted date strings with a pre-created `DateFormat` object.

`Dates.Time` – Method.

```
| Time(h, [mi, s, ms, us, ns]) -> Time
```

Construct a Time type by parts. Arguments must be convertible to `Int64`.

`Dates.Time` – Method.

```
| Time(period::TimePeriod...) -> Time
```

Construct a Time type by Period type parts. Arguments may be in any order. Time parts not provided will default to the value of `Dates.default(period)`.

`Dates.Time` – Method.

```
| Time(f::Function, h, mi=0; step::Period=Second(1), limit::Int=10000)
| Time(f::Function, h, mi, s; step::Period=Millisecond(1), limit::Int=10000)
| Time(f::Function, h, mi, s, ms; step::Period=Microsecond(1), limit::Int=10000)
| Time(f::Function, h, mi, s, ms, us; step::Period=Nanosecond(1), limit::Int=10000)
```

Create a Time through the adjuster API. The starting point will be constructed from the provided h, mi, s, ms, us arguments, and will be adjusted until `f::Function` returns true. The step size in adjusting can be provided manually through the `step` keyword. `limit` provides a limit to the max number of iterations the adjustment API will pursue before throwing an error (in the case that `f::Function` is never satisfied). Note that the default step will adjust to allow for greater precision for the given arguments; i.e. if hour, minute, and second arguments are provided, the default step will be `Millisecond(1)` instead of `Second(1)`.

Examples

```
julia> Time(t -> minute(t) == 30, 20)
20:30:00

julia> Time(t -> minute(t) == 0, 20)
20:00:00

julia> Time(t -> hour(t) == 10, 3; limit = 5)
ERROR: ArgumentError: Adjustment limit reached: 5 iterations
Stacktrace:
[...]
```

`Dates.Time` – Method.

```
| Time(dt::DateTime) -> Time
```

Convert a DateTime to a Time. The hour, minute, second, and millisecond parts of the DateTime are used to create the new Time. Microsecond and nanoseconds are zero by default.

Dates.Time – Method.

```
| Time(t::AbstractString, format::AbstractString; locale="english") -> Time
```

Construct a Time by parsing the t time string following the pattern given in the format string (see [DateFormat](#) for syntax).

Note

This method creates a DateFormat object each time it is called. It is recommended that you create a [DateFormat](#) object instead and use that as the second argument to avoid performance loss when using the same format repeatedly.

Example

```
julia> Time("12:34pm", "HH:MMp")
12:34:00

julia> a = ("12:34pm", "2:34am");

julia> [Time(d, dateformat"HH:MMp") for d ∈ a] # preferred
2-element Vector{Time}:
 12:34:00
 02:34:00
```

Dates.Time – Method.

```
| Time(t::AbstractString, df::DateFormat=ISOTimeFormat) -> Time
```

Construct a Time by parsing the t date time string following the pattern given in the [DateFormat](#) object, or dateformat"HH:MM:SS.s" if omitted.

Similar to Time(::AbstractString, ::AbstractString) but more efficient when repeatedly parsing similarly formatted time strings with a pre-created DateFormat object.

Dates.now – Method.

```
| now() -> DateTime
```

Return a DateTime corresponding to the user's system time including the system timezone locale.

Dates.now – Method.

```
| now(::Type{UTC}) -> DateTime
```

Return a DateTime corresponding to the user's system time as UTC/GMT. For other time zones, see the TimeZones.jl package.

Example

```
julia> now(UTC)
2023-01-04T10:52:24.864
```

Base.eps – Method.

```

eps(::Type{DateTime}) -> Millisecond
eps(::Type{Date}) -> Day
eps(::Type{Time}) -> Nanosecond
eps(::TimeType) -> Period

```

Return the smallest unit value supported by the TimeType.

Examples

```

julia> eps(DateTime)
1 millisecond

julia> eps(Date)
1 day

julia> eps(Time)
1 nanosecond

```

Accessor Functions

Dates.year – Function.

```

year(dt::TimeType) -> Int64

```

The year of a Date or DateTime as an Int64.

Dates.month – Function.

```

month(dt::TimeType) -> Int64

```

The month of a Date or DateTime as an Int64.

Dates.week – Function.

```

week(dt::TimeType) -> Int64

```

Return the ISO week date of a Date or DateTime as an Int64. Note that the first week of a year is the week that contains the first Thursday of the year, which can result in dates prior to January 4th being in the last week of the previous year. For example, week(Date(2005, 1, 1)) is the 53rd week of 2004.

Examples

```

julia> week(Date(1989, 6, 22))
25

julia> week(Date(2005, 1, 1))
53

julia> week(Date(2004, 12, 31))
53

```

Dates.day – Function.

```

day(dt::TimeType) -> Int64

```

The day of month of a Date or DateTime as an [Int64](#).

Dates.hour – Function.

```
| hour(dt::DateTime) -> Int64
```

The hour of day of a DateTime as an [Int64](#).

```
| hour(t::Time) -> Int64
```

The hour of a Time as an [Int64](#).

Dates.minute – Function.

```
| minute(dt::DateTime) -> Int64
```

The minute of a DateTime as an [Int64](#).

```
| minute(t::Time) -> Int64
```

The minute of a Time as an [Int64](#).

Dates.second – Function.

```
| second(dt::DateTime) -> Int64
```

The second of a DateTime as an [Int64](#).

```
| second(t::Time) -> Int64
```

The second of a Time as an [Int64](#).

Dates.millisecond – Function.

```
| millisecond(dt::DateTime) -> Int64
```

The millisecond of a DateTime as an [Int64](#).

```
| millisecond(t::Time) -> Int64
```

The millisecond of a Time as an [Int64](#).

Dates.microsecond – Function.

```
| microsecond(t::Time) -> Int64
```

The microsecond of a Time as an [Int64](#).

Dates.nanosecond – Function.

```
| nanosecond(t::Time) -> Int64
```

The nanosecond of a Time as an [Int64](#).

Dates.Year – Method.

```
| Year(v)
```

Construct a Year object with the given v value. Input must be losslessly convertible to an [Int64](#).

Dates.Month – Method.

```
| Month(v)
```

Construct a Month object with the given v value. Input must be losslessly convertible to an [Int64](#).

Dates.Week – Method.

```
| Week(v)
```

Construct a Week object with the given v value. Input must be losslessly convertible to an [Int64](#).

Dates.Day – Method.

```
| Day(v)
```

Construct a Day object with the given v value. Input must be losslessly convertible to an [Int64](#).

Dates.Hour – Method.

```
| Hour(dt::DateTime) -> Hour
```

The hour part of a DateTime as a Hour.

Dates.Minute – Method.

```
| Minute(dt::DateTime) -> Minute
```

The minute part of a DateTime as a Minute.

Dates.Second – Method.

```
| Second(dt::DateTime) -> Second
```

The second part of a DateTime as a Second.

Dates.Millisecond – Method.

```
| Millisecond(dt::DateTime) -> Millisecond
```

The millisecond part of a DateTime as a Millisecond.

Dates.Microsecond – Method.

```
| Microsecond(dt::Time) -> Microsecond
```

The microsecond part of a Time as a Microsecond.

Dates.Nanosecond – Method.

```
| Nanosecond(dt::Time) -> Nanosecond
```

The nanosecond part of a Time as a Nanosecond.

Dates.yearmonth – Function.

```
| yearmonth(dt::TimeType) -> (Int64, Int64)
```

Simultaneously return the year and month parts of a Date or DateTime.

Dates.monthday – Function.

```
| monthday(dt::TimeType) -> (Int64, Int64)
```

Simultaneously return the month and day parts of a Date or DateTime.

Dates.yearmonthday – Function.

```
| yearmonthday(dt::TimeType) -> (Int64, Int64, Int64)
```

Simultaneously return the year, month and day parts of a Date or DateTime.

Query Functions

Dates.dayname – Function.

```
| dayname(dt::TimeType; locale="english") -> String
| dayname(day::Integer; locale="english") -> String
```

Return the full day name corresponding to the day of the week of the Date or DateTime in the given locale. Also accepts Integer.

Examples

```
julia> dayname(Date("2000-01-01"))
"Saturday"

julia> dayname(4)
"Thursday"
```

Dates.dayabbr – Function.

```
| dayabbr(dt::TimeType; locale="english") -> String
| dayabbr(day::Integer; locale="english") -> String
```

Return the abbreviated name corresponding to the day of the week of the Date or DateTime in the given locale. Also accepts Integer.

Examples

```
julia> dayabbr(Date("2000-01-01"))
"Sat"

julia> dayabbr(3)
"Wed"
```

Dates.dayofweek – Function.

```
| dayofweek(dt::TimeType) -> Int64
```

Return the day of the week as an `Int64` with 1 = Monday, 2 = Tuesday, etc..

Examples

```
| julia> dayofweek(Date("2000-01-01"))
6
```

`Dates.dayofmonth` – Function.

```
| dayofmonth(dt::TimeType) -> Int64
```

The day of month of a `Date` or `DateTime` as an `Int64`.

`Dates.dayofweekofmonth` – Function.

```
| dayofweekofmonth(dt::TimeType) -> Int
```

For the day of week of `dt`, return which number it is in `dt`'s month. So if the day of the week of `dt` is Monday, then 1 = First Monday of the month, 2 = Second Monday of the month, etc. In the range 1:5.

Examples

```
| julia> dayofweekofmonth(Date("2000-02-01"))
1
| julia> dayofweekofmonth(Date("2000-02-08"))
2
| julia> dayofweekofmonth(Date("2000-02-15"))
3
```

`Dates.daysofweekinmonth` – Function.

```
| daysofweekinmonth(dt::TimeType) -> Int
```

For the day of week of `dt`, return the total number of that day of the week in `dt`'s month. Returns 4 or 5. Useful in temporal expressions for specifying the last day of a week in a month by including `dayofweekofmonth(dt) == daysofweekinmonth(dt)` in the adjuster function.

Examples

```
| julia> daysofweekinmonth(Date("2005-01-01"))
5
| julia> daysofweekinmonth(Date("2005-01-04"))
4
```

`Dates.monthname` – Function.

```
| monthname(dt::TimeType; locale="english") -> String
| monthname(month::Integer, locale="english") -> String
```

Return the full name of the month of the Date or DateTime or Integer in the given locale.

Examples

```
julia> monthname(Date("2005-01-04"))
"January"

julia> monthname(2)
"February"
```

Dates.monthabbr – Function.

```
monthabbr(dt::TimeType; locale="english") -> String
monthabbr(month::Integer, locale="english") -> String
```

Return the abbreviated month name of the Date or DateTime or Integer in the given locale.

Examples

```
julia> monthabbr(Date("2005-01-04"))
"Jan"

julia> monthabbr(2)
"Feb"
```

Dates.daysinmonth – Function.

```
daysinmonth(dt::TimeType) -> Int
```

Return the number of days in the month of dt. Value will be 28, 29, 30, or 31.

Examples

```
julia> daysinmonth(Date("2000-01"))
31

julia> daysinmonth(Date("2001-02"))
28

julia> daysinmonth(Date("2000-02"))
29
```

Dates.isleapyear – Function.

```
isleapyear(dt::TimeType) -> Bool
```

Return true if the year of dt is a leap year.

Examples

```
julia> isleapyear(Date("2004"))
true

julia> isleapyear(Date("2005"))
false
```

Dates.dayofyear – Function.

```
| dayofyear(dt::TimeType) -> Int
```

Return the day of the year for dt with January 1st being day 1.

Dates.daysinyear – Function.

```
| daysinyear(dt::TimeType) -> Int
```

Return 366 if the year of dt is a leap year, otherwise return 365.

Examples

```
| julia> daysinyear(1999)
365

| julia> daysinyear(2000)
366
```

Dates.quarterofyear – Function.

```
| quarterofyear(dt::TimeType) -> Int
```

Return the quarter that dt resides in. Range of value is 1:4.

Dates.dayofquarter – Function.

```
| dayofquarter(dt::TimeType) -> Int
```

Return the day of the current quarter of dt. Range of value is 1:92.

Adjuster Functions

Base.trunc – Method.

```
| trunc(dt::TimeType, ::Type{Period}) -> TimeType
```

Truncates the value of dt according to the provided Period type.

Examples

```
| julia> trunc(DateTime("1996-01-01T12:30:00"), Day)
1996-01-01T00:00:00
```

Dates.firstdayofweek – Function.

```
| firstdayofweek(dt::TimeType) -> TimeType
```

Adjusts dt to the Monday of its week.

Examples

```
| julia> firstdayofweek(DateTime("1996-01-05T12:30:00"))
1996-01-01T00:00:00
```

Dates.lastdayofweek – Function.

```
| lastdayofweek(dt::TimeType) -> TimeType
```

Adjusts dt to the Sunday of its week.

Examples

```
| julia> lastdayofweek(DateTime("1996-01-05T12:30:00"))  
1996-01-07T00:00:00
```

Dates.firstdayofmonth – Function.

```
| firstdayofmonth(dt::TimeType) -> TimeType
```

Adjusts dt to the first day of its month.

Examples

```
| julia> firstdayofmonth(DateTime("1996-05-20"))  
1996-05-01T00:00:00
```

Dates.lastdayofmonth – Function.

```
| lastdayofmonth(dt::TimeType) -> TimeType
```

Adjusts dt to the last day of its month.

Examples

```
| julia> lastdayofmonth(DateTime("1996-05-20"))  
1996-05-31T00:00:00
```

Dates.firstdayofyear – Function.

```
| firstdayofyear(dt::TimeType) -> TimeType
```

Adjusts dt to the first day of its year.

Examples

```
| julia> firstdayofyear(DateTime("1996-05-20"))  
1996-01-01T00:00:00
```

Dates.lastdayofyear – Function.

```
| lastdayofyear(dt::TimeType) -> TimeType
```

Adjusts dt to the last day of its year.

Examples

```
| julia> lastdayofyear(DateTime("1996-05-20"))  
1996-12-31T00:00:00
```

Dates.firstdayofquarter – Function.

```
| firstdayofquarter(dt::TimeType) -> TimeType
```

Adjusts dt to the first day of its quarter.

Examples

```
julia> firstdayofquarter(DateTime("1996-05-20"))
1996-04-01T00:00:00

julia> firstdayofquarter(DateTime("1996-08-20"))
1996-07-01T00:00:00
```

Dates.lastdayofquarter – Function.

```
| lastdayofquarter(dt::TimeType) -> TimeType
```

Adjusts dt to the last day of its quarter.

Examples

```
julia> lastdayofquarter(DateTime("1996-05-20"))
1996-06-30T00:00:00

julia> lastdayofquarter(DateTime("1996-08-20"))
1996-09-30T00:00:00
```

Dates.tonext – Method.

```
| tonext(dt::TimeType, dow::Int; same::Bool=false) -> TimeType
```

Adjusts dt to the next day of week corresponding to dow with 1 = Monday, 2 = Tuesday, etc. Setting same=true allows the current dt to be considered as the next dow, allowing for no adjustment to occur.

Dates.toprev – Method.

```
| toprev(dt::TimeType, dow::Int; same::Bool=false) -> TimeType
```

Adjusts dt to the previous day of week corresponding to dow with 1 = Monday, 2 = Tuesday, etc. Setting same=true allows the current dt to be considered as the previous dow, allowing for no adjustment to occur.

Dates.tofirst – Function.

```
| tofirst(dt::TimeType, dow::Int; of=Month) -> TimeType
```

Adjusts dt to the first dow of its month. Alternatively, of=Year will adjust to the first dow of the year.

Dates.tolast – Function.

```
| tolast(dt::TimeType, dow::Int; of=Month) -> TimeType
```

Adjusts dt to the last dow of its month. Alternatively, of=Year will adjust to the last dow of the year.

Dates.tonext – Method.

```
| tonext(func::Function, dt::TimeType; step=Day(1), limit=10000, same=false) -> TimeType
```

Adjusts dt by iterating at most limit iterations by step increments until func returns true. func must take a single TimeType argument and return a Bool. same allows dt to be considered in satisfying func.

Dates.toprev – Method.

```
| toprev(func::Function, dt::TimeType; step=Day(-1), limit=10000, same=false) -> TimeType
```

Adjusts dt by iterating at most limit iterations by step increments until func returns true. func must take a single TimeType argument and return a Bool. same allows dt to be considered in satisfying func.

Periods

Dates.Period – Method.

```
| Year(v)
| Quarter(v)
| Month(v)
| Week(v)
| Day(v)
| Hour(v)
| Minute(v)
| Second(v)
| Millisecond(v)
| Microsecond(v)
| Nanosecond(v)
```

Construct a Period type with the given v value. Input must be losslessly convertible to an Int64.

Dates.CompoundPeriod – Method.

```
| CompoundPeriod(periods) -> CompoundPeriod
```

Construct a CompoundPeriod from a Vector of Periods. All Periods of the same type will be added together.

Examples

```
| julia> Dates.CompoundPeriod(Dates.Hour(12), Dates.Hour(13))
25 hours
```

```
| julia> Dates.CompoundPeriod(Dates.Hour(-1), Dates.Minute(1))
-1 hour, 1 minute
```

```
| julia> Dates.CompoundPeriod(Dates.Month(1), Dates.Week(-2))
1 month, -2 weeks
```

```
| julia> Dates.CompoundPeriod(Dates.Minute(50000))
50000 minutes
```

Dates.canonicalize – Function.

```
| canonicalize(::CompoundPeriod) -> CompoundPeriod
```

Reduces the `CompoundPeriod` into its canonical form by applying the following rules:

- Any Period large enough to be partially representable by a coarser Period will be broken into multiple Periods (eg. `Hour(30)` becomes `Day(1) + Hour(6)`)
- Periods with opposite signs will be combined when possible (eg. `Hour(1) - Day(1)` becomes `-Hour(23)`)

Examples

```
julia> canonicalize(Dates.CompoundPeriod(Dates.Hour(12), Dates.Hour(13)))
1 day, 1 hour

julia> canonicalize(Dates.CompoundPeriod(Dates.Hour(-1), Dates.Minute(1)))
-59 minutes

julia> canonicalize(Dates.CompoundPeriod(Dates.Month(1), Dates.Week(-2)))
1 month, -2 weeks

julia> canonicalize(Dates.CompoundPeriod(Dates.Minute(50000)))
4 weeks, 6 days, 17 hours, 20 minutes
```

`Dates.value` – Function.

```
| Dates.value(x::Period) -> Int64
```

For a given period, return the value associated with that period. For example, `value(Millisecond(10))` returns 10 as an integer.

`Dates.default` – Function.

```
| default(p::Period) -> Period
```

Return a sensible "default" value for the input Period by returning `T(1)` for Year, Month, and Day, and `T(0)` for Hour, Minute, Second, and Millisecond.

`Dates.periods` – Function.

```
| Dates.periods(::CompoundPeriod) -> Vector{Period}
```

Return the Vector of Periods that comprise the given `CompoundPeriod`.

Julia 1.7

This function requires Julia 1.7 or later.

Rounding Functions

Date and DateTime values can be rounded to a specified resolution (e.g., 1 month or 15 minutes) with `floor`, `ceil`, or `round`.

`Base.floor` – Method.

```
| floor(dt::TimeType, p::Period) -> TimeType
```

Return the nearest Date or DateTime less than or equal to dt at resolution p.

For convenience, p may be a type instead of a value: floor(dt, Dates.Hour) is a shortcut for floor(dt, Dates.Hour(1)).

```
julia> floor(Date(1985, 8, 16), Month)
1985-08-01

julia> floor(DateTime(2013, 2, 13, 0, 31, 20), Minute(15))
2013-02-13T00:30:00

julia> floor(DateTime(2016, 8, 6, 12, 0, 0), Day)
2016-08-06T00:00:00
```

Base.ceil – Method.

```
| ceil(dt::TimeType, p::Period) -> TimeType
```

Return the nearest Date or DateTime greater than or equal to dt at resolution p.

For convenience, p may be a type instead of a value: ceil(dt, Dates.Hour) is a shortcut for ceil(dt, Dates.Hour(1)).

```
julia> ceil(Date(1985, 8, 16), Month)
1985-09-01

julia> ceil(DateTime(2013, 2, 13, 0, 31, 20), Minute(15))
2013-02-13T00:45:00

julia> ceil(DateTime(2016, 8, 6, 12, 0, 0), Day)
2016-08-07T00:00:00
```

Base.round – Method.

```
| round(dt::TimeType, p::Period, [r::RoundingMode]) -> TimeType
```

Return the Date or DateTime nearest to dt at resolution p. By default (RoundNearestTiesUp), ties (e.g., rounding 9:30 to the nearest hour) will be rounded up.

For convenience, p may be a type instead of a value: round(dt, Dates.Hour) is a shortcut for round(dt, Dates.Hour(1)).

```
julia> round(Date(1985, 8, 16), Month)
1985-08-01

julia> round(DateTime(2013, 2, 13, 0, 31, 20), Minute(15))
2013-02-13T00:30:00

julia> round(DateTime(2016, 8, 6, 12, 0, 0), Day)
2016-08-07T00:00:00
```

Valid rounding modes for `round(::TimeType, ::Period, ::RoundingMode)` are `RoundNearestTiesUp` (default), `RoundDown` (`floor`), and `RoundUp` (`ceil`).

Most `Period` values can also be rounded to a specified resolution:

`Base.floor` – Method.

```
| floor(x::Period, precision::T) where T <: Union{TimePeriod, Week, Day} -> T
```

Round `x` down to the nearest multiple of `precision`. If `x` and `precision` are different subtypes of `Period`, the return value will have the same type as `precision`.

For convenience, `precision` may be a type instead of a value: `floor(x, Dates.Hour)` is a shortcut for `floor(x, Dates.Hour(1))`.

```
| julia> floor(Day(16), Week)
2 weeks

| julia> floor(Minute(44), Minute(15))
30 minutes

| julia> floor(Hour(36), Day)
1 day
```

Rounding to a precision of `Months` or `Years` is not supported, as these `Periods` are of inconsistent length.

`Base.ceil` – Method.

```
| ceil(x::Period, precision::T) where T <: Union{TimePeriod, Week, Day} -> T
```

Round `x` up to the nearest multiple of `precision`. If `x` and `precision` are different subtypes of `Period`, the return value will have the same type as `precision`.

For convenience, `precision` may be a type instead of a value: `ceil(x, Dates.Hour)` is a shortcut for `ceil(x, Dates.Hour(1))`.

```
| julia> ceil(Day(16), Week)
3 weeks

| julia> ceil(Minute(44), Minute(15))
45 minutes

| julia> ceil(Hour(36), Day)
2 days
```

Rounding to a precision of `Months` or `Years` is not supported, as these `Periods` are of inconsistent length.

`Base.round` – Method.

```
| round(x::Period, precision::T, [r::RoundingMode]) where T <: Union{TimePeriod, Week, Day} ->
| ↪ T
```

Round x to the nearest multiple of precision. If x and precision are different subtypes of `Period`, the return value will have the same type as precision. By default (`RoundNearestTiesUp`), ties (e.g., rounding 90 minutes to the nearest hour) will be rounded up.

For convenience, precision may be a type instead of a value: `round(x, Dates.Hour)` is a shortcut for `round(x, Dates.Hour(1))`.

```
julia> round(Day(16), Week)
2 weeks

julia> round(Minute(44), Minute(15))
45 minutes

julia> round(Hour(36), Day)
2 days
```

Valid rounding modes for `round(::Period, ::T, ::RoundingMode)` are `RoundNearestTiesUp` (default), `RoundDown` (`floor`), and `RoundUp` (`ceil`).

Rounding to a precision of `Months` or `Years` is not supported, as these `Periods` are of inconsistent length.

The following functions are not exported:

`Dates.floorceil` – Function.

```
| floorceil(dt::TimeType, p::Period) -> (TimeType, TimeType)
```

Simultaneously return the floor and ceil of a `Date` or `DateTime` at resolution p . More efficient than calling both `floor` and `ceil` individually.

```
| floorceil(x::Period, precision::T) where T <: Union{TimePeriod, Week, Day} -> (T, T)
```

Simultaneously return the floor and ceil of `Period` at resolution p . More efficient than calling both `floor` and `ceil` individually.

`Dates.epochdays2date` – Function.

```
| epochdays2date(days) -> Date
```

Take the number of days since the rounding epoch (0000-01-01T00:00:00) and return the corresponding `Date`.

`Dates.epochms2datetime` – Function.

```
| epochms2datetime(milliseconds) -> DateTime
```

Take the number of milliseconds since the rounding epoch (0000-01-01T00:00:00) and return the corresponding `DateTime`.

`Dates.date2epochdays` – Function.

```
| date2epochdays(dt::Date) -> Int64
```

Take the given `Date` and return the number of days since the rounding epoch (0000-01-01T00:00:00) as an `Int64`.

Dates.datetime2epochms – Function.

```
| datetime2epochms(dt::DateTime) -> Int64
```

Take the given DateTime and return the number of milliseconds since the rounding epoch (0000-01-01T00:00:00) as an Int64.

Conversion Functions

Dates.today – Function.

```
| today() -> Date
```

Return the date portion of now().

Dates.unix2datetime – Function.

```
| unix2datetime(x) -> DateTime
```

Take the number of seconds since unix epoch 1970-01-01T00:00:00 and convert to the corresponding DateTime.

Dates.datetime2unix – Function.

```
| datetime2unix(dt::DateTime) -> Float64
```

Take the given DateTime and return the number of seconds since the unix epoch 1970-01-01T00:00:00 as a Float64.

Dates.julian2datetime – Function.

```
| julian2datetime(julian_days) -> DateTime
```

Take the number of Julian calendar days since epoch -4713-11-24T12:00:00 and return the corresponding DateTime.

Dates.datetime2julian – Function.

```
| datetime2julian(dt::DateTime) -> Float64
```

Take the given DateTime and return the number of Julian calendar days since the julian epoch -4713-11-24T12:00:00 as a Float64.

Dates.rata2datetime – Function.

```
| rata2datetime(days) -> DateTime
```

Take the number of Rata Die days since epoch 0000-12-31T00:00:00 and return the corresponding DateTime.

Dates.datetime2rata – Function.

```
| datetime2rata(dt::TimeType) -> Int64
```

Return the number of Rata Die days since epoch from the given Date or DateTime.

| Variable | Abbr. | Value (Int) |

Common Date Formatters

Dates.ISODateTimeFormat – Constant.

```
| Dates.ISODateTimeFormat
```

Describes the ISO8601 formatting for a date and time. This is the default value for Dates.format of a DateTime.

Example

```
| julia> Dates.format(DateTime(2018, 8, 8, 12, 0, 43, 1), ISODateTimeFormat)
| "2018-08-08T12:00:43.001"
```

Dates.ISODateFormat – Constant.

```
| Dates.ISODateFormat
```

Describes the ISO8601 formatting for a date. This is the default value for Dates.format of a Date.

Example

```
| julia> Dates.format(Date(2018, 8, 8), ISODateFormat)  
"2018-08-08"
```

Dates.ISOTimeFormat – Constant.

```
| Dates.ISOTimeFormat
```

Describes the ISO8601 formatting for a time. This is the default value for Dates.format of a Time.

Example

```
| julia> Dates.format(Time(12, 0, 43, 1), ISOTimeFormat)  
"12:00:43.001"
```

Dates.RFC1123Format – Constant.

```
| Dates.RFC1123Format
```

Describes the RFC1123 formatting for a date and time.

Example

```
| julia> Dates.format(DateTime(2018, 8, 8, 12, 0, 43, 1), RFC1123Format)  
"Wed, 08 Aug 2018 12:00:43"
```

Chapter 67

Delimited Files

DelimitedFiles.readlm - Method.

```
readlm(source, delim::AbstractChar, T::Type, eol::AbstractChar; header=false, skipstart=0,  
↳ skipblanks=true, use_mmap, quotes=true, dims, comments=false, comment_char='#')
```

Read a matrix from the source where each line (separated by `eol`) gives one row, with elements separated by the given delimiter. The source can be a text file, stream or byte array. Memory mapped files can be used by passing the byte array representation of the mapped segment as source.

If `T` is a numeric type, the result is an array of that type, with any non-numeric elements as `NaN` for floating-point types, or zero. Other useful values of `T` include `String`, `AbstractString`, and `Any`.

If `header` is `true`, the first row of data will be read as header and the tuple (`data_cells`, `header_cells`) is returned instead of only `data_cells`.

Specifying `skipstart` will ignore the corresponding number of initial lines from the input.

If `skipblanks` is `true`, blank lines in the input will be ignored.

If `use_mmap` is `true`, the file specified by `source` is memory mapped for potential speedups if the file is large. Default is `false`. On a Windows filesystem, `use_mmap` should not be set to `true` unless the file is only read once and is also not written to. Some edge cases exist where an OS is Unix-like but the filesystem is Windows-like.

If `quotes` is `true`, columns enclosed within double-quote (") characters are allowed to contain new lines and column delimiters. Double-quote characters within a quoted field must be escaped with another double-quote. Specifying `dims` as a tuple of the expected rows and columns (including header, if any) may speed up reading of large files. If `comments` is `true`, lines beginning with `comment_char` and text following `comment_char` in any line are ignored.

Examples

```
julia> using DelimitedFiles  
  
julia> x = [1; 2; 3; 4];  
  
julia> y = [5; 6; 7; 8];  
  
julia> open("delim_file.txt", "w") do io  
    writelm(io, [x y])  
end
```

```

        end

julia> readlm("delim_file.txt", '\t', Int, '\n')
4×2 Matrix{Int64}:
 1  5
 2  6
 3  7
 4  8

julia> rm("delim_file.txt")

```

[source](#)

DelimitedFiles.readlm – Method.

```
| readlm(source, delim::AbstractChar, eol::AbstractChar; options...)
```

If all data is numeric, the result will be a numeric array. If some elements cannot be parsed as numbers, a heterogeneous array of numbers and strings is returned.

[source](#)

DelimitedFiles.readlm – Method.

```
| readlm(source, delim::AbstractChar, T::Type; options...)
```

The end of line delimiter is taken as `\n`.

Examples

```

julia> using DelimitedFiles

julia> x = [1; 2; 3; 4];

julia> y = [1.1; 2.2; 3.3; 4.4];

julia> open("delim_file.txt", "w") do io
        writelm(io, [x y], ',')
    end;

julia> readlm("delim_file.txt", ',', Float64)
4×2 Matrix{Float64}:
 1.0  1.1
 2.0  2.2
 3.0  3.3
 4.0  4.4

julia> rm("delim_file.txt")

```

[source](#)

DelimitedFiles.readlm – Method.

```
| readlm(source, delim::AbstractChar; options...)
```

The end of line delimiter is taken as `\n`. If all data is numeric, the result will be a numeric array. If some elements cannot be parsed as numbers, a heterogeneous array of numbers and strings is returned.

Examples

```
julia> using DelimitedFiles

julia> x = [1; 2; 3; 4];

julia> y = [1.1; 2.2; 3.3; 4.4];

julia> open("delim_file.txt", "w") do io
    writedlm(io, [x y], ',')
end;

julia> readldm("delim_file.txt", ',')
4×2 Matrix{Float64}:
 1.0  1.1
 2.0  2.2
 3.0  3.3
 4.0  4.4

julia> z = ["a"; "b"; "c"; "d"];

julia> open("delim_file.txt", "w") do io
    writedlm(io, [x z], ',')
end;

julia> readldm("delim_file.txt", ',')
4×2 Matrix{Any}:
 1  "a"
 2  "b"
 3  "c"
 4  "d"

julia> rm("delim_file.txt")
```

[source](#)

`DelimitedFiles.readldm` – Method.

```
| readldm(source, T::Type; options...)
```

The columns are assumed to be separated by one or more whitespaces. The end of line delimiter is taken as `\n`.

Examples

```
julia> using DelimitedFiles

julia> x = [1; 2; 3; 4];

julia> y = [5; 6; 7; 8];
```

```

julia> open("delim_file.txt", "w") do io
    writedlm(io, [x y])
end;

julia> readldm("delim_file.txt", Int64)
4×2 Matrix{Int64}:
 1  5
 2  6
 3  7
 4  8

julia> readldm("delim_file.txt", Float64)
4×2 Matrix{Float64}:
 1.0  5.0
 2.0  6.0
 3.0  7.0
 4.0  8.0

julia> rm("delim_file.txt")

```

[source](#)

DelimitedFiles.readldm - Method.

```
| readldm(source; options...)
```

The columns are assumed to be separated by one or more whitespaces. The end of line delimiter is taken as `\n`. If all data is numeric, the result will be a numeric array. If some elements cannot be parsed as numbers, a heterogeneous array of numbers and strings is returned.

Examples

```

julia> using DelimitedFiles

julia> x = [1; 2; 3; 4];

julia> y = ["a"; "b"; "c"; "d"];

julia> open("delim_file.txt", "w") do io
    writedlm(io, [x y])
end;

julia> readldm("delim_file.txt")
4×2 Matrix{Any}:
 1  "a"
 2  "b"
 3  "c"
 4  "d"

julia> rm("delim_file.txt")

```

[source](#)

DelimitedFiles.writedlm - Function.

```
writedlm(f, A, delim='\t'; opts)
```

Write A (a vector, matrix, or an iterable collection of iterable rows) as text to f (either a filename string or an IO stream) using the given delimiter `delim` (which defaults to tab, but can be any printable Julia object, typically a Char or AbstractString).

For example, two vectors `x` and `y` of the same length can be written as two columns of tab-delimited text to `f` by either `writedlm(f, [x y])` or by `writedlm(f, zip(x, y))`.

Examples

```
julia> using DelimitedFiles

julia> x = [1; 2; 3; 4];

julia> y = [5; 6; 7; 8];

julia> open("delim_file.txt", "w") do io
    writedlm(io, [x y])
end

julia> readlm("delim_file.txt", '\t', Int, '\n')
4×2 Matrix{Int64}:
 1  5
 2  6
 3  7
 4  8

julia> rm("delim_file.txt")
```

[source](#)

Chapter 68

Distributed Computing

Tools for distributed parallel processing.

Distributed.addprocs – Function.

```
| addprocs(manager::ClusterManager; kwargs...) -> List of process identifiers
```

Launches worker processes via the specified cluster manager.

For example, Beowulf clusters are supported via a custom cluster manager implemented in the package ClusterManagers.jl.

The number of seconds a newly launched worker waits for connection establishment from the master can be specified via variable JULIA_WORKER_TIMEOUT in the worker process's environment. Relevant only when using TCP/IP as transport.

To launch workers without blocking the REPL, or the containing function if launching workers programmatically, execute addprocs in its own task.

Examples

```
| # On busy clusters, call `addprocs` asynchronously
| t = @async addprocs(...)

| # Utilize workers as and when they come online
| if nprocs() > 1 # Ensure at least one new worker is available
|     .... # perform distributed execution
| end

| # Retrieve newly launched worker IDs, or any error messages
| if istaskdone(t) # Check if `addprocs` has completed to ensure `fetch` doesn't block
|     if nworkers() == N
|         new_pids = fetch(t)
|     else
|         fetch(t)
|     end
| end
```

[source](#)

```
addprocs(machines; tunnel=false, sshflags='', max_parallel=10, kwargs...) -> List of process
    identifiers
```

Add worker processes on remote machines via SSH. Configuration is done with keyword arguments (see below). In particular, the `exename` keyword can be used to specify the path to the `julia` binary on the remote machine(s).

`machines` is a vector of "machine specifications" which are given as strings of the form `[user@]host[:port]` `[bind_addr[:port]]`. `user` defaults to current user and `port` to the standard SSH port. If `[bind_addr[:port]]` is specified, other workers will connect to this worker at the specified `bind_addr` and `port`.

It is possible to launch multiple processes on a remote host by using a tuple in the `machines` vector or the form `(machine_spec, count)`, where `count` is the number of workers to be launched on the specified host. Passing `:auto` as the worker count will launch as many workers as the number of CPU threads on the remote host.

Examples:

```
addprocs([
    "remote1",           # one worker on 'remote1' logging in with the current username
    "user@remote2",      # one worker on 'remote2' logging in with the 'user' username
    "user@remote3:2222", # specifying SSH port to '2222' for 'remote3'
    ("user@remote4", 4),  # launch 4 workers on 'remote4'
    ("user@remote5", :auto), # launch as many workers as CPU threads on 'remote5'
])
```

Keyword arguments:

- `tunnel`: if `true` then SSH tunneling will be used to connect to the worker from the master process. Default is `false`.
- `multiplex`: if `true` then SSH multiplexing is used for SSH tunneling. Default is `false`.
- `ssh`: the name or path of the SSH client executable used to start the workers. Default is `"ssh"`.
- `sshflags`: specifies additional ssh options, e.g. `sshflags='-i /home/foo/bar.pem'`
- `max_parallel`: specifies the maximum number of workers connected to in parallel at a host. Defaults to 10.
- `shell`: specifies the type of shell to which ssh connects on the workers.
 - `shell=:posix`: a POSIX-compatible Unix/Linux shell (`sh`, `ksh`, `bash`, `dash`, `zsh`, etc.). The default.
 - `shell=:csh`: a Unix C shell (`csh`, `tcsh`).
 - `shell=:wincmd`: Microsoft Windows `cmd.exe`.
- `dir`: specifies the working directory on the workers. Defaults to the host's current directory (as found by `pwd()`)
- `enable_threaded_blas`: if `true` then BLAS will run on multiple threads in added processes. Default is `false`.
- `exename`: name of the `julia` executable. Defaults to `"$(Sys.BINDIR)/julia"` or `"$(Sys.BINDIR)/julia-debug"` as the case may be. It is recommended that a common Julia version is used on all remote machines because serialization and code distribution might fail otherwise.
- `exeflags`: additional flags passed to the worker processes.

- **topology**: Specifies how the workers connect to each other. Sending a message between unconnected workers results in an error.
 - **topology=:all_to_all**: All processes are connected to each other. The default.
 - **topology=:master_worker**: Only the driver process, i.e. pid 1 connects to the workers. The workers do not connect to each other.
 - **topology=:custom**: The launch method of the cluster manager specifies the connection topology via fields **ident** and **connect_ids** in **WorkerConfig**. A worker with a cluster manager identity **ident** will connect to all workers specified in **connect_ids**.
- **lazy**: Applicable only with **topology=:all_to_all**. If **true**, worker-worker connections are setup lazily, i.e. they are setup at the first instance of a remote call between workers. Default is **true**.
- **env**: provide an array of string pairs such as **env=["JULIA_DEPOT_PATH"=>"/depot"]** to request that environment variables are set on the remote machine. By default only the environment variable **JULIA_WORKER_TIMEOUT** is passed automatically from the local to the remote environment.
- **cmdline_cookie**: pass the authentication cookie via the **--worker** commandline option. The (more secure) default behaviour of passing the cookie via **ssh stdio** may hang with Windows workers that use older (pre-ConPTY) Julia or Windows versions, in which case **cmdline_cookie=true** offers a work-around.

Julia 1.6

The keyword arguments **ssh**, **shell**, **env** and **cmdline_cookie** were added in Julia 1.6.

Environment variables:

If the master process fails to establish a connection with a newly launched worker within 60.0 seconds, the worker treats it as a fatal situation and terminates. This timeout can be controlled via environment variable **JULIA_WORKER_TIMEOUT**. The value of **JULIA_WORKER_TIMEOUT** on the master process specifies the number of seconds a newly launched worker waits for connection establishment.

source

```
addprocs(np::Integer=Sys.CPU_THREADS; restrict=true, kwargs...) -> List of process
identifiers
```

Launch **np** workers on the local host using the in-built **LocalManager**.

Local workers inherit the current package environment (i.e., active project, **LOAD_PATH**, and **DEPOT_PATH**) from the main process.

Keyword arguments:

- **restrict::Bool**: if **true** (default) binding is restricted to 127.0.0.1.
- **dir**, **exename**, **exeflags**, **env**, **topology**, **lazy**, **enable_threaded_blas**: same effect as for **SSHManager**, see documentation for **addprocs(machines::AbstractVector)**.

Julia 1.9

The inheriting of the package environment and the **env** keyword argument were added in Julia 1.9.

source

Distributed.nprocs - Function.

```
| nprocs()
```

Get the number of available processes.

Examples

```
| julia> nprocs()
3

julia> workers()
2-element Array{Int64,1}:
 2
 3
```

[source](#)

Distributed.nworkers - Function.

```
| nworkers()
```

Get the number of available worker processes. This is one less than `nprocs()`. Equal to `nprocs()` if `nprocs() == 1`.

Examples

```
| $ julia -p 2

julia> nprocs()
3

julia> nworkers()
2
```

[source](#)

Distributed.procs - Method.

```
| procs()
```

Return a list of all process identifiers, including pid 1 (which is not included by `workers()`).

Examples

```
| $ julia -p 2

julia> procs()
3-element Array{Int64,1}:
 1
 2
 3
```

[source](#)

Distributed.procs – Method.

```
|procs(pid::Integer)
```

Return a list of all process identifiers on the same physical node. Specifically all workers bound to the same ip-address as pid are returned.

[source](#)

Distributed.workers – Function.

```
|workers()
```

Return a list of all worker process identifiers.

Examples

```
$ julia -p 2

julia> workers()
2-element Array{Int64,1}:
 2
 3
```

[source](#)

Distributed.rmprocs – Function.

```
|rmprocs(pids...; waitfor=typemax{Int})
```

Remove the specified workers. Note that only process 1 can add or remove workers.

Argument waitfor specifies how long to wait for the workers to shut down:

- If unspecified, rmprocs will wait until all requested pids are removed.
- An `ErrorException` is raised if all workers cannot be terminated before the requested waitfor seconds.
- With a waitfor value of 0, the call returns immediately with the workers scheduled for removal in a different task. The scheduled `Task` object is returned. The user should call `wait` on the task before invoking any other parallel calls.

Examples

```
$ julia -p 5

julia> t = rmprocs(2, 3, waitfor=0)
Task (runnable) @0x0000000107c718d0

julia> wait(t)

julia> workers()
3-element Array{Int64,1}:
 4
 5
 6
```

source

Distributed.interrupt – Function.

```
| interrupt(pids::Integer...)
```

Interrupt the current executing task on the specified workers. This is equivalent to pressing Ctrl-C on the local machine. If no arguments are given, all workers are interrupted.

source

```
| interrupt(pids::AbstractVector=workers())
```

Interrupt the current executing task on the specified workers. This is equivalent to pressing Ctrl-C on the local machine. If no arguments are given, all workers are interrupted.

source

Distributed.myid – Function.

```
| myid()
```

Get the id of the current process.

Examples

```
| julia> myid()
1
| julia> remotecall_fetch(() -> myid(), 4)
4
```

source

Distributed.pmap – Function.

```
| pmap(f, [::AbstractWorkerPool], c...; distributed=true, batch_size=1, on_error=nothing,
↪ retry_delays=[], retry_check=nothing) -> collection
```

Transform collection *c* by applying *f* to each element using available workers and tasks.

For multiple collection arguments, apply *f* elementwise.

Note that *f* must be made available to all worker processes; see [Code Availability and Loading Packages](#) for details.

If a worker pool is not specified, all available workers, i.e., the default worker pool is used.

By default, *pmap* distributes the computation over all specified workers. To use only the local process and distribute over tasks, specify *distributed=false*. This is equivalent to using *asynccmap*. For example, *pmap(f, c; distributed=false)* is equivalent to *asynccmap(f, c; ntasks=()->nworkers())*

pmap can also use a mix of processes and tasks via the *batch_size* argument. For batch sizes greater than 1, the collection is processed in multiple batches, each of length *batch_size* or less. A batch is sent as a single request to a free worker, where a local *asynccmap* processes elements from the batch using multiple concurrent tasks.

Any error stops `pmap` from processing the remainder of the collection. To override this behavior you can specify an error handling function via argument `on_error` which takes in a single argument, i.e., the exception. The function can stop the processing by rethrowing the error, or, to continue, return any value which is then returned inline with the results to the caller.

Consider the following two examples. The first one returns the exception object inline, the second a 0 in place of any exception:

```
julia> pmap(x->iseven(x) ? error("foo") : x, 1:4; on_error=identity)
4-element Array{Any,1}:
 1
  ExceptionException("foo")
 3
  ExceptionException("foo")

julia> pmap(x->iseven(x) ? error("foo") : x, 1:4; on_error=ex->0)
4-element Array{Int64,1}:
 1
  0
  3
  0
```

Errors can also be handled by retrying failed computations. Keyword arguments `retry_delays` and `retry_check` are passed through to `retry` as keyword arguments `delays` and `check` respectively. If batching is specified, and an entire batch fails, all items in the batch are retried.

Note that if both `on_error` and `retry_delays` are specified, the `on_error` hook is called before retrying. If `on_error` does not throw (or rethrow) an exception, the element will not be retried.

Example: On errors, retry `f` on an element a maximum of 3 times without any delay between retries.

```
pmap(f, c; retry_delays = zeros(3))
```

Example: Retry `f` only if the exception is not of type `InexactError`, with exponentially increasing delays up to 3 times. Return a `NaN` in place for all `InexactError` occurrences.

```
pmap(f, c; on_error = e->(isa(e, InexactError) ? NaN : rethrow()), retry_delays =
↳ ExponentialBackOff(n = 3))
```

[source](#)

`Distributed.RemoteException` – Type.

```
RemoteException(captured)
```

Exceptions on remote computations are captured and rethrown locally. A `RemoteException` wraps the `pid` of the worker and a captured exception. A `CapturedException` captures the remote exception and a serializable form of the call stack when the exception was raised.

[source](#)

`Distributed.ProcessExitedException` – Type.

```
ProcessExitedException(worker_id::Int)
```

After a client Julia process has exited, further attempts to reference the dead child will throw this exception.

[source](#)

Distributed.Future – Type.

```
| Future(w::Int, rrid::RRID, v::Union{Some, Nothing}=nothing)
```

A Future is a placeholder for a single computation of unknown termination status and time. For multiple potential computations, see RemoteChannel. See remoteref_id for identifying an AbstractRemoteRef.

[source](#)

Distributed.RemoteChannel – Type.

```
| RemoteChannel(pid::Integer=myid())
```

Make a reference to a Channel{Any}(1) on process pid. The default pid is the current process.

```
| RemoteChannel(f::Function, pid::Integer=myid())
```

Create references to remote channels of a specific size and type. f is a function that when executed on pid must return an implementation of an AbstractChannel.

For example, RemoteChannel(()->Channel{Int}(10), pid), will return a reference to a channel of type Int and size 10 on pid.

The default pid is the current process.

[source](#)

Base.fetch – Method.

```
| fetch(x::Future)
```

Wait for and get the value of a Future. The fetched value is cached locally. Further calls to fetch on the same reference return the cached value. If the remote value is an exception, throws a RemoteException which captures the remote exception and backtrace.

[source](#)

Base.fetch – Method.

```
| fetch(c::RemoteChannel)
```

Wait for and get a value from a RemoteChannel. Exceptions raised are the same as for a Future. Does not remove the item fetched.

[source](#)

```
| fetch(x::Any)
```

Return x.

[source](#)

Distributed.remotecall – Method.

```
| remotecall(f, id::Integer, args...; kwargs...) -> Future
```

Call a function `f` asynchronously on the given arguments on the specified process. Return a [Future](#). Keyword arguments, if any, are passed through to `f`.

[source](#)

Distributed.remotecall_wait – Method.

```
| remotecall_wait(f, id::Integer, args...; kwargs...)
```

Perform a faster `wait(remotecall(...))` in one message on the Worker specified by worker id `id`. Keyword arguments, if any, are passed through to `f`.

See also [wait](#) and [remotecall](#).

[source](#)

Distributed.remotecall_fetch – Method.

```
| remotecall_fetch(f, id::Integer, args...; kwargs...)
```

Perform `fetch(remotecall(...))` in one message. Keyword arguments, if any, are passed through to `f`. Any remote exceptions are captured in a [RemoteException](#) and thrown.

See also [fetch](#) and [remotecall](#).

Examples

```
$ julia -p 2

julia> remotecall_fetch(sqrt, 2, 4)
2.0

julia> remotecall_fetch(sqrt, 2, -4)
ERROR: On worker 2:
DomainError with -4.0:
sqrt was called with a negative real argument but will only return a complex result if called
↪ with a complex argument. Try sqrt(Complex(x)).
...
```

[source](#)

Distributed.remote_do – Method.

```
| remote_do(f, id::Integer, args...; kwargs...) -> nothing
```

Executes `f` on worker `id` asynchronously. Unlike [remotecall](#), it does not store the result of computation, nor is there a way to wait for its completion.

A successful invocation indicates that the request has been accepted for execution on the remote node.

While consecutive `remotecalls` to the same worker are serialized in the order they are invoked, the order of executions on the remote worker is undetermined. For example, `remote_do(f1, 2); remotecall(f2,`

2); `remote_do(f3, 2)` will serialize the call to `f1`, followed by `f2` and `f3` in that order. However, it is not guaranteed that `f1` is executed before `f3` on worker 2.

Any exceptions thrown by `f` are printed to `stderr` on the remote worker.

Keyword arguments, if any, are passed through to `f`.

source

`Base.put!` – Method.

```
| put!(rr::RemoteChannel, args...)
```

Store a set of values to the `RemoteChannel`. If the channel is full, blocks until space is available. Return the first argument.

source

`Base.put!` – Method.

```
| put!(rr::Future, v)
```

Store a value to a `Future` `rr`. Futures are write-once remote references. A `put!` on an already set Future throws an Exception. All asynchronous remote calls return Futures and set the value to the return value of the call upon completion.

source

`Base.take!` – Method.

```
| take!(rr::RemoteChannel, args...)
```

Fetch value(s) from a `RemoteChannel` `rr`, removing the value(s) in the process.

source

`Base.isready` – Method.

```
| isready(rr::RemoteChannel, args...)
```

Determine whether a `RemoteChannel` has a value stored to it. Note that this function can cause race conditions, since by the time you receive its result it may no longer be true. However, it can be safely used on a `Future` since they are assigned only once.

source

`Base.isready` – Method.

```
| isready(rr::Future)
```

Determine whether a `Future` has a value stored to it.

If the argument Future is owned by a different node, this call will block to wait for the answer. It is recommended to wait for `rr` in a separate task instead or to use a local `Channel` as a proxy:

```
| p = 1
| f = Future(p)
| errormonitor(@async put!(f, remotecall_fetch(long_computation, p)))
| isready(f) # will not block
```

source

Distributed.AbstractWorkerPool – Type.

```
| AbstractWorkerPool
```

Supertype for worker pools such as [WorkerPool](#) and [CachingPool](#). An AbstractWorkerPool should implement:

- [push!](#) - add a new worker to the overall pool (available + busy)
- [put!](#) - put back a worker to the available pool
- [take!](#) - take a worker from the available pool (to be used for remote function execution)
- [length](#) - number of workers available in the overall pool
- [isready](#) - return false if a [take!](#) on the pool would block, else true

The default implementations of the above (on a AbstractWorkerPool) require fields

- `channel::Channel{Int}`
- `workers::Set{Int}`

where `channel` contains free worker pids and `workers` is the set of all workers associated with this pool.

source

Distributed.WorkerPool – Type.

```
| WorkerPool(workers::Union{Vector{Int},AbstractRange{Int}})
```

Create a WorkerPool from a vector or range of worker ids.

Examples

```
$ julia -p 3

julia> WorkerPool([2, 3])
WorkerPool(Channel{Int64}(sz_max:9223372036854775807,sz_curr:2), Set([2, 3]),
↪ RemoteChannel{Channel{Any}}(1, 1, 6))

julia> WorkerPool(2:4)
WorkerPool(Channel{Int64}(sz_max:9223372036854775807,sz_curr:2), Set([4, 2, 3]),
↪ RemoteChannel{Channel{Any}}(1, 1, 7))
```

source

Distributed.CachingPool – Type.

```
| CachingPool(workers::Vector{Int})
```

An implementation of an `AbstractWorkerPool`. `remote`, `remotecall_fetch`, `pmap` (and other remote calls which execute functions remotely) benefit from caching the serialized/deserialized functions on the worker nodes, especially closures (which may capture large amounts of data).

The remote cache is maintained for the lifetime of the returned `CachingPool` object. To clear the cache earlier, use `clear!(pool)`.

For global variables, only the bindings are captured in a closure, not the data. `let` blocks can be used to capture global data.

Examples

```
const foo = rand(10^8);
wp = CachingPool(workers())
let foo = foo
  pmap(i -> sum(foo) + i, wp, 1:100);
end
```

The above would transfer `foo` only once to each worker.

[source](#)

`Distributed.default_worker_pool` - Function.

```
| default_worker_pool()
```

`AbstractWorkerPool` containing idle `workers` - used by `remote(f)` and `pmap` (by default). Unless one is explicitly set via `default_worker_pool!(pool)`, the default worker pool is initialized to a `WorkerPool`.

Examples

```
$ julia -p 3

julia> default_worker_pool()
WorkerPool{Channel{Int64}}(sz_max:9223372036854775807,sz_curr:3), Set{([4, 2, 3])},
↳ RemoteChannel{Channel{Any}}(1, 1, 4))
```

[source](#)

`Distributed.clear!` - Method.

```
| clear!(pool::CachingPool) -> pool
```

Removes all cached functions from all participating workers.

[source](#)

`Distributed.remote` - Function.

```
| remote([p::AbstractWorkerPool], f) -> Function
```

Return an anonymous function that executes function `f` on an available worker (drawn from `WorkerPool p` if provided) using `remotecall_fetch`.

[source](#)

`Distributed.remotecall` - Method.

```
| remotecall(f, pool::AbstractWorkerPool, args...; kwargs...) -> Future
```

WorkerPool variant of `remotecall(f, pid,)`. Wait for and take a free worker from pool and perform a `remotecall` on it.

Examples

```
$ julia -p 3

julia> wp = WorkerPool([2, 3]);

julia> A = rand(3000);

julia> f = remotecall(maximum, wp, A)
Future(2, 1, 6, nothing)
```

In this example, the task ran on pid 2, called from pid 1.

[source](#)

`Distributed.remotecall_wait` - Method.

```
| remotecall_wait(f, pool::AbstractWorkerPool, args...; kwargs...) -> Future
```

WorkerPool variant of `remotecall_wait(f, pid,)`. Wait for and take a free worker from pool and perform a `remotecall_wait` on it.

Examples

```
$ julia -p 3

julia> wp = WorkerPool([2, 3]);

julia> A = rand(3000);

julia> f = remotecall_wait(maximum, wp, A)
Future(3, 1, 9, nothing)

julia> fetch(f)
0.9995177101692958
```

[source](#)

`Distributed.remotecall_fetch` - Method.

```
| remotecall_fetch(f, pool::AbstractWorkerPool, args...; kwargs...) -> result
```

WorkerPool variant of `remotecall_fetch(f, pid,)`. Waits for and takes a free worker from pool and performs a `remotecall_fetch` on it.

Examples

```
$ julia -p 3
```

```
julia> wp = WorkerPool([2, 3]);

julia> A = rand(3000);

julia> remotecall_fetch(maximum, wp, A)
0.9995177101692958
```

[source](#)

Distributed.remote_do – Method.

```
| remote_do(f, pool::AbstractWorkerPool, args...; kwargs...) -> nothing
```

[WorkerPool](#) variant of `remote_do(f, pid, ...)`. Wait for and take a free worker from pool and perform a `remote_do` on it.

[source](#)

Distributed.@spawnat – Macro.

```
| @spawnat p expr
```

Create a closure around an expression and run the closure asynchronously on process `p`. Return a [Future](#) to the result. If `p` is the quoted literal symbol `:any`, then the system will pick a processor to use automatically.

Examples

```
julia> addprocs(3);

julia> f = @spawnat 2 myid()
Future(2, 1, 3, nothing)

julia> fetch(f)
2

julia> f = @spawnat :any myid()
Future(3, 1, 7, nothing)

julia> fetch(f)
3
```

Julia 1.3

The `:any` argument is available as of Julia 1.3.

[source](#)

Distributed.@fetch – Macro.

```
| @fetch expr
```

Equivalent to `fetch(@spawnat :any expr)`. See [fetch](#) and [@spawnat](#).

Examples

```
julia> addprocs(3);

julia> @fetch myid()
2

julia> @fetch myid()
3

julia> @fetch myid()
4

julia> @fetch myid()
2
```

[source](#)

Distributed.@fetchfrom – Macro.

```
| @fetchfrom
```

Equivalent to `fetch(@spawnat p expr)`. See [fetch](#) and [@spawnat](#).

Examples

```
julia> addprocs(3);

julia> @fetchfrom 2 myid()
2

julia> @fetchfrom 4 myid()
4
```

[source](#)

Distributed.@distributed – Macro.

```
| @distributed
```

A distributed memory, parallel for loop of the form :

```
@distributed [reducer] for var = range
    body
end
```

The specified range is partitioned and locally executed across all workers. In case an optional reducer function is specified, `@distributed` performs local reductions on each worker with a final reduction on the calling process.

Note that without a reducer function, `@distributed` executes asynchronously, i.e. it spawns independent tasks on all available workers and returns immediately without waiting for completion. To wait for completion, prefix the call with [@sync](#), like :

```
@sync @distributed for var = range
    body
end
```

source

Distributed.@everywhere - Macro.

```
| @everywhere [procs()] expr
```

Execute an expression under Main on all procs. Errors on any of the processes are collected into a [CompositeException](#) and thrown. For example:

```
| @everywhere bar = 1
```

will define Main.bar on all current processes. Any processes added later (say with [addprocs\(\)](#)) will not have the expression defined.

Unlike [@spawnat](#), @everywhere does not capture any local variables. Instead, local variables can be broadcast using interpolation:

```
| foo = 1
| @everywhere bar = $foo
```

The optional argument procs allows specifying a subset of all processes to have execute the expression.

Similar to calling `remotecall_eval(Main, procs, expr)`, but with two extra features:

- ``using`` and ``import`` statements run on the calling process first, to ensure packages are precompiled.
- The current source file path used by ``include`` is propagated to other processes.

source

Distributed.clear! - Method.

```
| clear!(syms, pids=workers(); mod=Main)
```

Clears global bindings in modules by initializing them to nothing. syms should be of type [Symbol](#) or a collection of Symbols. pids and mod identify the processes and the module in which global variables are to be reinitialized. Only those names found to be defined under mod are cleared.

An exception is raised if a global constant is requested to be cleared.

source

Distributed.remoteref_id - Function.

```
| remoteref_id(r::AbstractRemoteRef) -> RRID
```

Futures and RemoteChannels are identified by fields:

- where - refers to the node where the underlying object/storage referred to by the reference actually exists.
- whence - refers to the node the remote reference was created from. Note that this is different from the node where the underlying object referred to actually exists. For example calling `RemoteChannel(2)` from the master process would result in a where value of 2 and a whence value of 1.
- id is unique across all references created from the worker specified by whence.

Taken together, whence and id uniquely identify a reference across all workers.

remoteref_id is a low-level API which returns a RRID object that wraps whence and id values of a remote reference.

[source](#)

Distributed.channel_from_id - Function.

```
| channel_from_id(id) -> c
```

A low-level API which returns the backing AbstractChannel for an id returned by remoteref_id. The call is valid only on the node where the backing channel exists.

[source](#)

Distributed.worker_id_from_socket - Function.

```
| worker_id_from_socket(s) -> pid
```

A low-level API which, given a IO connection or a Worker, returns the pid of the worker it is connected to. This is useful when writing custom serialize methods for a type, which optimizes the data written out depending on the receiving process id.

[source](#)

Distributed.cluster_cookie - Method.

```
| cluster_cookie() -> cookie
```

Return the cluster cookie.

[source](#)

Distributed.cluster_cookie - Method.

```
| cluster_cookie(cookie) -> cookie
```

Set the passed cookie as the cluster cookie, then returns it.

[source](#)

68.1 Cluster Manager Interface

This interface provides a mechanism to launch and manage Julia workers on different cluster environments. There are two types of managers present in Base: LocalManager, for launching additional workers on the same host, and SSHManager, for launching on remote hosts via ssh. TCP/IP sockets are used to connect and transport messages between processes. It is possible for Cluster Managers to provide a different transport.

Distributed.ClusterManager - Type.

```
| ClusterManager
```

Supertype for cluster managers, which control workers processes as a cluster. Cluster managers implement how workers can be added, removed and communicated with. SSHManager and LocalManager are subtypes of this.

[source](#)

Distributed.WorkerConfig – Type.

WorkerConfig

Type used by [ClusterManagers](#) to control workers added to their clusters. Some fields are used by all cluster managers to access a host:

- `io` – the connection used to access the worker (a subtype of `IO` or `Nothing`)
- `host` – the host address (either a `String` or `Nothing`)
- `port` – the port on the host used to connect to the worker (either an `Int` or `Nothing`)

Some are used by the cluster manager to add workers to an already-initialized host:

- `count` – the number of workers to be launched on the host
- `exename` – the path to the Julia executable on the host, defaults to `"$(Sys.BINDIR)/julia"` or `"$(Sys.BINDIR)/julia-debug"`
- `exeflags` – flags to use when launching Julia remotely

The `userdata` field is used to store information for each worker by external managers.

Some fields are used by `SSHManager` and similar managers:

- `tunnel` – `true` (use tunneling), `false` (do not use tunneling), or `nothing` (use default for the manager)
- `multiplex` – `true` (use SSH multiplexing for tunneling) or `false`
- `forward` – the forwarding option used for `-L` option of `ssh`
- `bind_addr` – the address on the remote host to bind to
- `sshflags` – flags to use in establishing the SSH connection
- `max_parallel` – the maximum number of workers to connect to in parallel on the host

Some fields are used by both `LocalManagers` and `SSHManagers`:

- `connect_at` – determines whether this is a worker-to-worker or driver-to-worker setup call
- `process` – the process which will be connected (usually the manager will assign this during [addprocs](#))
- `ospid` – the process ID according to the host OS, used to interrupt worker processes
- `environ` – private dictionary used to store temporary information by Local/SSH managers
- `ident` – worker as identified by the [ClusterManager](#)
- `connect_idents` – list of worker ids the worker must connect to if using a custom topology
- `enable_threaded_blas` – `true`, `false`, or `nothing`, whether to use threaded BLAS or not on the workers

source

Distributed.launch – Function.

```
| launch(manager::ClusterManager, params::Dict, launched::Array, launch_ntfy::Condition)
```

Implemented by cluster managers. For every Julia worker launched by this function, it should append a `WorkerConfig` entry to `launched` and notify `launch_ntfy`. The function MUST exit once all workers, requested by manager have been launched. `params` is a dictionary of all keyword arguments `addprocs` was called with.

[source](#)

`Distributed.manage` – Function.

```
| manage(manager::ClusterManager, id::Integer, config::WorkerConfig, op::Symbol)
```

Implemented by cluster managers. It is called on the master process, during a worker's lifetime, with appropriate `op` values:

- with `:register`/`:deregister` when a worker is added / removed from the Julia worker pool.
- with `:interrupt` when `interrupt(workers)` is called. The `ClusterManager` should signal the appropriate worker with an interrupt signal.
- with `:finalize` for cleanup purposes.

[source](#)

`Base.kill` – Method.

```
| kill(manager::ClusterManager, pid::Int, config::WorkerConfig)
```

Implemented by cluster managers. It is called on the master process, by `rmprocs`. It should cause the remote worker specified by `pid` to exit. `kill(manager::ClusterManager....)` executes a remote `exit()` on `pid`.

[source](#)

`Sockets.connect` – Method.

```
| connect(manager::ClusterManager, pid::Int, config::WorkerConfig) -> (instrm::IO, outstrm::IO)
```

Implemented by cluster managers using custom transports. It should establish a logical connection to worker with id `pid`, specified by `config` and return a pair of `IO` objects. Messages from `pid` to current process will be read off `instrm`, while messages to be sent to `pid` will be written to `outstrm`. The custom transport implementation must ensure that messages are delivered and received completely and in order. `connect(manager::ClusterManager....)` sets up TCP/IP socket connections in-between workers.

[source](#)

`Distributed.init_worker` – Function.

```
| init_worker(cookie::AbstractString, manager::ClusterManager=DefaultClusterManager())
```

Called by cluster managers implementing custom transports. It initializes a newly launched process as a worker. Command line argument `--worker[=<cookie>]` has the effect of initializing a process as a worker using TCP/IP sockets for transport. `cookie` is a `cluster_cookie`.

[source](#)

Distributed.start_worker - Function.

```
| start_worker([out::IO=stdout], cookie::AbstractString=readline(stdin);  
| ↪ close_stdin::Bool=true, stderr_to_stdout::Bool=true)
```

start_worker is an internal function which is the default entry point for worker processes connecting via TCP/IP. It sets up the process as a Julia cluster worker.

host:port information is written to stream out (defaults to stdout).

The function reads the cookie from stdin if required, and listens on a free port (or if specified, the port in the --bind-to command line option) and schedules tasks to process incoming TCP connections and requests. It also (optionally) closes stdin and redirects stderr to stdout.

It does not return.

[source](#)

Distributed.process_messages - Function.

```
| process_messages(r_stream::IO, w_stream::IO, incoming::Bool=true)
```

Called by cluster managers using custom transports. It should be called when the custom transport implementation receives the first message from a remote worker. The custom transport must manage a logical connection to the remote worker and provide two IO objects, one for incoming messages and the other for messages addressed to the remote worker. If incoming is true, the remote peer initiated the connection. Whichever of the pair initiates the connection sends the cluster cookie and its Julia version number to perform the authentication handshake.

See also [cluster_cookie](#).

[source](#)

Distributed.default_addprocs_params - Function.

```
| default_addprocs_params(mgr::ClusterManager) -> Dict{Symbol, Any}
```

Implemented by cluster managers. The default keyword parameters passed when calling addprocs(mgr). The minimal set of options is available by calling default_addprocs_params()

[source](#)

Chapter 69

Downloads

Downloads.download – Function.

```
download(url, [ output = tempname() ];
  [ method = "GET", ]
  [ headers = <none>, ]
  [ timeout = <none>, ]
  [ progress = <none>, ]
  [ verbose = false, ]
  [ debug = <none>, ]
  [ downloader = <default>, ]
) -> output

url      :: AbstractString
output   :: Union{AbstractString, AbstractCmd, IO}
method   :: AbstractString
headers  :: Union{AbstractVector, AbstractDict}
timeout  :: Real
progress :: (total::Integer, now::Integer) --> Any
verbose  :: Bool
debug    :: (type, message) --> Any
downloader :: Downloader
```

Download a file from the given url, saving it to output or if not specified, a temporary path. The output can also be an IO handle, in which case the body of the response is streamed to that handle and the handle is returned. If output is a command, the command is run and output is sent to it on stdin.

If the downloader keyword argument is provided, it must be a Downloader object. Resources and connections will be shared between downloads performed by the same Downloader and cleaned up automatically when the object is garbage collected or there have been no downloads performed with it for a grace period. See Downloader for more info about configuration and usage.

If the headers keyword argument is provided, it must be a vector or dictionary whose elements are all pairs of strings. These pairs are passed as headers when downloading URLs with protocols that supports them, such as HTTP/S.

The timeout keyword argument specifies a timeout for the download to complete in seconds, with a resolution of milliseconds. By default no timeout is set, but this can also be explicitly requested by passing a timeout value of Inf. Separately, if 20 seconds elapse without receiving any data, the download will timeout. See extended help for how to disable this timeout.

If the `progress` keyword argument is provided, it must be a callback function which will be called whenever there are updates about the size and status of the ongoing download. The callback must take two integer arguments: `total` and `now` which are the total size of the download in bytes, and the number of bytes which have been downloaded so far. Note that `total` starts out as zero and remains zero until the server gives an indication of the total size of the download (e.g. with a `Content-Length` header), which may never happen. So a well-behaved progress callback should handle a total size of zero gracefully.

If the `verbose` option is set to `true`, `libcurl`, which is used to implement the download functionality will print debugging information to `stderr`. If the `debug` option is set to a function accepting two `String` arguments, then the `verbose` option is ignored and instead the data that would have been printed to `stderr` is passed to the debug callback with `type` and `message` arguments. The `type` argument indicates what kind of event has occurred, and is one of: `TEXT`, `HEADER IN`, `HEADER OUT`, `DATA IN`, `DATA OUT`, `SSL DATA IN` or `SSL DATA OUT`. The `message` argument is the description of the debug event.

Extended Help

For further customization, use a [Downloader](#) and [easy_hooks](#). For example, to disable the 20 second timeout when no data is received, you may use the following:

```
download = Downloads.Downloader()
download.easy_hook = (easy, info) -> Downloads.Curl.setopt(easy, Downloads.Curl.
    CURLOPT_LOW_SPEED_TIME, 0)

Downloads.download("https://httpbingo.org/delay/30"; download)
```

`Downloads.request` – Function.

```
request(url;
    [ input = <none>, ]
    [ output = <none>, ]
    [ method = input ? "PUT" : output ? "GET" : "HEAD", ]
    [ headers = <none>, ]
    [ timeout = <none>, ]
    [ progress = <none>, ]
    [ verbose = false, ]
    [ debug = <none>, ]
    [ throw = true, ]
    [ downloader = <default>, ]
) -> Union{Response, RequestError}

url      :: AbstractString
input    :: Union{AbstractString, AbstractCmd, IO}
output   :: Union{AbstractString, AbstractCmd, IO}
method   :: AbstractString
headers  :: Union{AbstractVector, AbstractDict}
timeout  :: Real
progress :: (dl_total, dl_now, ul_total, ul_now) --> Any
verbose  :: Bool
debug    :: (type, message) --> Any
throw    :: Bool
downloader :: Downloader
```

Make a request to the given `url`, returning a `Response` object capturing the status, headers and other information about the response. The body of the response is written to `output` if specified and discarded

otherwise. For HTTP/S requests, if an input stream is given, a PUT request is made; otherwise if an output stream is given, a GET request is made; if neither is given a HEAD request is made. For other protocols, appropriate default methods are used based on what combination of input and output are requested. The following options differ from the `download` function:

- `input` allows providing a request body; if provided default to PUT request
- `progress` is a callback taking four integers for upload and download progress
- `throw` controls whether to throw or return a `RequestError` on request error

Note that unlike `download` which throws an error if the requested URL could not be downloaded (indicated by non-2xx status code), `request` returns a `Response` object no matter what the status code of the response is. If there is an error with getting a response at all, then a `RequestError` is thrown or returned.

`Downloads.Response` – Type.

```
struct Response
  proto  :: String
  url    :: String
  status :: Int
  message :: String
  headers :: Vector{Pair{String,String}}
end
```

`Response` is a type capturing the properties of a successful response to a request as an object. It has the following fields:

- `proto`: the protocol that was used to get the response
- `url`: the URL that was ultimately requested after following redirects
- `status`: the status code of the response, indicating success, failure, etc.
- `message`: a textual message describing the nature of the response
- `headers`: any headers that were returned with the response

The meaning and availability of some of these responses depends on the protocol used for the request. For many protocols, including HTTP/S and S/FTP, a 2xx status code indicates a successful response. For responses in protocols that do not support headers, the headers vector will be empty. HTTP/2 does not include a status message, only a status code, so the message will be empty.

`Downloads.RequestError` – Type.

```
struct RequestError <: Exception
  url      :: String
  code     :: Int
  message  :: String
  response :: Response
end
```

`RequestError` is a type capturing the properties of a failed response to a request as an exception object:

- url: the original URL that was requested without any redirects
- code: the libcurl error code; 0 if a protocol-only error occurred
- message: the libcurl error message indicating what went wrong
- response: response object capturing what response info is available

The same `RequestError` type is thrown by `download` if the request was successful but there was a protocol-level error indicated by a status code that is not in the 2xx range, in which case code will be zero and the message field will be the empty string. The request API only throws a `RequestError` if the libcurl error code is non-zero, in which case the included response object is likely to have a status of zero and an empty message. There are, however, situations where a curl-level error is thrown due to a protocol error, in which case both the inner and outer code and message may be of interest.

`Downloads.Downloader` – Type.

```
| Downloader(; [ grace::Real = 30 ])
```

`Downloader` objects are used to perform individual download operations. Connections, name lookups and other resources are shared within a `Downloader`. These connections and resources are cleaned up after a configurable grace period (default: 30 seconds) since anything was downloaded with it, or when it is garbage collected, whichever comes first. If the grace period is set to zero, all resources will be cleaned up immediately as soon as there are no more ongoing downloads in progress. If the grace period is set to `Inf` then resources are not cleaned up until `Downloader` is garbage collected.

Chapter 70

File Events

FileWatching.poll_fd - Function.

```
| poll_fd(fd, timeout_s::Real=-1; readable=false, writable=false)
```

Monitor a file descriptor `fd` for changes in the read or write availability, and with a timeout given by `timeout_s` seconds.

The keyword arguments determine which of read and/or write status should be monitored; at least one of them must be set to true.

The returned value is an object with boolean fields `readable`, `writable`, and `timedout`, giving the result of the polling.

FileWatching.poll_file - Function.

```
| poll_file(path::AbstractString, interval_s::Real=5.007, timeout_s::Real=-1) ->  
| ↪ (previous::StatStruct, current)
```

Monitor a file for changes by polling every `interval_s` seconds until a change occurs or `timeout_s` seconds have elapsed. The `interval_s` should be a long period; the default is 5.007 seconds.

Returns a pair of status objects (`previous`, `current`) when a change is detected. The previous status is always a `StatStruct`, but it may have all of the fields zeroed (indicating the file didn't previously exist, or wasn't previously accessible).

The current status object may be a `StatStruct`, an `E0FError` (indicating the timeout elapsed), or some other `Exception` subtype (if the stat operation failed - for example, if the path does not exist).

To determine when a file was modified, compare `current isa StatStruct && mtime(prev) != mtime(current)` to detect notification of changes. However, using [watch_file](#) for this operation is preferred, since it is more reliable and efficient, although in some situations it may not be available.

FileWatching.watch_file - Function.

```
| watch_file(path::AbstractString, timeout_s::Real=-1)
```

Watch file or directory path for changes until a change occurs or `timeout_s` seconds have elapsed. This function does not poll the file system and instead uses platform-specific functionality to receive notifications from the operating system (e.g. via `inotify` on Linux). See the NodeJS documentation linked below for details.

The returned value is an object with boolean fields `renamed`, `changed`, and `timedout`, giving the result of watching the file.

This behavior of this function varies slightly across platforms. See https://nodejs.org/api/fs.html#fs_caveats for more detailed information.

`FileWatching.watch_folder` – Function.

```
| watch_folder(path::AbstractString, timeout_s::Real=-1)
```

Watches a file or directory path for changes until a change has occurred or `timeout_s` seconds have elapsed. This function does not poll the file system and instead uses platform-specific functionality to receive notifications from the operating system (e.g. via `inotify` on Linux). See the NodeJS documentation linked below for details.

This will continue tracking changes for `path` in the background until `unwatch_folder` is called on the same path.

The returned value is a pair where the first field is the name of the changed file (if available) and the second field is an object with boolean fields `renamed`, `changed`, and `timedout`, giving the event.

This behavior of this function varies slightly across platforms. See https://nodejs.org/api/fs.html#fs_caveats for more detailed information.

`FileWatching.unwatch_folder` – Function.

```
| unwatch_folder(path::AbstractString)
```

Stop background tracking of changes for `path`. It is not recommended to do this while another task is waiting for `watch_folder` to return on the same path, as the result may be unpredictable.

Chapter 71

Pidfile

A simple utility tool for creating advisory pidfiles (lock files).

71.1 Primary Functions

FileWatching.Pidfile.mkpidlock – Function.

```
| mkpidlock([f::Function], at::String, [pid::Cint, proc::Process]; kwopts...)
```

Create a pidfile lock for the path "at" for the current process or the process identified by pid or proc. Can take a function to execute once locked, for usage in do blocks, after which the lock will be automatically closed. If the lock fails and wait is false, then an error is thrown.

The lock will be released by either close, a finalizer, or shortly after proc exits. Make sure the return value is live through the end of the critical section of your program, so the finalizer does not reclaim it early.

Optional keyword arguments:

- mode: file access mode (modified by the process umask). Defaults to world-readable.
- poll_interval: Specify the maximum time to between attempts (if watch_file doesn't work)
- stale_age: Delete an existing pidfile (ignoring the lock) if it is older than this many seconds, based on its mtime. The file won't be deleted until 5x longer than this if the pid in the file appears that it may be valid. Or 25x longer if refresh is overridden to 0 to disable lock refreshing. By default this is disabled (stale_age = 0), but a typical recommended value would be about 3-5x an estimated normal completion time.
- refresh: Keeps a lock from becoming stale by updating the mtime every interval of time that passes. By default, this is set to stale_age/2, which is the recommended value.
- wait: If true, block until we get the lock, if false, raise error if lock fails.

FileWatching.Pidfile.trymkpidlock – Function.

```
| trymkpidlock([f::Function], at::String, [pid::Cint, proc::Process]; kwopts...)
```

Like mkpidlock except returns false instead of waiting if the file is already locked.

Julia 1.10

This function requires at least Julia 1.10.

`Base.close` – Method.

```
| close(lock::LockMonitor)
```

Release a pidfile lock.

71.2 Helper Functions

`FileWatching.Pidfile.open_exclusive` – Function.

```
| open_exclusive(path::String; mode, poll_interval, wait, stale_age, refresh) :: File
```

Create a new a file for read-write advisory-exclusive access. If `wait` is `false` then error out if the lock files exist otherwise block until we get the lock.

For a description of the keyword arguments, see [mkpidlock](#).

`FileWatching.Pidfile.tryopen_exclusive` – Function.

```
| tryopen_exclusive(path::String, mode::Integer = 0o444) :: Union{Void, File}
```

Try to create a new file for read-write advisory-exclusive access, return nothing if it already exists.

`FileWatching.Pidfile.write_pidfile` – Function.

```
| write_pidfile(io, pid)
```

Write our pidfile format to an open IO descriptor.

`FileWatching.Pidfile.parse_pidfile` – Function.

```
| parse_pidfile(file::Union{IO, String}) => (pid, hostname, age)
```

Attempt to parse our pidfile format, replaced an element with (0, "", 0.0), respectively, for any read that failed.

`FileWatching.Pidfile.stale_pidfile` – Function.

```
| stale_pidfile(path::String, stale_age::Real, refresh::Real) :: Bool
```

Helper function for `open_exclusive` for deciding if a pidfile is stale.

`FileWatching.Pidfile.isvalidpid` – Function.

```
| isvalidpid(hostname::String, pid::Cuint) :: Bool
```

Attempt to conservatively estimate whether pid is a valid process id.

`Base.Filesystem.touch` – Method.

```
| Base.touch(::Pidfile.LockMonitor)
```

Update the mtime on the lock, to indicate it is still fresh.

See also the `refresh` keyword in the [mkpidlock](#) constructor.

Chapter 72

Future

The Future module implements future behavior of already existing functions, which will replace the current version in a future release of Julia.

`Future.copy!` – Function.

```
| Future.copy!(dst, src) -> dst
```

Copy src into dst.

Julia 1.1

This function has moved to Base with Julia 1.1, consider using `copy!(dst, src)` instead. `Future.copy!` will be deprecated in the future.

`Future.randjump` – Function.

```
| randjump(r::MersenneTwister, steps::Integer) -> MersenneTwister
```

Create an initialized MersenneTwister object, whose state is moved forward (without generating numbers) from r by steps steps. One such step corresponds to the generation of two Float64 numbers. For each different value of steps, a large polynomial has to be generated internally. One is already pre-computed for steps=big(10)^20.

Chapter 73

Interactive Utilities

This module is intended for interactive work. It is loaded automatically in [interactive mode](#).

`Base.Docs.apropos` – Function.

```
| apropos([io::IO=stdout], pattern::Union{AbstractString,Regex})
```

Search available docstrings for entries containing pattern.

When pattern is a string, case is ignored. Results are printed to io.

`apropos` can be called from the help mode in the REPL by wrapping the query in double quotes:

```
| help?> "pattern"
```

`InteractiveUtils.varinfo` – Function.

```
| varinfo(m::Module=Main, pattern::Regex=r""; all=false, imported=false, recursive=false,  
| ↪ sortby::Symbol=:name, minsize::Int=0)
```

Return a markdown table giving information about exported global variables in a module, optionally restricted to those matching pattern.

The memory consumption estimate is an approximate lower bound on the size of the internal structure of the object.

- `all` : also list non-exported objects defined in the module, deprecated objects, and compiler-generated objects.
- `imported` : also list objects explicitly imported from other modules.
- `recursive` : recursively include objects in sub-modules, observing the same settings in each.
- `sortby` : the column to sort results by. Options are `:name` (default), `:size`, and `:summary`.
- `minsize` : only includes objects with size at least `minsize` bytes. Defaults to 0.

The output of `varinfo` is intended for display purposes only. See also [names](#) to get an array of symbols defined in a module, which is suitable for more general manipulations.

`InteractiveUtils.versioninfo` – Function.

```
| versioninfo(io::IO=stdout; verbose::Bool=false)
```

Print information about the version of Julia in use. The output is controlled with boolean keyword arguments:

- `verbose`: print all additional information

Warning

The output of this function may contain sensitive information. Before sharing the output, please review the output and remove any data that should not be shared publicly.

See also: [VERSION](#).

`InteractiveUtils.methodswith` – Function.

```
| methodswith(typ[, module or function]; supertypes::Bool=false])
```

Return an array of methods with an argument of type `typ`.

The optional second argument restricts the search to a particular module or function (the default is all top-level modules).

If keyword `supertypes` is true, also return arguments with a parent type of `typ`, excluding type `Any`.

`InteractiveUtils.subtypes` – Function.

```
| subtypes(T::DataType)
```

Return a list of immediate subtypes of `DataType T`. Note that all currently loaded subtypes are included, including those not visible in the current module.

See also [supertype](#), [supertypes](#), [methodswith](#).

Examples

```
| julia> subtypes(Integer)
3-element Vector{Any}:
 Bool
 Signed
 Unsigned
```

`InteractiveUtils.supertypes` – Function.

```
| supertypes(T::Type)
```

Return a tuple `(T, ..., Any)` of `T` and all its supertypes, as determined by successive calls to the [supertype](#) function, listed in order of `<:` and terminated by `Any`.

See also [subtypes](#).

Examples

```
| julia> supertypes(Int)
(Int64, Signed, Integer, Real, Number, Any)
```

`InteractiveUtils.edit` – Method.

```
| edit(path::AbstractString, line::Integer=0, column::Integer=0)
```

Edit a file or directory optionally providing a line number to edit the file at. Return to the julia prompt when you quit the editor. The editor can be changed by setting JULIA_EDITOR, VISUAL or EDITOR as an environment variable.

See also [define_editor](#).

InteractiveUtils.edit - Method.

```
| edit(function, [types])
| edit(module)
```

Edit the definition of a function, optionally specifying a tuple of types to indicate which method to edit. For modules, open the main source file. The module needs to be loaded with using or import first.

Julia 1.1

edit on modules requires at least Julia 1.1.

To ensure that the file can be opened at the given line, you may need to call [define_editor](#) first.

InteractiveUtils.@edit - Macro.

```
| @edit
```

Evaluates the arguments to the function or macro call, determines their types, and calls the [edit](#) function on the resulting expression.

See also: [@less](#), [@which](#).

InteractiveUtils.define_editor - Function.

```
| define_editor(fn, pattern; wait=false)
```

Define a new editor matching pattern that can be used to open a file (possibly at a given line number) using fn.

The fn argument is a function that determines how to open a file with the given editor. It should take four arguments, as follows:

- cmd - a base command object for the editor
- path - the path to the source file to open
- line - the line number to open the editor at
- column - the column number to open the editor at

Editors which cannot open to a specific line with a command or a specific column may ignore the line and/or column argument. The fn callback must return either an appropriate Cmd object to open a file or nothing to indicate that they cannot edit this file. Use nothing to indicate that this editor is not appropriate for the current environment and another editor should be attempted. It is possible to add more general editing hooks that need not spawn external commands by pushing a callback directly to the vector EDITOR_CALLBACKS.

The pattern argument is a string, regular expression, or an array of strings and regular expressions. For the fn to be called, one of the patterns must match the value of EDITOR, VISUAL or JULIA_EDITOR. For strings, the string must equal the [basename](#) of the first word of the editor command, with its extension, if any, removed. E.g. "vi" doesn't match "vim -g" but matches "/usr/bin/vi -m"; it also matches vi.exe. If pattern is a regex it is matched against all of the editor command as a shell-escaped string. An array pattern matches if any of its items match. If multiple editors match, the one added most recently is used.

By default julia does not wait for the editor to close, running it in the background. However, if the editor is terminal based, you will probably want to set wait=true and julia will wait for the editor to close before resuming.

If one of the editor environment variables is set, but no editor entry matches it, the default editor entry is invoked:

```
| (cmd, path, line, column) -> ` $cmd $path`
```

Note that many editors are already defined. All of the following commands should already work:

- emacs
- emacsclient
- vim
- nvim
- nano
- micro
- kak
- helix
- textmate
- mate
- kate
- subl
- atom
- notepad++
- Visual Studio Code
- open
- pycharm
- bbedit

Example:

The following defines the usage of terminal-based emacs:

```
| define_editor(  
|     r"\bemacs\b.*\s(-nw|--no-window-system)\b", wait=true) do cmd, path, line  
|     ` $cmd +$line $path`  
| end
```

Julia 1.4

`define_editor` was introduced in Julia 1.4.

`InteractiveUtils.less` – Method.

```
| less(file::AbstractString, [line::Integer])
```

Show a file using the default pager, optionally providing a starting line number. Returns to the `julia` prompt when you quit the pager.

`InteractiveUtils.less` – Method.

```
| less(function, [types])
```

Show the definition of a function using the default pager, optionally specifying a tuple of types to indicate which method to see.

`InteractiveUtils.@less` – Macro.

```
| @less
```

Evaluates the arguments to the function or macro call, determines their types, and calls the `less` function on the resulting expression.

See also: `@edit`, `@which`, `@code_lowered`.

`InteractiveUtils.@which` – Macro.

```
| @which
```

Applied to a function or macro call, it evaluates the arguments to the specified call, and returns the Method object for the method that would be called for those arguments. Applied to a variable, it returns the module in which the variable was bound. It calls out to the `which` function.

See also: `@less`, `@edit`.

`InteractiveUtils.@functionloc` – Macro.

```
| @functionloc
```

Applied to a function or macro call, it evaluates the arguments to the specified call, and returns a tuple `(filename, line)` giving the location for the method that would be called for those arguments. It calls out to the `functionloc` function.

`InteractiveUtils.@code_lowered` – Macro.

```
| @code_lowered
```

Evaluates the arguments to the function or macro call, determines their types, and calls `code_lowered` on the resulting expression.

`InteractiveUtils.@code_typed` – Macro.

```
| @code_typed
```

Evaluates the arguments to the function or macro call, determines their types, and calls `code_typed` on the resulting expression. Use the optional argument `optimize` with

```
| @code_typed optimize=true foo(x)
```

to control whether additional optimizations, such as inlining, are also applied.

`InteractiveUtils.code_warntype` - Function.

```
| code_warntype([io::IO], f, types; debuginfo=:default)
```

Prints lowered and type-inferred ASTs for the methods matching the given generic function and type signature to `io` which defaults to `stdout`. The ASTs are annotated in such a way as to cause "non-leaf" types which may be problematic for performance to be emphasized (if color is available, displayed in red). This serves as a warning of potential type instability.

Not all non-leaf types are particularly problematic for performance, and the performance characteristics of a particular type is an implementation detail of the compiler. `code_warntype` will err on the side of coloring types red if they might be a performance concern, so some types may be colored red even if they do not impact performance. Small unions of concrete types are usually not a concern, so these are highlighted in yellow.

Keyword argument `debuginfo` may be one of `:source` or `:none` (default), to specify the verbosity of code comments.

See the `@code_warntype` section in the Performance Tips page of the manual for more information.

`InteractiveUtils.@code_warntype` - Macro.

```
| @code_warntype
```

Evaluates the arguments to the function or macro call, determines their types, and calls `code_warntype` on the resulting expression.

`InteractiveUtils.code_llvm` - Function.

```
| code_llvm([io=stdout,], f, types; raw=false, dump_module=false, optimize=true,  
↪ debuginfo=:default)
```

Prints the LLVM bitcodes generated for running the method matching the given generic function and type signature to `io`.

If the `optimize` keyword is unset, the code will be shown before LLVM optimizations. All metadata and `dbg.*` calls are removed from the printed bytecode. For the full IR, set the `raw` keyword to `true`. To dump the entire module that encapsulates the function (with declarations), set the `dump_module` keyword to `true`. Keyword argument `debuginfo` may be one of `source` (default) or `none`, to specify the verbosity of code comments.

`InteractiveUtils.@code_llvm` - Macro.

```
| @code_llvm
```

Evaluates the arguments to the function or macro call, determines their types, and calls `code_llvm` on the resulting expression. Set the optional keyword arguments `raw`, `dump_module`, `debuginfo`, `optimize` by putting them and their value before the function call, like this:

```
|@code_llvm raw=true dump_module=true debuginfo=:default f(x)
|@code_llvm optimize=false f(x)
```

`optimize` controls whether additional optimizations, such as inlining, are also applied. `raw` makes all metadata and `dbg.*` calls visible. `debuginfo` may be one of `:source` (default) or `:none`, to specify the verbosity of code comments. `dump_module` prints the entire module that encapsulates the function.

`InteractiveUtils.code_native` - Function.

```
|code_native([io=stdout,], f, types; syntax=:intel, debuginfo=:default, binary=false,
|↪ dump_module=true)
```

Prints the native assembly instructions generated for running the method matching the given generic function and type signature to `io`.

- Set assembly syntax by setting `syntax` to `:intel` (default) for intel syntax or `:att` for AT&T syntax.
- Specify verbosity of code comments by setting `debuginfo` to `:source` (default) or `:none`.
- If `binary` is `true`, also print the binary machine code for each instruction preceded by an abbreviated address.
- If `dump_module` is `false`, do not print metadata such as rodata or directives.
- If `raw` is `false`, uninteresting instructions (like the safepoint function prologue) are elided.

See also: [@code_native](#), [code_llvm](#), [code_typed](#) and [code_lowered](#)

`InteractiveUtils.@code_native` - Macro.

```
|@code_native
```

Evaluates the arguments to the function or macro call, determines their types, and calls [code_native](#) on the resulting expression.

Set any of the optional keyword arguments `syntax`, `debuginfo`, `binary` or `dump_module` by putting it before the function call, like this:

```
|@code_native syntax=:intel debuginfo=:default binary=true dump_module=false f(x)
```

- Set assembly syntax by setting `syntax` to `:intel` (default) for Intel syntax or `:att` for AT&T syntax.
- Specify verbosity of code comments by setting `debuginfo` to `:source` (default) or `:none`.
- If `binary` is `true`, also print the binary machine code for each instruction preceded by an abbreviated address.
- If `dump_module` is `false`, do not print metadata such as rodata or directives.

See also: [code_native](#), [@code_llvm](#), [@code_typed](#) and [@code_lowered](#)

`InteractiveUtils.@time_imports` - Macro.

```
|@time_imports
```

A macro to execute an expression and produce a report of any time spent importing packages and their dependencies. Any compilation time will be reported as a percentage, and how much of which was recompilation, if any.

One line is printed per package or package extension. The duration shown is the time to import that package itself, not including the time to load any of its dependencies.

On Julia 1.9+ [package extensions](#) will show as Parent → Extension.

Note

During the load process a package sequentially imports all of its dependencies, not just its direct dependencies.

```
julia> @time_imports using CSV
50.7 ms  Parsers 17.52% compilation time
0.2 ms  DataValueInterfaces
1.6 ms  DataAPI
0.1 ms  IteratorInterfaceExtensions
0.1 ms  TableTraits
17.5 ms  Tables
26.8 ms  PooledArrays
193.7 ms SentinelArrays 75.12% compilation time
8.6 ms  InlineStrings
20.3 ms  WeakRefStrings
2.0 ms  TranscodingStreams
1.4 ms  Zlib_jll
1.8 ms  CodecZlib
0.8 ms  Compat
13.1 ms  FilePathsBase 28.39% compilation time
1681.2 ms CSV 92.40% compilation time
```

Julia 1.8

This macro requires at least Julia 1.8

InteractiveUtils.clipboard - Function.

```
| clipboard(x)
```

Send a printed form of x to the operating system clipboard ("copy").

```
| clipboard() -> String
```

Return a string with the contents of the operating system clipboard ("paste").

Chapter 74

Lazy Artifacts

In order for a package to download artifacts lazily, `LazyArtifacts` must be explicitly listed as a dependency of that package.

For further information on artifacts, see [Artifacts](#).

Chapter 75

LibCURL

This is a simple Julia wrapper around <http://curl.haxx.se/libcurl/> generated using [Clang.jl](#). Please see the [libcurl API documentation](#) for help on how to use this package.

Chapter 76

LibGit2

The LibGit2 module provides bindings to [libgit2](#), a portable C library that implements core functionality for the [Git](#) version control system. These bindings are currently used to power Julia's package manager. It is expected that this module will eventually be moved into a separate package.

Functionality

Some of this documentation assumes some prior knowledge of the libgit2 API. For more information on some of the objects and methods referenced here, consult the upstream [libgit2 API reference](#).

LibGit2.Buffer – Type.

| LibGit2.Buffer

A data buffer for exporting data from libgit2. Matches the [git_buf](#) struct.

When fetching data from LibGit2, a typical usage would look like:

```
buf_ref = Ref{Buffer{}}
@check ccall(..., (Ptr{Buffer},), buf_ref)
# operation on buf_ref
free(buf_ref)
```

In particular, note that LibGit2.free should be called afterward on the Ref object.

LibGit2.CheckoutOptions – Type.

| LibGit2.CheckoutOptions

Matches the [git_checkout_options](#) struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `checkout_strategy`: determine how to handle conflicts and whether to force the checkout/recreate missing files.
- `disable_filters`: if nonzero, do not apply filters like CLRF (to convert file newlines between UNIX and DOS).

- `dir_mode`: read/write/access mode for any directories involved in the checkout. Default is 0755.
- `file_mode`: read/write/access mode for any files involved in the checkout. Default is 0755 or 0644, depending on the blob.
- `file_open_flags`: bitflags used to open any files during the checkout.
- `notify_flags`: Flags for what sort of conflicts the user should be notified about.
- `notify_cb`: An optional callback function to notify the user if a checkout conflict occurs. If this function returns a non-zero value, the checkout will be cancelled.
- `notify_payload`: Payload for the notify callback function.
- `progress_cb`: An optional callback function to display checkout progress.
- `progress_payload`: Payload for the progress callback.
- `paths`: If not empty, describes which paths to search during the checkout. If empty, the checkout will occur over all files in the repository.
- `baseline`: Expected content of the `workdir`, captured in a (pointer to a) `GitTree`. Defaults to the state of the tree at HEAD.
- `baseline_index`: Expected content of the `workdir`, captured in a (pointer to a) `GitIndex`. Defaults to the state of the index at HEAD.
- `target_directory`: If not empty, checkout to this directory instead of the `workdir`.
- `ancestor_label`: In case of conflicts, the name of the common ancestor side.
- `our_label`: In case of conflicts, the name of "our" side.
- `their_label`: In case of conflicts, the name of "their" side.
- `perfddata_cb`: An optional callback function to display performance data.
- `perfddata_payload`: Payload for the performance callback.

`LibGit2.CloneOptions` - Type.

| `LibGit2.CloneOptions`

Matches the `git_clone_options` struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `checkout_opts`: The options for performing the checkout of the remote as part of the clone.
- `fetch_opts`: The options for performing the pre-checkout fetch of the remote as part of the clone.
- `bare`: If 0, clone the full remote repository. If non-zero, perform a bare clone, in which there is no local copy of the source files in the repository and the `gitdir` and `workdir` are the same.
- `localclone`: Flag whether to clone a local object database or do a fetch. The default is to let git decide. It will not use the git-aware transport for a local clone, but will use it for URLs which begin with `file://`.
- `checkout_branch`: The name of the branch to checkout. If an empty string, the default branch of the remote will be checked out.
- `repository_cb`: An optional callback which will be used to create the new repository into which the clone is made.

- `repository_cb_payload`: The payload for the repository callback.
- `remote_cb`: An optional callback used to create the [GitRemote](#) before making the clone from it.
- `remote_cb_payload`: The payload for the remote callback.

`LibGit2.DescribeOptions` - Type.

| `LibGit2.DescribeOptions`

Matches the [git_describe_options](#) struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `max_candidates_tags`: consider this many most recent tags in refs/tags to describe a commit. Defaults to 10 (so that the 10 most recent tags would be examined to see if they describe a commit).
- `describe_strategy`: whether to consider all entries in refs/tags (equivalent to `git-describe --tags`) or all entries in refs/ (equivalent to `git-describe --all`). The default is to only show annotated tags. If `Consts.DESCRIBE_TAGS` is passed, all tags, annotated or not, will be considered. If `Consts.DESCRIBE_ALL` is passed, any ref in refs/ will be considered.
- `pattern`: only consider tags which match pattern. Supports glob expansion.
- `only_follow_first_parent`: when finding the distance from a matching reference to the described object, only consider the distance from the first parent.
- `show_commit_oid_as_fallback`: if no matching reference can be found which describes a commit, show the commit's [GitHash](#) instead of throwing an error (the default behavior).

`LibGit2.DescribeFormatOptions` - Type.

| `LibGit2.DescribeFormatOptions`

Matches the [git_describe_format_options](#) struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `abbreviated_size`: lower bound on the size of the abbreviated [GitHash](#) to use, defaulting to 7.
- `always_use_long_format`: set to 1 to use the long format for strings even if a short format can be used.
- `dirty_suffix`: if set, this will be appended to the end of the description string if the [workdir](#) is dirty.

`LibGit2.DiffDelta` - Type.

| `LibGit2.DiffDelta`

Description of changes to one entry. Matches the [git_diff_delta](#) struct.

The fields represent:

- `status`: One of `Consts.DELTA_STATUS`, indicating whether the file has been added/modified/deleted.
- `flags`: Flags for the delta and the objects on each side. Determines whether to treat the file(s) as binary/text, whether they exist on each side of the diff, and whether the object ids are known to be correct.
- `similarity`: Used to indicate if a file has been renamed or copied.
- `nfiles`: The number of files in the delta (for instance, if the delta was run on a submodule commit id, it may contain more than one file).
- `old_file`: A [DiffFile](#) containing information about the file(s) before the changes.
- `new_file`: A [DiffFile](#) containing information about the file(s) after the changes.

`LibGit2.DiffFile` – Type.

| `LibGit2.DiffFile`

Description of one side of a delta. Matches the `git_diff_file` struct.

The fields represent:

- `id`: the [GitHash](#) of the item in the diff. If the item is empty on this side of the diff (for instance, if the diff is of the removal of a file), this will be `GitHash(0)`.
- `path`: a NULL terminated path to the item relative to the working directory of the repository.
- `size`: the size of the item in bytes.
- `flags`: a combination of the `git_diff_flag_t` flags. The `i`th bit of this integer sets the `i`th flag.
- `mode`: the `stat` mode for the item.
- `id_abbrev`: only present in LibGit2 versions newer than or equal to 0.25.0. The length of the `id` field when converted using [string](#). Usually equal to `OID_HEXSZ` (40).

`LibGit2.DiffOptionsStruct` – Type.

| `LibGit2.DiffOptionsStruct`

Matches the `git_diff_options` struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `flags`: flags controlling which files will appear in the diff. Defaults to `DIFF_NORMAL`.
- `ignore_submodules`: whether to look at files in submodules or not. Defaults to `SUBMODULE_IGNORE_UNSPECIFIED`, which means the submodule's configuration will control whether it appears in the diff or not.
- `pathspec`: path to files to include in the diff. Default is to use all files in the repository.
- `notify_cb`: optional callback which will notify the user of changes to the diff as file deltas are added to it.
- `progress_cb`: optional callback which will display diff progress. Only relevant on libgit2 versions at least as new as 0.24.0.
- `payload`: the payload to pass to `notify_cb` and `progress_cb`.

- `context_lines`: the number of unchanged lines used to define the edges of a hunk. This is also the number of lines which will be shown before/after a hunk to provide context. Default is 3.
- `interhunk_lines`: the maximum number of unchanged lines between two separate hunks allowed before the hunks will be combined. Default is 0.
- `id_abbrev`: sets the length of the abbreviated [GitHash](#) to print. Default is 7.
- `max_size`: the maximum file size of a blob. Above this size, it will be treated as a binary blob. The default is 512 MB.
- `old_prefix`: the virtual file directory in which to place old files on one side of the diff. Default is "a".
- `new_prefix`: the virtual file directory in which to place new files on one side of the diff. Default is "b".

`LibGit2.FetchHead` – Type.

| `LibGit2.FetchHead`

Contains the information about HEAD during a fetch, including the name and URL of the branch fetched from, the oid of the HEAD, and whether the fetched HEAD has been merged locally.

The fields represent:

- `name`: The name in the local reference database of the fetch head, for example, "refs/heads/master".
- `url`: The URL of the fetch head.
- `oid`: The [GitHash](#) of the tip of the fetch head.
- `ismerge`: Boolean flag indicating whether the changes at the remote have been merged into the local copy yet or not. If `true`, the local copy is up to date with the remote fetch head.

`LibGit2.FetchOptions` – Type.

| `LibGit2.FetchOptions`

Matches the `git_fetch_options` struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `callbacks`: remote callbacks to use during the fetch.
- `prune`: whether to perform a prune after the fetch or not. The default is to use the setting from the `GitConfig`.
- `update_fetchhead`: whether to update the [FetchHead](#) after the fetch. The default is to perform the update, which is the normal git behavior.
- `download_tags`: whether to download tags present at the remote or not. The default is to request the tags for objects which are being downloaded anyway from the server.
- `proxy_opts`: options for connecting to the remote through a proxy. See [ProxyOptions](#). Only present on libgit2 versions newer than or equal to 0.25.0.
- `custom_headers`: any extra headers needed for the fetch. Only present on libgit2 versions newer than or equal to 0.24.0.

LibGit2.GitAnnotated – Type.

```
GitAnnotated(repo::GitRepo, commit_id::GitHash)
GitAnnotated(repo::GitRepo, ref::GitReference)
GitAnnotated(repo::GitRepo, fh::FetchHead)
GitAnnotated(repo::GitRepo, committish::AbstractString)
```

An annotated git commit carries with it information about how it was looked up and why, so that rebase or merge operations have more information about the context of the commit. Conflict files contain information about the source/target branches in the merge which are conflicting, for instance. An annotated commit can refer to the tip of a remote branch, for instance when a [FetchHead](#) is passed, or to a branch head described using [GitReference](#).

LibGit2.GitBlame – Type.

```
GitBlame(repo::GitRepo, path::AbstractString; options::BlameOptions=BlameOptions())
```

Construct a [GitBlame](#) object for the file at path, using change information gleaned from the history of repo. The [GitBlame](#) object records who changed which chunks of the file when, and how. options controls how to separate the contents of the file and which commits to probe - see [BlameOptions](#) for more information.

LibGit2.GitBlob – Type.

```
GitBlob(repo::GitRepo, hash::AbstractGitHash)
GitBlob(repo::GitRepo, spec::AbstractString)
```

Return a [GitBlob](#) object from repo specified by hash/spec.

- hash is a full ([GitHash](#)) or partial ([GitShortHash](#)) hash.
- spec is a textual specification: see [the git docs](#) for a full list.

LibGit2.GitCommit – Type.

```
GitCommit(repo::GitRepo, hash::AbstractGitHash)
GitCommit(repo::GitRepo, spec::AbstractString)
```

Return a [GitCommit](#) object from repo specified by hash/spec.

- hash is a full ([GitHash](#)) or partial ([GitShortHash](#)) hash.
- spec is a textual specification: see [the git docs](#) for a full list.

LibGit2.GitConfig – Type.

```
GitConfig(path::AbstractString, level::Consts.GIT_CONFIG=Consts.CONFIG_LEVEL_APP,
↳ force::Bool=false)
```

Create a new [GitConfig](#) by loading configuration information from the file at path. See [addfile](#) for more information about the level, repo and force options.

```
GitConfig(repo::GitRepo)
```

Get the stored configuration for the git repository repo. If repo does not have a specific configuration file set, the default git configuration will be used.

```
| GitConfig(level::Consts.GIT_CONFIG=Consts.CONFIG_LEVEL_DEFAULT)
```

Get the default git configuration by loading the global and system configuration files into a prioritized configuration. This can be used to access default configuration options outside a specific git repository.

LibGit2.GitHash - Type.

```
| GitHash
```

A git object identifier, based on the sha-1 hash. It is a 20 byte string (40 hex digits) used to identify a GitObject in a repository.

LibGit2.GitObject - Type.

```
| GitObject(repo::GitRepo, hash::AbstractGitHash)
| GitObject(repo::GitRepo, spec::AbstractString)
```

Return the specified object (GitCommit, GitBlob, GitTree or GitTag) from repo specified by hash/spec.

- hash is a full (GitHash) or partial (GitShortHash) hash.
- spec is a textual specification: see [the git docs](#) for a full list.

LibGit2.GitRemote - Type.

```
| GitRemote(repo::GitRepo, rmt_name::AbstractString, rmt_url::AbstractString) -> GitRemote
```

Look up a remote git repository using its name and URL. Uses the default fetch refspec.

Examples

```
| repo = LibGit2.init(repo_path)
| remote = LibGit2.GitRemote(repo, "upstream", repo_url)
```

```
| GitRemote(repo::GitRepo, rmt_name::AbstractString, rmt_url::AbstractString, fetch_spec::
| AbstractString) -> GitRemote
```

Look up a remote git repository using the repository's name and URL, as well as specifications for how to fetch from the remote (e.g. which remote branch to fetch from).

Examples

```
| repo = LibGit2.init(repo_path)
| refspec = "+refs/heads/mybranch:refs/remotes/origin/mybranch"
| remote = LibGit2.GitRemote(repo, "upstream", repo_url, refspec)
```

LibGit2.GitRemoteAnon - Function.

```
| GitRemoteAnon(repo::GitRepo, url::AbstractString) -> GitRemote
```

Look up a remote git repository using only its URL, not its name.

Examples

```
| repo = LibGit2.init(repo_path)
| remote = LibGit2.GitRemoteAnon(repo, repo_url)
```

LibGit2.GitRepo - Type.

```
| LibGit2.GitRepo(path::AbstractString)
```

Open a git repository at path.

LibGit2.GitRepoExt - Function.

```
| LibGit2.GitRepoExt(path::AbstractString, flags::Cuint =
| ↪ Cuint(Consts.REPOSITORY_OPEN_DEFAULT))
```

Open a git repository at path with extended controls (for instance, if the current user must be a member of a special access group to read path).

LibGit2.GitRevWalker - Type.

```
| GitRevWalker(repo::GitRepo)
```

A GitRevWalker walks through the revisions (i.e. commits) of a git repository repo. It is a collection of the commits in the repository, and supports iteration and calls to [LibGit2.map](#) and [LibGit2.count](#) (for instance, LibGit2.count could be used to determine what percentage of commits in a repository were made by a certain author).

```
| cnt = LibGit2.with(LibGit2.GitRevWalker(repo)) do walker
|   LibGit2.count((oid,repo)->(oid == commit_oid1), walker, oid=commit_oid1,
|   ↪ by=LibGit2.Consts.SORT_TIME)
| end
```

Here, LibGit2.count finds the number of commits along the walk with a certain GitHash. Since the GitHash is unique to a commit, cnt will be 1.

LibGit2.GitShortHash - Type.

```
| GitShortHash(hash::GitHash, len::Integer)
```

A shortened git object identifier, which can be used to identify a git object when it is unique, consisting of the initial len hexadecimal digits of hash (the remaining digits are ignored).

LibGit2.GitSignature - Type.

```
| LibGit2.GitSignature
```

This is a Julia wrapper around a pointer to a [git_signature](#) object.

LibGit2.GitStatus - Type.

```
| LibGit2.GitStatus(repo::GitRepo; status_opts=StatusOptions())
```

Collect information about the status of each file in the git repository repo (e.g. is the file modified, staged, etc.). status_opts can be used to set various options, for instance whether or not to look at untracked files or whether to include submodules or not. See [StatusOptions](#) for more information.

LibGit2.GitTag – Type.

```
| GitTag(repo::GitRepo, hash::AbstractGitHash)
| GitTag(repo::GitRepo, spec::AbstractString)
```

Return a GitTag object from repo specified by hash/spec.

- hash is a full (GitHash) or partial (GitShortHash) hash.
- spec is a textual specification: see [the git docs](#) for a full list.

LibGit2.GitTree – Type.

```
| GitTree(repo::GitRepo, hash::AbstractGitHash)
| GitTree(repo::GitRepo, spec::AbstractString)
```

Return a GitTree object from repo specified by hash/spec.

- hash is a full (GitHash) or partial (GitShortHash) hash.
- spec is a textual specification: see [the git docs](#) for a full list.

LibGit2.IndexEntry – Type.

```
| LibGit2.IndexEntry
```

In-memory representation of a file entry in the index. Matches the [git_index_entry](#) struct.

LibGit2.IndexTime – Type.

```
| LibGit2.IndexTime
```

Matches the [git_index_time](#) struct.

LibGit2.BlameOptions – Type.

```
| LibGit2.BlameOptions
```

Matches the [git_blame_options](#) struct.

The fields represent:

- version: version of the struct in use, in case this changes later. For now, always 1.
- flags: one of `Consts.BLAME_NORMAL` or `Consts.BLAME_FIRST_PARENT` (the other blame flags are not yet implemented by libgit2).
- min_match_characters: the minimum number of alphanumeric characters which much change in a commit in order for the change to be associated with that commit. The default is 20. Only takes effect if one of the `Consts.BLAME_*_COPIES` flags are used, which libgit2 does not implement yet.
- newest_commit: the [GitHash](#) of the newest commit from which to look at changes.
- oldest_commit: the [GitHash](#) of the oldest commit from which to look at changes.
- min_line: the first line of the file from which to starting blaming. The default is 1.

- `max_line`: the last line of the file to which to blame. The default is 0, meaning the last line of the file.

`LibGit2.MergeOptions` - Type.

| `LibGit2.MergeOptions`

Matches the `git_merge_options` struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `flags`: an enum for flags describing merge behavior. Defined in `git_merge_flag_t`. The corresponding Julia enum is `GIT_MERGE` and has values:
 - `MERGE_FIND_RENAMES`: detect if a file has been renamed between the common ancestor and the "ours" or "theirs" side of the merge. Allows merges where a file has been renamed.
 - `MERGE_FAIL_ON_CONFLICT`: exit immediately if a conflict is found rather than trying to resolve it.
 - `MERGE_SKIP_REUC`: do not write the REUC extension on the index resulting from the merge.
 - `MERGE_NO_RECURSIVE`: if the commits being merged have multiple merge bases, use the first one, rather than trying to recursively merge the bases.
- `rename_threshold`: how similar two files must to consider one a rename of the other. This is an integer that sets the percentage similarity. The default is 50.
- `target_limit`: the maximum number of files to compare with to look for renames. The default is 200.
- `metric`: optional custom function to use to determine the similarity between two files for rename detection.
- `recursion_limit`: the upper limit on the number of merges of common ancestors to perform to try to build a new virtual merge base for the merge. The default is no limit. This field is only present on libgit2 versions newer than 0.24.0.
- `default_driver`: the merge driver to use if both sides have changed. This field is only present on libgit2 versions newer than 0.25.0.
- `file_favor`: how to handle conflicting file contents for the text driver.
 - `MERGE_FILE_FAVOR_NORMAL`: if both sides of the merge have changes to a section, make a note of the conflict in the index which git checkout will use to create a merge file, which the user can then reference to resolve the conflicts. This is the default.
 - `MERGE_FILE_FAVOR_OURS`: if both sides of the merge have changes to a section, use the version in the "ours" side of the merge in the index.
 - `MERGE_FILE_FAVOR_THEIRS`: if both sides of the merge have changes to a section, use the version in the "theirs" side of the merge in the index.
 - `MERGE_FILE_FAVOR_UNION`: if both sides of the merge have changes to a section, include each unique line from both sides in the file which is put into the index.
- `file_flags`: guidelines for merging files.

`LibGit2.ProxyOptions` - Type.

| LibGit2.ProxyOptions

Options for connecting through a proxy.

Matches the `git_proxy_options` struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `proxytype`: an enum for the type of proxy to use. Defined in `git_proxy_t`. The corresponding Julia enum is `GIT_PROXY` and has values:
 - `PROXY_NONE`: do not attempt the connection through a proxy.
 - `PROXY_AUTO`: attempt to figure out the proxy configuration from the git configuration.
 - `PROXY_SPECIFIED`: connect using the URL given in the `url` field of this struct.

Default is to auto-detect the proxy type.

- `url`: the URL of the proxy.
- `credential_cb`: a pointer to a callback function which will be called if the remote requires authentication to connect.
- `certificate_cb`: a pointer to a callback function which will be called if certificate verification fails. This lets the user decide whether or not to keep connecting. If the function returns 1, connecting will be allowed. If it returns 0, the connection will not be allowed. A negative value can be used to return errors.
- `payload`: the payload to be provided to the two callback functions.

Examples

```
julia> fo = LibGit2.FetchOptions(
    proxy_opts = LibGit2.ProxyOptions(url = Cstring("https://my_proxy_url.com")))

julia> fetch(remote, "master", options=fo)
```

LibGit2.PushOptions - Type.

| LibGit2.PushOptions

Matches the `git_push_options` struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `parallelism`: if a pack file must be created, this variable sets the number of worker threads which will be spawned by the packbuilder. If 0, the packbuilder will auto-set the number of threads to use. The default is 1.
- `callbacks`: the callbacks (e.g. for authentication with the remote) to use for the push.
- `proxy_opts`: only relevant if the LibGit2 version is greater than or equal to 0.25.0. Sets options for using a proxy to communicate with a remote. See [ProxyOptions](#) for more information.
- `custom_headers`: only relevant if the LibGit2 version is greater than or equal to 0.24.0. Extra headers needed for the push operation.

LibGit2.RebaseOperation - Type.

| LibGit2.RebaseOperation

Describes a single instruction/operation to be performed during the rebase. Matches the `git_rebase_operation` struct.

The fields represent:

- `optype`: the type of rebase operation currently being performed. The options are:
 - `REBASE_OPERATION_PICK`: cherry-pick the commit in question.
 - `REBASE_OPERATION_REWORD`: cherry-pick the commit in question, but rewrite its message using the prompt.
 - `REBASE_OPERATION_EDIT`: cherry-pick the commit in question, but allow the user to edit the commit's contents and its message.
 - `REBASE_OPERATION_SQUASH`: squash the commit in question into the previous commit. The commit messages of the two commits will be merged.
 - `REBASE_OPERATION_FIXUP`: squash the commit in question into the previous commit. Only the commit message of the previous commit will be used.
 - `REBASE_OPERATION_EXEC`: do not cherry-pick a commit. Run a command and continue if the command exits successfully.
- `id`: the [GitHash](#) of the commit being worked on during this rebase step.
- `exec`: in case `REBASE_OPERATION_EXEC` is used, the command to run during this step (for instance, running the test suite after each commit).

LibGit2.RebaseOptions - Type.

| LibGit2.RebaseOptions

Matches the `git_rebase_options` struct.

The fields represent:

- `version`: version of the struct in use, in case this changes later. For now, always 1.
- `quiet`: inform other git clients helping with/working on the rebase that the rebase should be done "quietly". Used for interoperability. The default is 1.
- `inmemory`: start an in-memory rebase. Callers working on the rebase can go through its steps and commit any changes, but cannot rewind HEAD or update the repository. The `workdir` will not be modified. Only present on libgit2 versions newer than or equal to 0.24.0.
- `rewrite_notes_ref`: name of the reference to notes to use to rewrite the commit notes as the rebase is finished.
- `merge_opts`: merge options controlling how the trees will be merged at each rebase step. Only present on libgit2 versions newer than or equal to 0.24.0.
- `checkout_opts`: checkout options for writing files when initializing the rebase, stepping through it, and aborting it. See [CheckoutOptions](#) for more information.

LibGit2.RemoteCallbacks - Type.

| LibGit2.RemoteCallbacks

Callback settings. Matches the `git_remote_callbacks` struct.

LibGit2.SignatureStruct – Type.

| LibGit2.SignatureStruct

An action signature (e.g. for committers, taggers, etc). Matches the `git_signature` struct.

The fields represent:

- name: The full name of the committer or author of the commit.
- email: The email at which the committer/author can be contacted.
- when: a `TimeStruct` indicating when the commit was authored/committed into the repository.

LibGit2.StatusEntry – Type.

| LibGit2.StatusEntry

Providing the differences between the file as it exists in HEAD and the index, and providing the differences between the index and the working directory. Matches the `git_status_entry` struct.

The fields represent:

- status: contains the status flags for the file, indicating if it is current, or has been changed in some way in the index or work tree.
- head_to_index: a pointer to a `DiffDelta` which encapsulates the difference(s) between the file as it exists in HEAD and in the index.
- index_to_workdir: a pointer to a `DiffDelta` which encapsulates the difference(s) between the file as it exists in the index and in the `workdir`.

LibGit2.StatusOptions – Type.

| LibGit2.StatusOptions

Options to control how `git_status_foreach_ext()` will issue callbacks. Matches the `git_status_opt_t` struct.

The fields represent:

- version: version of the struct in use, in case this changes later. For now, always 1.
- show: a flag for which files to examine and in which order. The default is `CONSTS.STATUS_SHOW_INDEX_AND_WORKDIR`.
- flags: flags for controlling any callbacks used in a status call.
- pathspec: an array of paths to use for path-matching. The behavior of the path-matching will vary depending on the values of show and flags.
- The baseline is the tree to be used for comparison to the working directory and index; defaults to HEAD.

LibGit2.StrArrayStruct – Type.

```
| LibGit2.StrArrayStruct
```

A LibGit2 representation of an array of strings. Matches the `git_strarray` struct.

When fetching data from LibGit2, a typical usage would look like:

```
| sa_ref = Ref(StrArrayStruct())
| @check ccall(..., (Ptr{StrArrayStruct},), sa_ref)
| res = convert(Vector{String}, sa_ref[])
| free(sa_ref)
```

In particular, note that `LibGit2.free` should be called afterward on the `Ref` object.

Conversely, when passing a vector of strings to LibGit2, it is generally simplest to rely on implicit conversion:

```
| strs = String[...]
| @check ccall(..., (Ptr{StrArrayStruct},), strs)
```

Note that no call to `free` is required as the data is allocated by Julia.

`LibGit2.TimeStruct` – Type.

```
| LibGit2.TimeStruct
```

Time in a signature. Matches the `git_time` struct.

`LibGit2.addfile` – Function.

```
| addfile(cfg::GitConfig, path::AbstractString,
|         level::Consts.GIT_CONFIG=Consts.CONFIG_LEVEL_APP,
|         repo::Union{GitRepo, Nothing} = nothing,
|         force::Bool=false)
```

Add an existing git configuration file located at `path` to the current `GitConfig` `cfg`. If the file does not exist, it will be created.

- `level` sets the git configuration priority level and is determined by

`Consts.GIT_CONFIG`.

- `repo` is an optional repository to allow parsing of conditional includes.
- If `force` is `false` and a configuration for the given priority level already exists,

`addfile` will error. If `force` is `true`, the existing configuration will be replaced by the one in the file at `path`.

`LibGit2.add!` – Function.

```
| add!(repo::GitRepo, files::AbstractString...; flags::Cuint = Consts.INDEX_ADD_DEFAULT)
| add!(idx::GitIndex, files::AbstractString...; flags::Cuint = Consts.INDEX_ADD_DEFAULT)
```

Add all the files with paths specified by `files` to the index `idx` (or the index of the repo). If the file already exists, the index entry will be updated. If the file does not exist already, it will be newly added into the index. `files` may contain glob patterns which will be expanded and any matching files will be added (unless `INDEX_ADD_DISABLE_PATHSPEC_MATCH` is set, see below). If a file has been ignored (in `.gitignore` or in the config), it will not be added, unless it is already being tracked in the index, in which case it will be updated. The keyword argument `flags` is a set of bit-flags which control the behavior with respect to ignored files:

- `Consts.INDEX_ADD_DEFAULT` - default, described above.
- `Consts.INDEX_ADD_FORCE` - disregard the existing ignore rules and force addition of the file to the index even if it is already ignored.
- `Consts.INDEX_ADD_CHECK_PATHSPEC` - cannot be used at the same time as `INDEX_ADD_FORCE`. Check that each file in `files` which exists on disk is not in the ignore list. If one of the files is ignored, the function will return `EINVALIDSPEC`.
- `Consts.INDEX_ADD_DISABLE_PATHSPEC_MATCH` - turn off glob matching, and only add files to the index which exactly match the paths specified in `files`.

`LibGit2.add_fetch!` - Function.

```
| add_fetch!(repo::GitRepo, rmt::GitRemote, fetch_spec::String)
```

Add a fetch refspec for the specified `rmt`. This refspec will contain information about which branch(es) to fetch from.

Examples

```
| julia> LibGit2.add_fetch!(repo, remote, "upstream");
| julia> LibGit2.fetch_refsspecs(remote)
| String["+refs/heads/*:refs/remotes/upstream/*"]
```

`LibGit2.add_push!` - Function.

```
| add_push!(repo::GitRepo, rmt::GitRemote, push_spec::String)
```

Add a push refspec for the specified `rmt`. This refspec will contain information about which branch(es) to push to.

Examples

```
| julia> LibGit2.add_push!(repo, remote, "refs/heads/master");
| julia> remote = LibGit2.get(LibGit2.GitRemote, repo, branch);
| julia> LibGit2.push_refsspecs(remote)
| String["refs/heads/master"]
```

Note

You may need to `close` and reopen the `GitRemote` in question after updating its push refspecs in order for the change to take effect and for calls to `push` to work.

`LibGit2.addblob!` – Function.

```
| LibGit2.addblob!(repo::GitRepo, path::AbstractString)
```

Read the file at path and adds it to the object database of repo as a loose blob. Return the [GitHash](#) of the resulting blob.

Examples

```
| hash_str = string(commit_oid)
| blob_file = joinpath(repo_path, ".git", "objects", hash_str[1:2], hash_str[3:end])
| id = LibGit2.addblob!(repo, blob_file)
```

`LibGit2.author` – Function.

```
| author(c::GitCommit)
```

Return the Signature of the author of the commit c. The author is the person who made changes to the relevant file(s). See also [committer](#).

`LibGit2.authors` – Function.

```
| authors(repo::GitRepo) -> Vector{Signature}
```

Return all authors of commits to the repo repository.

Examples

```
| repo = LibGit2.GitRepo(repo_path)
| repo_file = open(joinpath(repo_path, test_file), "a")

| println(repo_file, commit_msg)
| flush(repo_file)
| LibGit2.add!(repo, test_file)
| sig = LibGit2.Signature("TEST", "TEST@TEST.COM", round(time(), 0), 0)
| commit_oid1 = LibGit2.commit(repo, "commit1"; author=sig, committer=sig)
| println(repo_file, randstring(10))
| flush(repo_file)
| LibGit2.add!(repo, test_file)
| commit_oid2 = LibGit2.commit(repo, "commit2"; author=sig, committer=sig)

| # will be a Vector of [sig, sig]
| auths = LibGit2.authors(repo)
```

`LibGit2.branch` – Function.

```
| branch(repo::GitRepo)
```

Equivalent to `git branch`. Create a new branch from the current HEAD.

`LibGit2.branch!` – Function.

```
| branch!(repo::GitRepo, branch_name::AbstractString, commit::AbstractString=""; kwargs...)
```

Checkout a new git branch in the repo repository. `commit` is the [GitHash](#), in string form, which will be the start of the new branch. If `commit` is an empty string, the current HEAD will be used.

The keyword arguments are:

- `track::AbstractString=""`: the name of the remote branch this new branch should track, if any. If empty (the default), no remote branch will be tracked.
- `force::Bool=false`: if true, branch creation will be forced.
- `set_head::Bool=true`: if true, after the branch creation finishes the branch head will be set as the HEAD of repo.

Equivalent to `git checkout [-b] -B <branch_name> [<commit>] [--track <track>]`.

Examples

```
repo = LibGit2.GitRepo(repo_path)
LibGit2.branch!(repo, "new_branch", set_head=false)
```

`LibGit2.checkout!` – Function.

```
checkout!(repo::GitRepo, commit::AbstractString=""; force::Bool=true)
```

Equivalent to `git checkout [-f] --detach <commit>`. Checkout the git commit `commit` (a [GitHash](#) in string form) in repo. If `force` is true, force the checkout and discard any current changes. Note that this detaches the current HEAD.

Examples

```
repo = LibGit2.GitRepo(repo_path)
open(joinpath(LibGit2.path(repo), "file1"), "w") do f
    write(f, "111")
end
LibGit2.add!(repo, "file1")
commit_oid = LibGit2.commit(repo, "add file1")
open(joinpath(LibGit2.path(repo), "file1"), "w") do f
    write(f, "112")
end
# would fail without the force=true
# since there are modifications to the file
LibGit2.checkout!(repo, string(commit_oid), force=true)
```

`LibGit2.clone` – Function.

```
clone(repo_url::AbstractString, repo_path::AbstractString, clone_opts::CloneOptions)
```

Clone the remote repository at `repo_url` (which can be a remote URL or a path on the local filesystem) to `repo_path` (which must be a path on the local filesystem). Options for the clone, such as whether to perform a bare clone or not, are set by [CloneOptions](#).

Examples

```
repo_url = "https://github.com/JuliaLang/Example.jl"
repo = LibGit2.clone(repo_url, "/home/me/projects/Example")
```

```
clone(repo_url::AbstractString, repo_path::AbstractString; kwargs...)
```

Clone a remote repository located at `repo_url` to the local filesystem location `repo_path`.

The keyword arguments are:

- `branch::AbstractString=""`: which branch of the remote to clone, if not the default repository branch (usually master).
- `isbare::Bool=false`: if true, clone the remote as a bare repository, which will make `repo_path` itself the git directory instead of `repo_path/.git`. This means that a working tree cannot be checked out. Plays the role of the git CLI argument `--bare`.
- `remote_cb::Ptr{Cvoid}=C_NULL`: a callback which will be used to create the remote before it is cloned. If `C_NULL` (the default), no attempt will be made to create the remote - it will be assumed to already exist.
- `credentials::Creds=nothing`: provides credentials and/or settings when authenticating against a private repository.
- `callbacks::Callbacks=Callbacks()`: user provided callbacks and payloads.

Equivalent to `git clone [-b <branch>] [--bare] <repo_url> <repo_path>`.

Examples

```
repo_url = "https://github.com/JuliaLang/Example.jl"
repo1 = LibGit2.clone(repo_url, "test_path")
repo2 = LibGit2.clone(repo_url, "test_path", isbare=true)
julia_url = "https://github.com/JuliaLang/julia"
julia_repo = LibGit2.clone(julia_url, "julia_path", branch="release-0.6")
```

`LibGit2.commit` – Function.

```
commit(repo::GitRepo, msg::AbstractString; kwargs...) -> GitHash
```

Wrapper around `git_commit_create`. Create a commit in the repository `repo`. `msg` is the commit message. Return the OID of the new commit.

The keyword arguments are:

- `refname::AbstractString=Consts.HEAD_FILE`: if not NULL, the name of the reference to update to point to the new commit. For example, "HEAD" will update the HEAD of the current branch. If the reference does not yet exist, it will be created.
- `author::Signature = Signature(repo)` is a Signature containing information about the person who authored the commit.
- `committer::Signature = Signature(repo)` is a Signature containing information about the person who committed the commit to the repository. Not necessarily the same as author, for instance if author emailed a patch to committer who committed it.
- `tree_id::GitHash = GitHash()` is a git tree to use to create the commit, showing its ancestry and relationship with any other history. `tree` must belong to `repo`.

- `parent_ids::Vector{GitHash}=GitHash[]` is a list of commits by `GitHash` to use as parent commits for the new one, and may be empty. A commit might have multiple parents if it is a merge commit, for example.

```
| LibGit2.commit(rb::GitRebase, sig::GitSignature)
```

Commit the current patch to the rebase `rb`, using `sig` as the committer. Is silent if the commit has already been applied.

`LibGit2.committer` – Function.

```
| committer(c::GitCommit)
```

Return the Signature of the committer of the commit `c`. The committer is the person who committed the changes originally authored by the `author`, but need not be the same as the author, for example, if the author emailed a patch to a committer who committed it.

`LibGit2.count` – Function.

```
| LibGit2.count(f::Function, walker::GitRevWalker; oid::GitHash=GitHash(),
↳ by::Cint=Consts.SORT_NONE, rev::Bool=false)
```

Using the `GitRevWalker` walker to "walk" over every commit in the repository's history, find the number of commits which return true when `f` is applied to them. The keyword arguments are: * `oid`: The `GitHash` of the commit to begin the walk from. The default is to use `push_head!` and therefore the HEAD commit and all its ancestors. * `by`: The sorting method. The default is not to sort. Other options are to sort by topology (`LibGit2.Consts.SORT_TOPOLOGICAL`), to sort forwards in time (`LibGit2.Consts.SORT_TIME`, most ancient first) or to sort backwards in time (`LibGit2.Consts.SORT_REVERSE`, most recent first). * `rev`: Whether to reverse the sorted order (for instance, if topological sorting is used).

Examples

```
| cnt = LibGit2.with(LibGit2.GitRevWalker(repo)) do walker
  LibGit2.count((oid, repo)->(oid == commit_oid1), walker, oid=commit_oid1,
↳ by=LibGit2.Consts.SORT_TIME)
end
```

`LibGit2.count` finds the number of commits along the walk with a certain `GitHash` `commit_oid1`, starting the walk from that commit and moving forwards in time from it. Since the `GitHash` is unique to a commit, `cnt` will be 1.

`LibGit2.counthunks` – Function.

```
| counthunks(blame::GitBlame)
```

Return the number of distinct "hunks" with a file. A hunk may contain multiple lines. A hunk is usually a piece of a file that was added/changed/removed together, for example, a function added to a source file or an inner loop that was optimized out of that function later.

`LibGit2.create_branch` – Function.

```
| LibGit2.create_branch(repo::GitRepo, bname::AbstractString, commit_obj::GitCommit;
↳ force::Bool=false)
```

Create a new branch in the repository `repo` with name `bname`, which points to commit `commit_obj` (which has to be part of `repo`). If `force` is `true`, overwrite an existing branch named `bname` if it exists. If `force` is `false` and a branch already exists named `bname`, this function will throw an error.

`LibGit2.credentials_callback` – Function.

```
| credential_callback(...) -> Cint
```

A `LibGit2` credential callback function which provides different credential acquisition functionality w.r.t. a connection protocol. The `payload_ptr` is required to contain a `LibGit2.CredentialPayload` object which will keep track of state and settings.

The `allowed_types` contains a bitmask of `LibGit2.Consts.GIT_CREDTYPE` values specifying which authentication methods should be attempted.

Credential authentication is done in the following order (if supported):

- SSH agent
- SSH private/public key pair
- Username/password plain text

If a user is presented with a credential prompt they can abort the prompt by typing `^D` (pressing the control key together with the `d` key).

Note: Due to the specifics of the `libgit2` authentication procedure, when authentication fails, this function is called again without any indication whether authentication was successful or not. To avoid an infinite loop from repeatedly using the same faulty credentials, we will keep track of state using the payload.

For addition details see the `LibGit2` guide on [authenticating against a server](#).

`LibGit2.credentials_cb` – Function.

C function pointer for `credentials_callback`

`LibGit2.default_signature` – Function.

Return signature object. Free it after use.

`LibGit2.delete_branch` – Function.

```
| LibGit2.delete_branch(branch::GitReference)
```

Delete the branch pointed to by `branch`.

`LibGit2.diff_files` – Function.

```
| diff_files(repo::GitRepo, branch1::AbstractString, branch2::AbstractString; kwarg...) ->
| ↪ Vector{AbstractString}
```

Show which files have changed in the git repository `repo` between branches `branch1` and `branch2`.

The keyword argument is:

- `filter::Set{Consts.DELTA_STATUS}=Set([Consts.DELTA_ADDED, Consts.DELTA_MODIFIED, Consts.DELTA_DELETED])` and it sets options for the diff. The default is to show files added, modified, or deleted.

Return only the names of the files which have changed, not their contents.

Examples

```
LibGit2.branch!(repo, "branch/a")
LibGit2.branch!(repo, "branch/b")
# add a file to repo
open(joinpath(LibGit2.path(repo), "file"), "w") do f
    write(f, "hello repo")
end
LibGit2.add!(repo, "file")
LibGit2.commit(repo, "add file")
# returns ["file"]
filt = Set{LibGit2.Consts.DELTA_ADDED}
files = LibGit2.diff_files(repo, "branch/a", "branch/b", filter=filt)
# returns [] because existing files weren't modified
filt = Set{LibGit2.Consts.DELTA_MODIFIED}
files = LibGit2.diff_files(repo, "branch/a", "branch/b", filter=filt)
```

Equivalent to `git diff --name-only --diff-filter=<filter> <branch1> <branch2>`.

`LibGit2.entryid` – Function.

```
| entryid(te::GitTreeEntry)
```

Return the [GitHash](#) of the object to which `te` refers.

`LibGit2.entrytype` – Function.

```
| entrytype(te::GitTreeEntry)
```

Return the type of the object to which `te` refers. The result will be one of the types which [objtype](#) returns, e.g. a `GitTree` or `GitBlob`.

`LibGit2.fetch` – Function.

```
| fetch(rmt::GitRemote, refsspecs; options::FetchOptions=FetchOptions(), msg="")
```

Fetch from the specified `rmt` remote git repository, using `refsspecs` to determine which remote branch(es) to fetch. The keyword arguments are:

- `options`: determines the options for the fetch, e.g. whether to prune afterwards. See [FetchOptions](#) for more information.
- `msg`: a message to insert into the reflogs.

```
| fetch(repo::GitRepo; kwargs...)
```

Fetches updates from an upstream of the repository `repo`.

The keyword arguments are:

- `remote::AbstractString="origin"`: which remote, specified by name, of `repo` to fetch from. If this is empty, the URL will be used to construct an anonymous remote.

- `remoteurl::AbstractString=""`: the URL of remote. If not specified, will be assumed based on the given name of remote.
- `refspecs=AbstractString[]`: determines properties of the fetch.
- `credentials=nothing`: provides credentials and/or settings when authenticating against a private remote.
- `callbacks=Callbacks()`: user provided callbacks and payloads.

Equivalent to `git fetch [<remoteurl>|<repo>] [<refspecs>]`.

`LibGit2.fetchheads` – Function.

```
| fetchheads(repo::GitRepo) -> Vector{FetchHead}
```

Return the list of all the fetch heads for repo, each represented as a `FetchHead`, including their names, URLs, and merge statuses.

Examples

```
julia> fetch_heads = LibGit2.fetchheads(repo);

julia> fetch_heads[1].name
"refs/heads/master"

julia> fetch_heads[1].ismerge
true

julia> fetch_heads[2].name
"refs/heads/test_branch"

julia> fetch_heads[2].ismerge
false
```

`LibGit2.fetch_refspecs` – Function.

```
| fetch_refspecs(rmt::GitRemote) -> Vector{String}
```

Get the fetch refspecs for the specified rmt. These refspecs contain information about which branch(es) to fetch from.

Examples

```
julia> remote = LibGit2.get(LibGit2.GitRemote, repo, "upstream");

julia> LibGit2.add_fetch!(repo, remote, "upstream");

julia> LibGit2.fetch_refspecs(remote)
String["+refs/heads/*:refs/remotes/upstream/*"]
```

`LibGit2.fetchhead_foreach_cb` – Function.

C function pointer for `fetchhead_foreach_callback`

`LibGit2.merge_base` – Function.

```
| merge_base(repo::GitRepo, one::AbstractString, two::AbstractString) -> GitHash
```

Find a merge base (a common ancestor) between the commits one and two. one and two may both be in string form. Return the `GitHash` of the merge base.

`LibGit2.merge!` – Method.

```
| merge!(repo::GitRepo; kwargs...) -> Bool
```

Perform a git merge on the repository `repo`, merging commits with diverging history into the current branch. Return true if the merge succeeded, false if not.

The keyword arguments are:

- `committish::AbstractString=""`: Merge the named commit(s) in `committish`.
- `branch::AbstractString=""`: Merge the branch `branch` and all its commits since it diverged from the current branch.
- `fastforward::Bool=false`: If `fastforward` is true, only merge if the merge is a fast-forward (the current branch head is an ancestor of the commits to be merged), otherwise refuse to merge and return false. This is equivalent to the git CLI option `--ff-only`.
- `merge_opts::MergeOptions=MergeOptions()`: `merge_opts` specifies options for the merge, such as merge strategy in case of conflicts.
- `checkout_opts::CheckoutOptions=CheckoutOptions()`: `checkout_opts` specifies options for the checkout step.

Equivalent to `git merge [--ff-only] [<committish> | <branch>]`.

Note

If you specify a branch, this must be done in reference format, since the string will be turned into a `GitReference`. For example, if you wanted to merge branch `branch_a`, you would call `merge!(repo, branch="refs/heads/branch_a")`.

`LibGit2.merge!` – Method.

```
| merge!(repo::GitRepo, anns::Vector{GitAnnotated}; kwargs...) -> Bool
```

Merge changes from the annotated commits (captured as `GitAnnotated` objects) `anns` into the HEAD of the repository `repo`. The keyword arguments are:

- `merge_opts::MergeOptions = MergeOptions()`: options for how to perform the merge, including whether fastforwarding is allowed. See [MergeOptions](#) for more information.
- `checkout_opts::CheckoutOptions = CheckoutOptions()`: options for how to perform the checkout. See [CheckoutOptions](#) for more information.

`anns` may refer to remote or local branch heads. Return true if the merge is successful, otherwise return false (for instance, if no merge is possible because the branches have no common ancestor).

Examples

```
upst_ann = LibGit2.GitAnnotated(repo, "branch/a")

# merge the branch in
LibGit2.merge!(repo, [upst_ann])
```

LibGit2.merge! – Method.

```
merge!(repo::GitRepo, anns::Vector{GitAnnotated}, fastforward::Bool; kwargs...) -> Bool
```

Merge changes from the annotated commits (captured as [GitAnnotated](#) objects) `anns` into the HEAD of the repository `repo`. If `fastforward` is true, only a fastforward merge is allowed. In this case, if conflicts occur, the merge will fail. Otherwise, if `fastforward` is false, the merge may produce a conflict file which the user will need to resolve.

The keyword arguments are:

- `merge_opts::MergeOptions = MergeOptions()`: options for how to perform the merge, including whether fastforwarding is allowed. See [MergeOptions](#) for more information.
- `checkout_opts::CheckoutOptions = CheckoutOptions()`: options for how to perform the checkout. See [CheckoutOptions](#) for more information.

`anns` may refer to remote or local branch heads. Return true if the merge is successful, otherwise return false (for instance, if no merge is possible because the branches have no common ancestor).

Examples

```
upst_ann_1 = LibGit2.GitAnnotated(repo, "branch/a")

# merge the branch in, fastforward
LibGit2.merge!(repo, [upst_ann_1], true)

# merge conflicts!
upst_ann_2 = LibGit2.GitAnnotated(repo, "branch/b")
# merge the branch in, try to fastforward
LibGit2.merge!(repo, [upst_ann_2], true) # will return false
LibGit2.merge!(repo, [upst_ann_2], false) # will return true
```

LibGit2.ffmerge! – Function.

```
ffmerge!(repo::GitRepo, ann::GitAnnotated)
```

Fastforward merge changes into current HEAD. This is only possible if the commit referred to by `ann` is descended from the current HEAD (e.g. if pulling changes from a remote branch which is simply ahead of the local branch tip).

LibGit2.fullname – Function.

```
LibGit2.fullname(ref::GitReference)
```

Return the name of the reference pointed to by the symbolic reference `ref`. If `ref` is not a symbolic reference, return an empty string.

LibGit2.features – Function.

```
| features()
```

Return a list of git features the current version of libgit2 supports, such as threading or using HTTPS or SSH.

`LibGit2.filename` - Function.

```
| filename(te::GitTreeEntry)
```

Return the filename of the object on disk to which `te` refers.

`LibGit2.filemode` - Function.

```
| filemode(te::GitTreeEntry) -> Cint
```

Return the UNIX filemode of the object on disk to which `te` refers as an integer.

`LibGit2.gitdir` - Function.

```
| LibGit2.gitdir(repo::GitRepo)
```

Return the location of the "git" files of `repo`:

- for normal repositories, this is the location of the `.git` folder.
- for bare repositories, this is the location of the repository itself.

See also [workdir](#), [path](#).

`LibGit2.git_url` - Function.

```
| LibGit2.git_url(; kwargs...) -> String
```

Create a string based upon the URL components provided. When the scheme keyword is not provided the URL produced will use the alternative [scp-like syntax](#).

Keywords

- `scheme::AbstractString=""`: the URL scheme which identifies the protocol to be used. For HTTP use "http", SSH use "ssh", etc. When scheme is not provided the output format will be "ssh" but using the scp-like syntax.
- `username::AbstractString=""`: the username to use in the output if provided.
- `password::AbstractString=""`: the password to use in the output if provided.
- `host::AbstractString=""`: the hostname to use in the output. A hostname is required to be specified.
- `port::Union{AbstractString,Integer}=""`: the port number to use in the output if provided. Cannot be specified when using the scp-like syntax.
- `path::AbstractString=""`: the path to use in the output if provided.

Warning

Avoid using passwords in URLs. Unlike the credential objects, Julia is not able to securely zero or destroy the sensitive data after use and the password may remain in memory; possibly to be exposed by an uninitialized memory.

Examples

```
julia> LibGit2.git_url(username="git", host="github.com", path="JuliaLang/julia.git")
"git@github.com:JuliaLang/julia.git"

julia> LibGit2.git_url(scheme="https", host="github.com", path="/JuliaLang/julia.git")
"https://github.com/JuliaLang/julia.git"

julia> LibGit2.git_url(scheme="ssh", username="git", host="github.com", port=2222,
↳ path="JuliaLang/julia.git")
"ssh://git@github.com:2222/JuliaLang/julia.git"
```

LibGit2.@githash_str – Macro.

```
| @githash_str -> AbstractGitHash
```

Construct a git hash object from the given string, returning a `GitShortHash` if the string is shorter than 40 hexadecimal digits, otherwise a `GitHash`.

Examples

```
julia> LibGit2.githash"d114feb74ce633"
GitShortHash("d114feb74ce633")

julia> LibGit2.githash"d114feb74ce63307afe878a5228ad014e0289a85"
GitHash("d114feb74ce63307afe878a5228ad014e0289a85")
```

LibGit2.head – Function.

```
| LibGit2.head(repo::GitRepo) -> GitReference
```

Return a `GitReference` to the current HEAD of repo.

```
| head(pkg::AbstractString) -> String
```

Return current HEAD `GitHash` of the pkg repo as a string.

LibGit2.head! – Function.

```
| LibGit2.head!(repo::GitRepo, ref::GitReference) -> GitReference
```

Set the HEAD of repo to the object pointed to by ref.

LibGit2.head_oid – Function.

```
| LibGit2.head_oid(repo::GitRepo) -> GitHash
```

Lookup the object id of the current HEAD of git repository repo.

LibGit2.headname – Function.

```
| LibGit2.headname(repo::GitRepo)
```

Lookup the name of the current HEAD of git repository repo. If repo is currently detached, return the name of the HEAD it's detached from.

LibGit2.init – Function.

```
| LibGit2.init(path::AbstractString, bare::Bool=false) -> GitRepo
```

Open a new git repository at path. If bare is false, the working tree will be created in path/.git. If bare is true, no working directory will be created.

LibGit2.is_ancestor_of – Function.

```
| is_ancestor_of(a::AbstractString, b::AbstractString, repo::GitRepo) -> Bool
```

Return true if a, a [GitHash](#) in string form, is an ancestor of b, a [GitHash](#) in string form.

Examples

```
julia> repo = GitRepo(repo_path);
julia> LibGit2.add!(repo, test_file1);
julia> commit_oid1 = LibGit2.commit(repo, "commit1");
julia> LibGit2.add!(repo, test_file2);
julia> commit_oid2 = LibGit2.commit(repo, "commit2");
julia> LibGit2.is_ancestor_of(string(commit_oid1), string(commit_oid2), repo)
true
```

LibGit2.isbinary – Function.

```
| isbinary(blob::GitBlob) -> Bool
```

Use a heuristic to guess if a file is binary: searching for NULL bytes and looking for a reasonable ratio of printable to non-printable characters among the first 8000 bytes.

LibGit2.iscommit – Function.

```
| iscommit(id::AbstractString, repo::GitRepo) -> Bool
```

Check if commit id (which is a [GitHash](#) in string form) is in the repository.

Examples

```
julia> repo = GitRepo(repo_path);
julia> LibGit2.add!(repo, test_file);
julia> commit_oid = LibGit2.commit(repo, "add test_file");
julia> LibGit2.iscommit(string(commit_oid), repo)
true
```

LibGit2.isdiff – Function.

```
LibGit2.isdiff(repo::GitRepo, treeish::AbstractString, pathspecs::AbstractString="";
↳ cached::Bool=false)
```

Checks if there are any differences between the tree specified by `treeish` and the tracked files in the working tree (if `cached=false`) or the index (if `cached=true`). `pathspecs` are the specifications for options for the diff.

Examples

```
repo = LibGit2.GitRepo(repo_path)
LibGit2.isdiff(repo, "HEAD") # should be false
open(joinpath(repo_path, new_file), "a") do f
    println(f, "here's my cool new file")
end
LibGit2.isdiff(repo, "HEAD") # now true
```

Equivalent to `git diff-index <treeish> [-- <pathspecs>]`.

`LibGit2.isdirty` – Function.

```
LibGit2.isdirty(repo::GitRepo, pathspecs::AbstractString=""; cached::Bool=false) -> Bool
```

Check if there have been any changes to tracked files in the working tree (if `cached=false`) or the index (if `cached=true`). `pathspecs` are the specifications for options for the diff.

Examples

```
repo = LibGit2.GitRepo(repo_path)
LibGit2.isdirty(repo) # should be false
open(joinpath(repo_path, new_file), "a") do f
    println(f, "here's my cool new file")
end
LibGit2.isdirty(repo) # now true
LibGit2.isdirty(repo, new_file) # now true
```

Equivalent to `git diff-index HEAD [-- <pathspecs>]`.

`LibGit2.isorphan` – Function.

```
LibGit2.isorphan(repo::GitRepo)
```

Check if the current branch is an "orphan" branch, i.e. has no commits. The first commit to this branch will have no parents.

`LibGit2.isset` – Function.

```
isset(val::Integer, flag::Integer)
```

Test whether the bits of `val` indexed by `flag` are set (1) or unset (0).

`LibGit2.iszero` – Function.

```
iszero(id::GitHash) -> Bool
```

Determine whether all hexadecimal digits of the given `GitHash` are zero.

LibGit2.lookup_branch - Function.

```
lookup_branch(repo::GitRepo, branch_name::AbstractString, remote::Bool=false) ->
↳ Union{GitReference, Nothing}
```

Determine if the branch specified by branch_name exists in the repository repo. If remote is true, repo is assumed to be a remote git repository. Otherwise, it is part of the local filesystem.

Return either a GitReference to the requested branch if it exists, or nothing if not.

LibGit2.map - Function.

```
LibGit2.map(f::Function, walker::GitRevWalker; oid::GitHash=GitHash(),
↳ range::AbstractString="", by::Cint=Consts.SORT_NONE, rev::Bool=false)
```

Using the GitRevWalker walker to "walk" over every commit in the repository's history, apply f to each commit in the walk. The keyword arguments are: * oid: The GitHash of the commit to begin the walk from. The default is to use push_head! and therefore the HEAD commit and all its ancestors. * range: A range of GitHashs in the format oid1..oid2. f will be applied to all commits between the two. * by: The sorting method. The default is not to sort. Other options are to sort by topology (LibGit2.Consts.SORT_TOPOLOGICAL), to sort forwards in time (LibGit2.Consts.SORT_TIME, most ancient first) or to sort backwards in time (LibGit2.Consts.SORT_REVERSE, most recent first). * rev: Whether to reverse the sorted order (for instance, if topological sorting is used).

Examples

```
oids = LibGit2.with(LibGit2.GitRevWalker(repo)) do walker
    LibGit2.map((oid, repo)->string(oid), walker, by=LibGit2.Consts.SORT_TIME)
end
```

Here, LibGit2.map visits each commit using the GitRevWalker and finds its GitHash.

LibGit2.mirror_callback - Function.

Mirror callback function

Function sets +refs/*:refs/* refsspecs and mirror flag for remote reference.

LibGit2.mirror_cb - Function.

C function pointer for mirror_callback

LibGit2.message - Function.

```
message(c::GitCommit, raw::Bool=false)
```

Return the commit message describing the changes made in commit c. If raw is false, return a slightly "cleaned up" message (which has any leading newlines removed). If raw is true, the message is not stripped of any such newlines.

LibGit2.merge_analysis - Function.

```
merge_analysis(repo::GitRepo, anns::Vector{GitAnnotated}) -> analysis, preference
```

Run analysis on the branches pointed to by the annotated branch tips `anns` and determine under what circumstances they can be merged. For instance, if `anns[1]` is simply an ancestor of `ann[2]`, then `merge_analysis` will report that a fast-forward merge is possible.

Return two outputs, `analysis` and `preference`. `analysis` has several possible values: `*MERGE_ANALYSIS_NONE`: it is not possible to merge the elements of `anns`. `*MERGE_ANALYSIS_NORMAL`: a regular merge, when `HEAD` and the commits that the user wishes to merge have all diverged from a common ancestor. In this case the changes have to be resolved and conflicts may occur. `*MERGE_ANALYSIS_UP_TO_DATE`: all the input commits the user wishes to merge can be reached from `HEAD`, so no merge needs to be performed. `*MERGE_ANALYSIS_FASTFORWARD`: the input commit is a descendant of `HEAD` and so no merge needs to be performed - instead, the user can simply checkout the input commit(s). `*MERGE_ANALYSIS_UNBORN`: the `HEAD` of the repository refers to a commit which does not exist. It is not possible to merge, but it may be possible to checkout the input commits. `preference` also has several possible values: `*MERGE_PREFERENCE_NONE`: the user has no preference. `*MERGE_PREFERENCE_NO_FASTFORWARD`: do not allow any fast-forward merges. `*MERGE_PREFERENCE_FASTFORWARD_ONLY`: allow only fast-forward merges and no other type (which may introduce conflicts). `preference` can be controlled through the repository or global git configuration.

`LibGit2.name` - Function.

```
| LibGit2.name(ref::GitReference)
```

Return the full name of `ref`.

```
| name(rmt::GitRemote)
```

Get the name of a remote repository, for instance "origin". If the remote is anonymous (see [GitRemoteAnon](#)) the name will be an empty string "".

Examples

```
julia> repo_url = "https://github.com/JuliaLang/Example.jl";
julia> repo = LibGit2.clone(cache_repo, "test_directory");
julia> remote = LibGit2.GitRemote(repo, "origin", repo_url);
julia> name(remote)
"origin"
```

```
| LibGit2.name(tag::GitTag)
```

The name of tag (e.g. "v0.5").

`LibGit2.need_update` - Function.

```
| need_update(repo::GitRepo)
```

Equivalent to `git update-index`. Return `true` if `repo` needs updating.

`LibGit2.objtype` - Function.

```
| objtype(obj_type::Consts.OBJECT)
```

Return the type corresponding to the enum value.

`LibGit2.path` – Function.

```
| LibGit2.path(repo::GitRepo)
```

Return the base file path of the repository `repo`.

- for normal repositories, this will typically be the parent directory of the ".git" directory (note: this may be different than the working directory, see `workdir` for more details).
- for bare repositories, this is the location of the "git" files.

See also [gitdir](#), [workdir](#).

`LibGit2.peel` – Function.

```
| peel([T,] ref::GitReference)
```

Recursively peel `ref` until an object of type `T` is obtained. If no `T` is provided, then `ref` will be peeled until an object other than a [GitTag](#) is obtained.

- A [GitTag](#) will be peeled to the object it references.
- A [GitCommit](#) will be peeled to a [GitTree](#).

Note

Only annotated tags can be peeled to [GitTag](#) objects. Lightweight tags (the default) are references under `refs/tags/` which point directly to [GitCommit](#) objects.

```
| peel([T,] obj::GitObject)
```

Recursively peel `obj` until an object of type `T` is obtained. If no `T` is provided, then `obj` will be peeled until the type changes.

- A [GitTag](#) will be peeled to the object it references.
- A [GitCommit](#) will be peeled to a [GitTree](#).

`LibGit2.posixpath` – Function.

```
| LibGit2.posixpath(path)
```

Standardise the path string `path` to use POSIX separators.

`LibGit2.push` – Function.

```
| push(rmt::GitRemote, refsspecs; force::Bool=false, options::PushOptions=PushOptions())
```

Push to the specified `rmt` remote git repository, using `refsspecs` to determine which remote branch(es) to push to. The keyword arguments are:

- `force`: if true, a force-push will occur, disregarding conflicts.

- `options`: determines the options for the push, e.g. which proxy headers to use. See [PushOptions](#) for more information.

Note

You can add information about the push refsspecs in two other ways: by setting an option in the repository's `GitConfig` (with `push.default` as the key) or by calling `add_push!`. Otherwise you will need to explicitly specify a push refspect in the call to push for it to have any effect, like so: `LibGit2.push(repo, refsspecs=["refs/heads/master"])`.

```
| push(repo::GitRepo; kwargs...)
```

Pushes updates to an upstream of `repo`.

The keyword arguments are:

- `remote::AbstractString="origin"`: the name of the upstream remote to push to.
- `remoteurl::AbstractString=""`: the URL of remote.
- `refsspecs=AbstractString[]`: determines properties of the push.
- `force::Bool=false`: determines if the push will be a force push, overwriting the remote branch.
- `credentials=nothing`: provides credentials and/or settings when authenticating against a private remote.
- `callbacks=Callbacks()`: user provided callbacks and payloads.

Equivalent to `git push [<remoteurl>|<repo>] [<refsspecs>]`.

`LibGit2.push!` – Method.

```
| LibGit2.push!(w::GitRevWalker, cid::GitHash)
```

Start the [GitRevWalker](#) walker at commit `cid`. This function can be used to apply a function to all commits since a certain year, by passing the first commit of that year as `cid` and then passing the resulting `w` to [LibGit2.map](#).

`LibGit2.push_head!` – Function.

```
| LibGit2.push_head!(w::GitRevWalker)
```

Push the HEAD commit and its ancestors onto the [GitRevWalker](#) `w`. This ensures that HEAD and all its ancestor commits will be encountered during the walk.

`LibGit2.push_refsspecs` – Function.

```
| push_refsspecs(rmt::GitRemote) -> Vector{String}
```

Get the push refsspecs for the specified `rmt`. These refsspecs contain information about which branch(es) to push to.

Examples

```

julia> remote = LibGit2.get(LibGit2.GitRemote, repo, "upstream");

julia> LibGit2.add_push!(repo, remote, "refs/heads/master");

julia> close(remote);

julia> remote = LibGit2.get(LibGit2.GitRemote, repo, "upstream");

julia> LibGit2.push_refsspecs(remote)
String["refs/heads/master"]

```

LibGit2.raw – Function.

```

| raw(id::GitHash) -> Vector{UInt8}

```

Obtain the raw bytes of the `GitHash` as a vector of length 20.

LibGit2.read_tree! – Function.

```

| LibGit2.read_tree!(idx::GitIndex, tree::GitTree)
| LibGit2.read_tree!(idx::GitIndex, treehash::AbstractGitHash)

```

Read the tree `tree` (or the tree pointed to by `treehash` in the repository owned by `idx`) into the index `idx`. The current index contents will be replaced.

LibGit2.rebase! – Function.

```

| LibGit2.rebase!(repo::GitRepo, upstream::AbstractString="", newbase::AbstractString="")

```

Attempt an automatic merge rebase of the current branch, from upstream if provided, or otherwise from the upstream tracking branch. `newbase` is the branch to rebase onto. By default this is upstream.

If any conflicts arise which cannot be automatically resolved, the rebase will abort, leaving the repository and working tree in its original state, and the function will throw a `GitError`. This is roughly equivalent to the following command line statement:

```

| git rebase --merge [<upstream>]
| if [ -d ".git/rebase-merge" ]; then
|     git rebase --abort
| fi

```

LibGit2.ref_list – Function.

```

| LibGit2.ref_list(repo::GitRepo) -> Vector{String}

```

Get a list of all reference names in the repo repository.

LibGit2.reftype – Function.

```

| LibGit2.reftype(ref::GitReference) -> Cint

```

Return a `Cint` corresponding to the type of `ref`:

- 0 if the reference is invalid

- 1 if the reference is an object id
- 2 if the reference is symbolic

`LibGit2.remotes` – Function.

```
| LibGit2.remotes(repo::GitRepo)
```

Return a vector of the names of the remotes of repo.

`LibGit2.remove!` – Function.

```
| remove!(repo::GitRepo, files::AbstractString...)
| remove!(idx::GitIndex, files::AbstractString...)
```

Remove all the files with paths specified by files in the index idx (or the index of the repo).

`LibGit2.reset` – Function.

```
| reset(val::Integer, flag::Integer)
```

Unset the bits of val indexed by flag, returning them to 0.

`LibGit2.reset!` – Function.

```
| reset!(payload, [config]) -> CredentialPayload
```

Reset the payload state back to the initial values so that it can be used again within the credential callback. If a config is provided the configuration will also be updated.

Updates some entries, determined by the pathspecs, in the index from the target commit tree.

Sets the current head to the specified commit oid and optionally resets the index and working tree to match.

```
git reset [<committish>] [-] <pathspecs>...
```

```
| reset!(repo::GitRepo, id::GitHash, mode::Cint=Consts.RESET_MIXED)
```

Reset the repository repo to its state at id, using one of three modes set by mode:

1. `Consts.RESET_SOFT` - move HEAD to id.
2. `Consts.RESET_MIXED` - default, move HEAD to id and reset the index to id.
3. `Consts.RESET_HARD` - move HEAD to id, reset the index to id, and discard all working changes.

Examples

```
# fetch changes
LibGit2.fetch(repo)
isfile(joinpath(repo_path, our_file)) # will be false

# fastforward merge the changes
LibGit2.merge!(repo, fastforward=true)

# because there was not any file locally, but there is
# a file remotely, we need to reset the branch
head_oid = LibGit2.head_oid(repo)
new_head = LibGit2.reset!(repo, head_oid, LibGit2.Consts.RESET_HARD)
```

In this example, the remote which is being fetched from does have a file called `our_file` in its index, which is why we must reset.

Equivalent to `git reset [--soft | --mixed | --hard] <id>`.

Examples

```
repo = LibGit2.GitRepo(repo_path)
head_oid = LibGit2.head_oid(repo)
open(joinpath(repo_path, "file1"), "w") do f
    write(f, "111
")
end
LibGit2.add!(repo, "file1")
mode = LibGit2.Consts.RESET_HARD
# will discard the changes to file1
# and unstage it
new_head = LibGit2.reset!(repo, head_oid, mode)
```

`LibGit2.restore` - Function.

```
restore(s::State, repo::GitRepo)
```

Return a repository `repo` to a previous State `s`, for example the HEAD of a branch before a merge attempt. `s` can be generated using the `snapshot` function.

`LibGit2.revcount` - Function.

```
LibGit2.revcount(repo::GitRepo, commit1::AbstractString, commit2::AbstractString)
```

List the number of revisions between `commit1` and `commit2` (committish OIDs in string form). Since `commit1` and `commit2` may be on different branches, `revcount` performs a "left-right" revision list (and count), returning a tuple of Ints - the number of left and right commits, respectively. A left (or right) commit refers to which side of a symmetric difference in a tree the commit is reachable from.

Equivalent to `git rev-list --left-right --count <commit1> <commit2>`.

Examples

```
repo = LibGit2.GitRepo(repo_path)
repo_file = open(joinpath(repo_path, test_file), "a")
println(repo_file, "hello world")
flush(repo_file)
LibGit2.add!(repo, test_file)
commit_oid1 = LibGit2.commit(repo, "commit 1")
println(repo_file, "hello world again")
flush(repo_file)
LibGit2.add!(repo, test_file)
commit_oid2 = LibGit2.commit(repo, "commit 2")
LibGit2.revcount(repo, string(commit_oid1), string(commit_oid2))
```

This will return `(-1, 0)`.

`LibGit2.set_remote_url` - Function.

```
set_remote_url(repo::GitRepo, remote_name, url)
set_remote_url(repo::String, remote_name, url)
```

Set both the fetch and push url for remote_name for the [GitRepo](#) or the git repository located at path. Typically git repos use "origin" as the remote name.

Examples

```
repo_path = joinpath(tempdir(), "Example")
repo = LibGit2.init(repo_path)
LibGit2.set_remote_url(repo, "upstream", "https://github.com/JuliaLang/Example.jl")
LibGit2.set_remote_url(repo_path, "upstream2", "https://github.com/JuliaLang/Example2.jl")
```

LibGit2.shortname – Function.

```
LibGit2.shortname(ref::GitReference)
```

Return a shortened version of the name of ref that's "human-readable".

```
julia> repo = GitRepo(path_to_repo);

julia> branch_ref = LibGit2.head(repo);

julia> LibGit2.name(branch_ref)
"refs/heads/master"

julia> LibGit2.shortname(branch_ref)
"master"
```

LibGit2.snapshot – Function.

```
snapshot(repo::GitRepo) -> State
```

Take a snapshot of the current state of the repository repo, storing the current HEAD, index, and any uncommitted work. The output State can be used later during a call to [restore](#) to return the repository to the snapshotted state.

LibGit2.split_cfg_entry – Function.

```
LibGit2.split_cfg_entry(ce::LibGit2.ConfigEntry) -> Tuple{String,String,String,String}
```

Break the ConfigEntry up to the following pieces: section, subsection, name, and value.

Examples

Given the git configuration file containing:

```
[credential "https://example.com"]
    username = me
```

The ConfigEntry would look like the following:

```
julia> entry
ConfigEntry("credential.https://example.com.username", "me")

julia> LibGit2.split_cfg_entry(entry)
("credential", "https://example.com", "username", "me")
```

Refer to the [git config syntax documentation](#) for more details.

`LibGit2.status` – Function.

```
| LibGit2.status(repo::GitRepo, path::String) -> Union{Cuint, Cvoid}
```

Lookup the status of the file at path in the git repository repo. For instance, this can be used to check if the file at path has been modified and needs to be staged and committed.

`LibGit2.stage` – Function.

```
| stage(ie::IndexEntry) -> Cint
```

Get the stage number of ie. The stage number 0 represents the current state of the working tree, but other numbers can be used in the case of a merge conflict. In such a case, the various stage numbers on an IndexEntry describe which side(s) of the conflict the current state of the file belongs to. Stage 0 is the state before the attempted merge, stage 1 is the changes which have been made locally, stages 2 and larger are for changes from other branches (for instance, in the case of a multi-branch "octopus" merge, stages 2, 3, and 4 might be used).

`LibGit2.tag_create` – Function.

```
| LibGit2.tag_create(repo::GitRepo, tag::AbstractString, commit; kwargs...)
```

Create a new git tag tag (e.g. "v0.5") in the repository repo, at the commit commit.

The keyword arguments are:

- `msg::AbstractString=""`: the message for the tag.
- `force::Bool=false`: if true, existing references will be overwritten.
- `sig::Signature=Signature(repo)`: the tagger's signature.

`LibGit2.tag_delete` – Function.

```
| LibGit2.tag_delete(repo::GitRepo, tag::AbstractString)
```

Remove the git tag tag from the repository repo.

`LibGit2.tag_list` – Function.

```
| LibGit2.tag_list(repo::GitRepo) -> Vector{String}
```

Get a list of all tags in the git repository repo.

`LibGit2.target` – Function.

```
| LibGit2.target(tag::GitTag)
```

The GitHash of the target object of tag.

`LibGit2.toggle` – Function.

```
| toggle(val::Integer, flag::Integer)
```

Flip the bits of `val` indexed by `flag`, so that if a bit is 0 it will be 1 after the toggle, and vice-versa.

`LibGit2.transact` – Function.

```
| transact(f::Function, repo::GitRepo)
```

Apply function `f` to the git repository `repo`, taking a [snapshot](#) before applying `f`. If an error occurs within `f`, `repo` will be returned to its snapshot state using [restore](#). The error which occurred will be rethrown, but the state of `repo` will not be corrupted.

`LibGit2.treewalk` – Function.

```
| treewalk(f, tree::GitTree, post::Bool=false)
```

Traverse the entries in `tree` and its subtrees in post or pre order. Preorder means beginning at the root and then traversing the leftmost subtree (and recursively on down through that subtree's leftmost subtrees) and moving right through the subtrees. Postorder means beginning at the bottom of the leftmost subtree, traversing upwards through it, then traversing the next right subtree (again beginning at the bottom) and finally visiting the tree root last of all.

The function parameter `f` should have following signature:

```
| (String, GitTreeEntry) -> Cint
```

A negative value returned from `f` stops the tree walk. A positive value means that the entry will be skipped if `post` is `false`.

`LibGit2.upstream` – Function.

```
| upstream(ref::GitReference) -> Union{GitReference, Nothing}
```

Determine if the branch containing `ref` has a specified upstream branch.

Return either a `GitReference` to the upstream branch if it exists, or [nothing](#) if the requested branch does not have an upstream counterpart.

`LibGit2.update!` – Function.

```
| update!(repo::GitRepo, files::AbstractString...)
| update!(idx::GitIndex, files::AbstractString...)
```

Update all the files with paths specified by `files` in the index `idx` (or the index of the `repo`). Match the state of each file in the index with the current state on disk, removing it if it has been removed on disk, or updating its entry in the object database.

`LibGit2.url` – Function.

```
| url(rmt::GitRemote)
```

Get the fetch URL of a remote git repository.

Examples

```
julia> repo_url = "https://github.com/JuliaLang/Example.jl";

julia> repo = LibGit2.init(mktempdir());

julia> remote = LibGit2.GitRemote(repo, "origin", repo_url);

julia> LibGit2.url(remote)
"https://github.com/JuliaLang/Example.jl"
```

`LibGit2.version` – Function.

```
| version() -> VersionNumber
```

Return the version of libgit2 in use, as a [VersionNumber](#).

`LibGit2.with` – Function.

```
| with(f::Function, obj)
```

Resource management helper function. Applies `f` to `obj`, making sure to call `close` on `obj` after `f` successfully returns or throws an error. Ensures that allocated git resources are finalized as soon as they are no longer needed.

`LibGit2.with_warn` – Function.

```
| with_warn(f::Function, ::Type{T}, args...)
```

Resource management helper function. Apply `f` to `args`, first constructing an instance of type `T` from `args`. Makes sure to call `close` on the resulting object after `f` successfully returns or throws an error. Ensures that allocated git resources are finalized as soon as they are no longer needed. If an error is thrown by `f`, a warning is shown containing the error.

`LibGit2.workdir` – Function.

```
| LibGit2.workdir(repo::GitRepo)
```

Return the location of the working directory of `repo`. This will throw an error for bare repositories.

Note

This will typically be the parent directory of `gitdir(repo)`, but can be different in some cases: e.g. if either the `core.worktree` configuration variable or the `GIT_WORK_TREE` environment variable is set.

See also [gitdir](#), [path](#).

`LibGit2.GitObject` – Method.

```
| (::Type{T})(te::GitTreeEntry) where T<:GitObject
```

Get the git object to which `te` refers and return it as its actual type (the type `entrytype` would show), for instance a `GitBlob` or `GitTag`.

Examples

```
| tree = LibGit2.GitTree(repo, "HEAD^{tree}")
| tree_entry = tree[1]
| blob = LibGit2.GitBlob(tree_entry)
```

LibGit2.UserPasswordCredential – Type.

Credential that support only user and password parameters

LibGit2.SSHCredential – Type.

SSH credential type

LibGit2.isfilled – Function.

```
| isfilled(cred::AbstractCredential) -> Bool
```

Verifies that a credential is ready for use in authentication.

LibGit2.CachedCredentials – Type.

Caches credential information for re-use

LibGit2.CredentialPayload – Type.

```
| LibGit2.CredentialPayload
```

Retains the state between multiple calls to the credential callback for the same URL. A **CredentialPayload** instance is expected to be reset! whenever it will be used with a different URL.

LibGit2.approve – Function.

```
| approve(payload::CredentialPayload; shred::Bool=true) -> Nothing
```

Store the payload credential for re-use in a future authentication. Should only be called when authentication was successful.

The **shred** keyword controls whether sensitive information in the payload credential field should be destroyed. Should only be set to **false** during testing.

LibGit2.reject – Function.

```
| reject(payload::CredentialPayload; shred::Bool=true) -> Nothing
```

Discard the payload credential from begin re-used in future authentication. Should only be called when authentication was unsuccessful.

The **shred** keyword controls whether sensitive information in the payload credential field should be destroyed. Should only be set to **false** during testing.

LibGit2.Consts.GIT_CONFIG – Type.

Priority level of a config file.

These priority levels correspond to the natural escalation logic (from higher to lower) when searching for config entries in git.

- `CONFIG_LEVEL_DEFAULT` - Open the global, XDG and system configuration files if any available.
- `CONFIG_LEVEL_PROGRAMDATA` - System-wide on Windows, for compatibility with portable git
- `CONFIG_LEVEL_SYSTEM` - System-wide configuration file; `/etc/gitconfig` on Linux systems
- `CONFIG_LEVEL_XDG` - XDG compatible configuration file; typically `~/.config/git/config`
- `CONFIG_LEVEL_GLOBAL` - User-specific configuration file (also called Global configuration file); typically `~/.gitconfig`
- `CONFIG_LEVEL_LOCAL` - Repository specific configuration file; `$WORK_DIR/.git/config` on non-bare repos
- `CONFIG_LEVEL_APP` - Application specific configuration file; freely defined by applications
- `CONFIG_HIGHEST_LEVEL` - Represents the highest level available config file (i.e. the most specific config file available that actually is loaded)

Chapter 77

Dynamic Linker

Base.Libc.Libdl.dlopen – Function.

```
| dlopen(libfile::AbstractString [, flags::Integer]; throw_error::Bool = true)
```

Load a shared library, returning an opaque handle.

The extension given by the constant `dlext` (`.so`, `.dll`, or `.dylib`) can be omitted from the `libfile` string, as it is automatically appended if needed. If `libfile` is not an absolute path name, then the paths in the array `DL_LOAD_PATH` are searched for `libfile`, followed by the system load path.

The optional `flags` argument is a bitwise-or of zero or more of `RTLD_LOCAL`, `RTLD_GLOBAL`, `RTLD_LAZY`, `RTLD_NOW`, `RTLD_NODELETE`, `RTLD_NOLOAD`, `RTLD_DEEPBIND`, and `RTLD_FIRST`. These are converted to the corresponding flags of the POSIX (and/or GNU libc and/or MacOS) `dlopen` command, if possible, or are ignored if the specified functionality is not available on the current platform. The default flags are platform specific. On MacOS the default `dlopen` flags are `RTLD_LAZY|RTLD_DEEPBIND|RTLD_GLOBAL` while on other platforms the defaults are `RTLD_LAZY|RTLD_DEEPBIND|RTLD_LOCAL`. An important usage of these flags is to specify non default behavior for when the dynamic library loader binds library references to exported symbols and if the bound references are put into process local or global scope. For instance `RTLD_LAZY|RTLD_DEEPBIND|RTLD_GLOBAL` allows the library's symbols to be available for usage in other shared libraries, addressing situations where there are dependencies between shared libraries.

If the library cannot be found, this method throws an error, unless the keyword argument `throw_error` is set to `false`, in which case this method returns nothing.

Note

From Julia 1.6 on, this method replaces paths starting with `@executable_path/` with the path to the Julia executable, allowing for relocatable relative-path loads. In Julia 1.5 and earlier, this only worked on macOS.

source

Base.Libc.Libdl.dlopen_e – Function.

```
| dlopen_e(libfile::AbstractString [, flags::Integer])
```

Similar to [dlopen](#), except returns `C_NULL` instead of raising errors. This method is now deprecated in favor of `dlopen(libfile::AbstractString [, flags::Integer]; throw_error=false)`.

[source](#)

`Base.Libc.Libdl.RTLD_NOW` – Constant.

```
| RTLD_DEEPBIND
| RTLD_FIRST
| RTLD_GLOBAL
| RTLD_LAZY
| RTLD_LOCAL
| RTLD_NODELETE
| RTLD_NOLOAD
| RTLD_NOW
```

Enum constant for [dlopen](#). See your platform man page for details, if applicable.

[source](#)

`Base.Libc.Libdl.dlsym` – Function.

```
| dlsym(handle, sym; throw_error::Bool = true)
```

Look up a symbol from a shared library handle, return callable function pointer on success.

If the symbol cannot be found, this method throws an error, unless the keyword argument `throw_error` is set to `false`, in which case this method returns nothing.

[source](#)

`Base.Libc.Libdl.dlsym_e` – Function.

```
| dlsym_e(handle, sym)
```

Look up a symbol from a shared library handle, silently return `C_NULL` on lookup failure. This method is now deprecated in favor of `dlsym(handle, sym; throw_error=false)`.

[source](#)

`Base.Libc.Libdl.dlclose` – Function.

```
| dlclose(handle)
```

Close shared library referenced by handle.

[source](#)

```
| dlclose(::Nothing)
```

For the very common pattern usage pattern of

```
| try
|     hdl = dlopen(library_name)
|     ... do something
| finally
|     dlclose(hdl)
| end
```

We define a `dlclose()` method that accepts a parameter of type `Nothing`, so that user code does not have to change its behavior for the case that `library_name` was not found.

[source](#)

`Base.Libc.Libdl.dlext` – Constant.

| `dlext`

File extension for dynamic libraries (e.g. `dll`, `dylib`, `so`) on the current platform.

[source](#)

`Base.Libc.Libdl.dllist` – Function.

| `dllist()`

Return the paths of dynamic libraries currently loaded in a `Vector{String}`.

[source](#)

`Base.Libc.Libdl.dlpath` – Function.

| `dlpath(handle::Ptr{Cvoid})`

Given a library handle from `dlopen`, return the full path.

[source](#)

| `dlpath(libname::Union{AbstractString, Symbol})`

Get the full path of the library `libname`.

Example

| `julia> dlpath("libjulia")`

[source](#)

`Base.Libc.Libdl.find_library` – Function.

| `find_library(names [, locations])`

Searches for the first library in `names` in the paths in the `locations` list, `DL_LOAD_PATH`, or system library paths (in that order) which can successfully be `dlopen'd`. On success, the return value will be one of the names (potentially prefixed by one of the paths in `locations`). This string can be assigned to a `global const` and used as the library name in future `ccall's`. On failure, it returns the empty string.

[source](#)

`Base.DL_LOAD_PATH` – Constant.

| `DL_LOAD_PATH`

When calling `dlopen`, the paths in this list will be searched first, in order, before searching the system locations for a valid library handle.

[source](#)

Chapter 78

Linear Algebra

In addition to (and as part of) its support for multi-dimensional arrays, Julia provides native implementations of many common and useful linear algebra operations which can be loaded with using `LinearAlgebra`. Basic operations, such as `tr`, `det`, and `inv` are all supported:

```
julia> A = [1 2 3; 4 1 6; 7 8 1]
3×3 Matrix{Int64}:
 1  2  3
 4  1  6
 7  8  1

julia> tr(A)
3

julia> det(A)
104.0

julia> inv(A)
3×3 Matrix{Float64}:
-0.451923  0.211538  0.0865385
 0.365385 -0.192308  0.0576923
 0.240385  0.0576923 -0.0673077
```

As well as other useful operations, such as finding eigenvalues or eigenvectors:

```
julia> A = [-4. -17.; 2. 2.]
2×2 Matrix{Float64}:
-4.0 -17.0
 2.0  2.0

julia> eigvals(A)
2-element Vector{ComplexF64}:
-1.0 - 5.0im
-1.0 + 5.0im

julia> eigvecs(A)
2×2 Matrix{ComplexF64}:
```

```

0.945905-0.0im      0.945905+0.0im
-0.166924+0.278207im -0.166924-0.278207im

```

In addition, Julia provides many [factorizations](#) which can be used to speed up problems such as linear solve or matrix exponentiation by pre-factorizing a matrix into a form more amenable (for performance or memory reasons) to the problem. See the documentation on [factorize](#) for more information. As an example:

```

julia> A = [1.5 2 -4; 3 -1 -6; -10 2.3 4]
3×3 Matrix{Float64}:
 1.5  2.0 -4.0
 3.0 -1.0 -6.0
-10.0 2.3  4.0

julia> factorize(A)
LU{Float64, Matrix{Float64}, Vector{Int64}}
L factor:
3×3 Matrix{Float64}:
 1.0  0.0  0.0
-0.15 1.0  0.0
-0.3 -0.132196 1.0
U factor:
3×3 Matrix{Float64}:
-10.0 2.3  4.0
 0.0 2.345 -3.4
 0.0 0.0 -5.24947

```

Since A is not Hermitian, symmetric, triangular, tridiagonal, or bidiagonal, an LU factorization may be the best we can do. Compare with:

```

julia> B = [1.5 2 -4; 2 -1 -3; -4 -3 5]
3×3 Matrix{Float64}:
 1.5  2.0 -4.0
 2.0 -1.0 -3.0
-4.0 -3.0  5.0

julia> factorize(B)
BunchKaufman{Float64, Matrix{Float64}, Vector{Int64}}
D factor:
3×3 Tridiagonal{Float64, Vector{Float64}}:
-1.64286  0.0  .
 0.0     -2.8  0.0
 .       0.0  5.0
U factor:
3×3 UnitUpperTriangular{Float64, Matrix{Float64}}:
 1.0  0.142857 -0.8
 .   1.0     -0.6
 .   .       1.0
permutation:
3-element Vector{Int64}:
 1

```

```
2
3
```

Here, Julia was able to detect that B is in fact symmetric, and used a more appropriate factorization. Often it's possible to write more efficient code for a matrix that is known to have certain properties e.g. it is symmetric, or tridiagonal. Julia provides some special types so that you can "tag" matrices as having these properties. For instance:

```
julia> B = [1.5 2 -4; 2 -1 -3; -4 -3 5]
3×3 Matrix{Float64}:
 1.5  2.0 -4.0
 2.0 -1.0 -3.0
-4.0 -3.0  5.0

julia> sB = Symmetric(B)
3×3 Symmetric{Float64, Matrix{Float64}}:
 1.5  2.0 -4.0
 2.0 -1.0 -3.0
-4.0 -3.0  5.0
```

sB has been tagged as a matrix that's (real) symmetric, so for later operations we might perform on it, such as eigenfactorization or computing matrix-vector products, efficiencies can be found by only referencing half of it. For example:

```
julia> B = [1.5 2 -4; 2 -1 -3; -4 -3 5]
3×3 Matrix{Float64}:
 1.5  2.0 -4.0
 2.0 -1.0 -3.0
-4.0 -3.0  5.0

julia> sB = Symmetric(B)
3×3 Symmetric{Float64, Matrix{Float64}}:
 1.5  2.0 -4.0
 2.0 -1.0 -3.0
-4.0 -3.0  5.0

julia> x = [1; 2; 3]
3-element Vector{Int64}:
 1
 2
 3

julia> sB\x
3-element Vector{Float64}:
-1.7391304347826084
-1.1086956521739126
-1.4565217391304346
```

The `\` operation here performs the linear solution. The left-division operator is pretty powerful and it's easy to write compact, readable code that is flexible enough to solve all sorts of systems of linear equations.

78.1 Special matrices

Matrices with special symmetries and structures arise often in linear algebra and are frequently associated with various matrix factorizations. Julia features a rich collection of special matrix types, which allow for fast computation with specialized routines that are specially developed for particular matrix types.

The following tables summarize the types of special matrices that have been implemented in Julia, as well as whether hooks to various optimized methods for them in LAPACK are available.

| Type | Description |
|-------------------------------------|--|
| Symmetric | Symmetric matrix |
| Hermitian | Hermitian matrix |
| UpperTriangular | Upper triangular matrix |
| UnitUpperTriangular | Upper triangular matrix with unit diagonal |
| LowerTriangular | Lower triangular matrix |
| UnitLowerTriangular | Lower triangular matrix with unit diagonal |
| UpperHessenberg | Upper Hessenberg matrix |
| Tridiagonal | Tridiagonal matrix |
| SymTridiagonal | Symmetric tridiagonal matrix |
| Bidiagonal | Upper/lower bidiagonal matrix |
| Diagonal | Diagonal matrix |
| UniformScaling | Uniform scaling operator |

Elementary operations

| Matrix type | + | - | * | \ | Other functions with optimized methods |
|-------------------------------------|---|---|-----|-----|--|
| Symmetric | | | | MV | inv , sqrt , exp |
| Hermitian | | | | MV | inv , sqrt , exp |
| UpperTriangular | | | MV | MV | inv , det , logdet |
| UnitUpperTriangular | | | MV | MV | inv , det , logdet |
| LowerTriangular | | | MV | MV | inv , det , logdet |
| UnitLowerTriangular | | | MV | MV | inv , det , logdet |
| UpperHessenberg | | | | MM | inv , det |
| SymTridiagonal | M | M | MS | MV | eigmax , eigmin |
| Tridiagonal | M | M | MS | MV | |
| Bidiagonal | M | M | MS | MV | |
| Diagonal | M | M | MV | MV | inv , det , logdet , / |
| UniformScaling | M | M | MVS | MVS | / |

Legend:

| Key | Description |
|------------|---|
| M (matrix) | An optimized method for matrix-matrix operations is available |
| V (vector) | An optimized method for matrix-vector operations is available |
| S (scalar) | An optimized method for matrix-scalar operations is available |

| Matrix type | LAPACK | eigen | eigvals | eigvecs | svd | svdvals |
|-------------------------------------|--------|-------|---------|---------|-----|---------|
| Symmetric | SY | | ARI | | | |
| Hermitian | HE | | ARI | | | |
| UpperTriangular | TR | A | A | A | | |
| UnitUpperTriangular | TR | A | A | A | | |
| LowerTriangular | TR | A | A | A | | |
| UnitLowerTriangular | TR | A | A | A | | |
| SymTridiagonal | ST | A | ARI | AV | | |
| Tridiagonal | GT | | | | | |
| Bidiagonal | BD | | | | A | A |
| Diagonal | DI | | A | | | |

Matrix factorizations

Legend:

| Key | Description | Example |
|--------------|--|---------------------------------|
| A (all) | An optimized method to find all the characteristic values and/or vectors is available | e.g. <code>eigvals(M)</code> |
| R (range) | An optimized method to find the <i>il</i> th through the <i>ih</i> th characteristic values are available | <code>eigvals(M, il, ih)</code> |
| I (interval) | An optimized method to find the characteristic values in the interval [<i>vl</i> , <i>vh</i>] is available | <code>eigvals(M, vl, vh)</code> |
| V (vectors) | An optimized method to find the characteristic vectors corresponding to the characteristic values $x=[x_1, x_2, \dots]$ is available | <code>eigvecs(M, x)</code> |

The uniform scaling operator

A [UniformScaling](#) operator represents a scalar times the identity operator, $\lambda \cdot I$. The identity operator *I* is defined as a constant and is an instance of `UniformScaling`. The size of these operators are generic and match the other matrix in the binary operations `+`, `-`, `*` and `\`. For `A+I` and `A-I` this means that *A* must be square. Multiplication with the identity operator *I* is a noop (except for checking that the scaling factor is one) and therefore almost without overhead.

To see the `UniformScaling` operator in action:

```
julia> U = UniformScaling(2);

julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> a + U
2×2 Matrix{Int64}:
 3  2
 3  6
```

```
julia> a * U
2×2 Matrix{Int64}:
 2  4
 6  8

julia> [a U]
2×4 Matrix{Int64}:
 1  2  2  0
 3  4  0  2

julia> b = [1 2 3; 4 5 6]
2×3 Matrix{Int64}:
 1  2  3
 4  5  6

julia> b - U
ERROR: DimensionMismatch: matrix is not square: dimensions are (2, 3)
Stacktrace:
 [...]
```

If you need to solve many systems of the form $(A + \mu I)x = b$ for the same A and different μ , it might be beneficial to first compute the Hessenberg factorization F of A via the [hessenberg](#) function. Given F , Julia employs an efficient algorithm for $(F + \mu I) \setminus b$ (equivalent to $(A + \mu I)x \setminus b$) and related operations like determinants.

78.2 Matrix factorizations

[Matrix factorizations](#) (a.k.a. [matrix decompositions](#)) compute the factorization of a matrix into a product of matrices, and are one of the central concepts in (numerical) linear algebra.

The following table summarizes the types of matrix factorizations that have been implemented in Julia. Details of their associated methods can be found in the [Standard functions](#) section of the Linear Algebra documentation.

Adjoint and transposes of [Factorization](#) objects are lazily wrapped in [AdjointFactorization](#) and [TransposeFactorization](#) objects, respectively. Generically, transpose of real Factorizations are wrapped as [AdjointFactorization](#).

78.3 Orthogonal matrices (AbstractQ)

Some matrix factorizations generate orthogonal/unitary "matrix" factors. These factorizations include QR-related factorizations obtained from calls to [qr](#), i.e., QR, QRCompactWY and QRPivoted, the Hessenberg factorization obtained from calls to [hessenberg](#), and the LQ factorization obtained from [lq](#). While these orthogonal/unitary factors admit a matrix representation, their internal representation is, for performance and memory reasons, different. Hence, they should be rather viewed as matrix-backed, function-based linear operators. In particular, reading, for instance, a column of its matrix representation requires running "matrix"-vector multiplication code, rather than simply reading out data from memory (possibly filling parts of the vector with structural zeros). Another clear distinction from other, non-triangular matrix types is that the underlying multiplication code allows for in-place modification during multiplication. Furthermore, objects of specific AbstractQ subtypes as those created via [qr](#), [hessenberg](#) and [lq](#) can behave like a square or a rectangular matrix depending on context:

| Type | Description |
|------------------|--|
| BunchKaufman | Bunch-Kaufman factorization |
| Cholesky | Cholesky factorization |
| CholeskyPivoted | Pivoted Cholesky factorization |
| LDLt | LDL(T) factorization |
| LU | LU factorization |
| QR | QR factorization |
| QRCompactWY | Compact WY form of the QR factorization |
| QRPivoted | Pivoted QR factorization |
| LQ | QR factorization of transpose(A) |
| Hessenberg | Hessenberg decomposition |
| Eigen | Spectral decomposition |
| GeneralizedEigen | Generalized spectral decomposition |
| SVD | Singular value decomposition |
| GeneralizedSVD | Generalized SVD |
| Schur | Schur decomposition |
| GeneralizedSchur | Generalized Schur decomposition |

```

julia> using LinearAlgebra

julia> Q = qr(rand(3,2)).Q
3×3 LinearAlgebra.QRCompactWYQ{Float64, Matrix{Float64}, Matrix{Float64}}

julia> Matrix(Q)
3×2 Matrix{Float64}:
-0.320597  0.865734
-0.765834 -0.475694
-0.557419  0.155628

julia> Q*I
3×3 Matrix{Float64}:
-0.320597  0.865734 -0.384346
-0.765834 -0.475694 -0.432683
-0.557419  0.155628  0.815514

julia> Q*ones(2)
3-element Vector{Float64}:
 0.5451367118802273
-1.241527373086654
-0.40179067589600226

julia> Q*ones(3)
3-element Vector{Float64}:
 0.16079054743832022
-1.674209978965636
 0.41372375588835797

julia> ones(1,2) * Q'
1×3 Matrix{Float64}:
 0.545137 -1.24153 -0.401791

```

```
julia> ones(1,3) * Q'
1×3 Matrix{Float64}:
 0.160791 -1.67421 0.413724
```

Due to this distinction from dense or structured matrices, the abstract `AbstractQ` type does not subtype `AbstractMatrix`, but instead has its own type hierarchy. Custom types that subtype `AbstractQ` can rely on generic fallbacks if the following interface is satisfied. For example, for

```
struct MyQ{T} <: LinearAlgebra.AbstractQ{T}
    # required fields
end
```

provide overloads for

```
Base.size(Q::MyQ) # size of corresponding square matrix representation
Base.convert(::Type{AbstractQ{T}}, Q::MyQ) # eltype promotion [optional]
LinearAlgebra.lmul!(Q::MyQ, x::AbstractVecOrMat) # left-multiplication
LinearAlgebra.rmul!(A::AbstractMatrix, Q::MyQ) # right-multiplication
```

If eltype promotion is not of interest, the `convert` method is unnecessary, since by default `convert(::Type{AbstractQ{T}}, Q::AbstractQ{T})` returns `Q` itself. Adjoints of `AbstractQ`-typed objects are lazily wrapped in an `AdjointQ` wrapper type, which requires its own `LinearAlgebra.lmul!` and `LinearAlgebra.rmul!` methods. Given this set of methods, any `Q::MyQ` can be used like a matrix, preferably in a multiplicative context: multiplication via `*` with scalars, vectors and matrices from left and right, obtaining a matrix representation of `Q` via `Matrix(Q)` (or `Q*I`) and indexing into the matrix representation all work. In contrast, addition and subtraction as well as more generally broadcasting over elements in the matrix representation fail because that would be highly inefficient. For such use cases, consider computing the matrix representation up front and cache it for future reuse.

78.4 Standard functions

Linear algebra functions in Julia are largely implemented by calling functions from [LAPACK](#). Sparse matrix factorizations call functions from [SuiteSparse](#). Other sparse solvers are available as Julia packages.

`Base.*` – Method.

```
| *(A::AbstractMatrix, B::AbstractMatrix)
```

Matrix multiplication.

Examples

```
julia> [1 1; 0 1] * [1 0; 1 1]
2×2 Matrix{Int64}:
 2  1
 1  1
```

`Base.\` – Method.

| \ (A, B)

Matrix division using a polyalgorithm. For input matrices A and B, the result X is such that $A \cdot X == B$ when A is square. The solver that is used depends upon the structure of A. If A is upper or lower triangular (or diagonal), no factorization of A is required and the system is solved with either forward or backward substitution. For non-triangular square matrices, an LU factorization is used.

For rectangular A the result is the minimum-norm least squares solution computed by a pivoted QR factorization of A and a rank estimate of A based on the R factor.

When A is sparse, a similar polyalgorithm is used. For indefinite matrices, the LDLt factorization does not use pivoting during the numerical factorization and therefore the procedure can fail even for invertible matrices.

See also: [factorize](#), [pinv](#).

Examples

```
julia> A = [1 0; 1 -2]; B = [32; -4];

julia> X = A \ B
2-element Vector{Float64}:
 32.0
 18.0

julia> A * X == B
true
```

Base.: / - Method.

| A / B

Matrix right-division: A / B is equivalent to $(B' \setminus A')'$ where \setminus is the left-division operator. For square matrices, the result X is such that $A == X \cdot B$.

See also: [rdiv!](#).

Examples

```
julia> A = Float64[1 4 5; 3 9 2]; B = Float64[1 4 2; 3 4 2; 8 7 1];

julia> X = A / B
2×3 Matrix{Float64}:
-0.65   3.75  -1.2
 3.25  -2.75   1.0

julia> isapprox(A, X*B)
true

julia> isapprox(X, A*pinv(B))
true
```

LinearAlgebra.SingularException - Type.

| SingularException

Exception thrown when the input matrix has one or more zero-valued eigenvalues, and is not invertible. A linear solve involving such a matrix cannot be computed. The `info` field indicates the location of (one of) the singular value(s).

`LinearAlgebra.PosDefException` – Type.

```
| PosDefException
```

Exception thrown when the input matrix was not **positive definite**. Some linear algebra functions and factorizations are only applicable to positive definite matrices. The `info` field indicates the location of (one of) the eigenvalue(s) which is (are) less than/equal to 0.

`LinearAlgebra.ZeroPivotException` – Type.

```
| ZeroPivotException <: Exception
```

Exception thrown when a matrix factorization/solve encounters a zero in a pivot (diagonal) position and cannot proceed. This may not mean that the matrix is singular: it may be fruitful to switch to a different factorization such as pivoted LU that can re-order variables to eliminate spurious zero pivots. The `info` field indicates the location of (one of) the zero pivot(s).

`LinearAlgebra.dot` – Function.

```
| dot(x, y)
| x · y
```

Compute the dot product between two vectors. For complex vectors, the first vector is conjugated.

`dot` also works on arbitrary iterable objects, including arrays of any dimension, as long as `dot` is defined on the elements.

`dot` is semantically equivalent to `sum(dot(vx,vy) for (vx,vy) in zip(x, y))`, with the added restriction that the arguments must have equal lengths.

`x · y` (where `·` can be typed by tab-completing `\cdot` in the REPL) is a synonym for `dot(x, y)`.

Examples

```
julia> dot([1; 1], [2; 3])
5

julia> dot([im; im], [1; 1])
0 - 2im

julia> dot(1:5, 2:6)
70

julia> x = fill(2., (5,5));

julia> y = fill(3., (5,5));

julia> dot(x, y)
150.0
```

`LinearAlgebra.dot` – Method.

```
| dot(x, A, y)
```

Compute the generalized dot product `dot(x, A*y)` between two vectors `x` and `y`, without storing the intermediate result of `A*y`. As for the two-argument `dot(_,_)`, this acts recursively. Moreover, for complex vectors, the first vector is conjugated.

Julia 1.4

Three-argument `dot` requires at least Julia 1.4.

Examples

```
julia> dot([1; 1], [1 2; 3 4], [2; 3])
26

julia> dot(1:5, reshape(1:25, 5, 5), 2:6)
4850

julia> dot(1:5, reshape(1:25, 5, 5), 2:6) == dot(1:5, reshape(1:25, 5, 5), 2:6)
true
```

`LinearAlgebra.cross` – Function.

```
| cross(x, y)
|x(x,y)
```

Compute the cross product of two 3-vectors.

Examples

```
julia> a = [0;1;0]
3-element Vector{Int64}:
 0
 1
 0

julia> b = [0;0;1]
3-element Vector{Int64}:
 0
 0
 1

julia> cross(a,b)
3-element Vector{Int64}:
 1
 0
 0
```

`LinearAlgebra.axy!` – Function.

```
| axy!(α, x::AbstractArray, y::AbstractArray)
```

Overwrite `y` with `x * α + y` and return `y`. If `x` and `y` have the same axes, it's equivalent with `y .+= x .* a`.

Examples

```
julia> x = [1; 2; 3];

julia> y = [4; 5; 6];

julia> axpy!(2, x, y)
3-element Vector{Int64}:
 6
 9
12
```

LinearAlgebra.axpy! – Function.

```
| axpy!(α, x::AbstractArray, β, y::AbstractArray)
```

Overwrite y with $x * \alpha + y * \beta$ and return y . If x and y have the same axes, it's equivalent with $y .= x .* \alpha .+ y .* \beta$.

Examples

```
julia> x = [1; 2; 3];

julia> y = [4; 5; 6];

julia> axpby!(2, x, 2, y)
3-element Vector{Int64}:
10
14
18
```

LinearAlgebra.rotate! – Function.

```
| rotate!(x, y, c, s)
```

Overwrite x with $c*x + s*y$ and y with $-\text{conj}(s)*x + c*y$. Returns x and y .

Julia 1.5

rotate! requires at least Julia 1.5.

LinearAlgebra.reflect! – Function.

```
| reflect!(x, y, c, s)
```

Overwrite x with $c*x + s*y$ and y with $\text{conj}(s)*x - c*y$. Returns x and y .

Julia 1.5

reflect! requires at least Julia 1.5.

LinearAlgebra.factorize – Function.

```
| factorize(A)
```

| Properties of A | type of factorization |
|----------------------------|---|
| Positive-definite | Cholesky (see cholesky) |
| Dense Symmetric/Hermitian | Bunch-Kaufman (see bunchkaufman) |
| Sparse Symmetric/Hermitian | LDLt (see ldlt) |
| Triangular | Triangular |
| Diagonal | Diagonal |
| Bidiagonal | Bidiagonal |
| Tridiagonal | LU (see lu) |
| Symmetric real tridiagonal | LDLt (see ldlt) |
| General square | LU (see lu) |
| General non-square | QR (see qr) |

Compute a convenient factorization of A, based upon the type of the input matrix. `factorize` checks A to see if it is symmetric/triangular/etc. if A is passed as a generic matrix. `factorize` checks every element of A to verify/rule out each property. It will short-circuit as soon as it can rule out symmetry/triangular structure. The return value can be reused for efficient solving of multiple systems. For example: `A=factorize(A); x=A\b; y=A\C`.

If `factorize` is called on a Hermitian positive-definite matrix, for instance, then `factorize` will return a Cholesky factorization.

Examples

```
julia> A = Array{Bidiagonal}(fill(1.0, (5, 5)), :U))
5×5 Matrix{Float64}:
 1.0  1.0  0.0  0.0  0.0
 0.0  1.0  1.0  0.0  0.0
 0.0  0.0  1.0  1.0  0.0
 0.0  0.0  0.0  1.0  1.0
 0.0  0.0  0.0  0.0  1.0

julia> factorize(A) # factorize will check to see that A is already factorized
5×5 Bidiagonal{Float64, Vector{Float64}}:
 1.0  1.0  .  .  .
 .  1.0  1.0  .  .
 .  .  1.0  1.0  .
 .  .  .  1.0  1.0
 .  .  .  .  1.0
```

This returns a `5×5 Bidiagonal{Float64}`, which can now be passed to other linear algebra functions (e.g. eigensolvers) which will use specialized methods for Bidiagonal types.

LinearAlgebra.Diagonal - Type.

Diagonal(V::AbstractVector)

Construct a lazy matrix with V as its diagonal.

See also [UniformScaling](#) for the lazy identity matrix I, [diagm](#) to make a dense matrix, and [diag](#) to extract diagonal elements.

Examples

```
julia> d = Diagonal([1, 10, 100])
3×3 Diagonal{Int64, Vector{Int64}}:
 1  .  .
 . 10  .
 .  . 100

julia> diagm([7, 13])
2×2 Matrix{Int64}:
 7  0
 0 13

julia> ans + I
2×2 Matrix{Int64}:
 8  0
 0 14

julia> I(2)
2×2 Diagonal{Bool, Vector{Bool}}:
 1  .
 . 1
```

Note that a one-column matrix is not treated like a vector, but instead calls the method `Diagonal(A::AbstractMatrix)` which extracts 1-element `diag(A)`:

```
julia> A = transpose([7.0 13.0])
2×1 transpose(::Matrix{Float64}) with eltype Float64:
 7.0
13.0

julia> Diagonal(A)
1×1 Diagonal{Float64, Vector{Float64}}:
 7.0
```

```
Diagonal(A::AbstractMatrix)
```

Construct a matrix from the diagonal of A.

Examples

```
julia> A = permutedims(reshape(1:15, 5, 3))
3×5 Matrix{Int64}:
 1  2  3  4  5
 6  7  8  9 10
11 12 13 14 15

julia> Diagonal(A)
3×3 Diagonal{Int64, Vector{Int64}}:
 1  .  .
 . 7  .
 .  . 13

julia> diag(A, 2)
3-element Vector{Int64}:
```

```
| 3
| 9
| 15
```

```
| Diagonal{T}(undef, n)
```

Construct an uninitialized `Diagonal{T}` of length `n`. See `undef`.

`LinearAlgebra.Bidiagonal` – Type.

```
| Bidiagonal{V}(dv::V, ev::V, uplo::Symbol) where V <: AbstractVector
```

Constructs an upper (`uplo=:U`) or lower (`uplo=:L`) bidiagonal matrix using the given diagonal (`dv`) and off-diagonal (`ev`) vectors. The result is of type `Bidiagonal` and provides efficient specialized linear solvers, but may be converted into a regular matrix with `convert(Array, _)` (or `Array(_)` for short). The length of `ev` must be one less than the length of `dv`.

Examples

```
julia> dv = [1, 2, 3, 4]
4-element Vector{Int64}:
 1
 2
 3
 4

julia> ev = [7, 8, 9]
3-element Vector{Int64}:
 7
 8
 9

julia> Bu = Bidiagonal{Int64, Vector{Int64}}(dv, ev, :U) # ev is on the first superdiagonal
4×4 Bidiagonal{Int64, Vector{Int64}}:
 1  7  .  .
 .  2  8  .
 .  .  3  9
 .  .  .  4

julia> Bl = Bidiagonal{Int64, Vector{Int64}}(dv, ev, :L) # ev is on the first subdiagonal
4×4 Bidiagonal{Int64, Vector{Int64}}:
 1  .  .  .
 7  2  .  .
 .  8  3  .
 .  .  9  4
```

```
| Bidiagonal(A, uplo::Symbol)
```

Construct a `Bidiagonal` matrix from the main diagonal of `A` and its first super- (if `uplo=:U`) or sub-diagonal (if `uplo=:L`).

Examples

```

julia> A = [1 1 1 1; 2 2 2 2; 3 3 3 3; 4 4 4 4]
4×4 Matrix{Int64}:
 1  1  1  1
 2  2  2  2
 3  3  3  3
 4  4  4  4

julia> Bidiagonal(A, :U) # contains the main diagonal and first superdiagonal of A
4×4 Bidiagonal{Int64, Vector{Int64}}:
 1  1  .  .
 .  2  2  .
 .  .  3  3
 .  .  .  4

julia> Bidiagonal(A, :L) # contains the main diagonal and first subdiagonal of A
4×4 Bidiagonal{Int64, Vector{Int64}}:
 1  .  .  .
 2  2  .  .
 .  3  3  .
 .  .  4  4

```

LinearAlgebra.SymTridiagonal – Type.

SymTridiagonal(dv::V, ev::V) where V <: **AbstractVector**

Construct a symmetric tridiagonal matrix from the diagonal (dv) and first sub/super-diagonal (ev), respectively. The result is of type SymTridiagonal and provides efficient specialized eigensolvers, but may be converted into a regular matrix with `convert(Array, _)` (or `Array(_)` for short).

For SymTridiagonal block matrices, the elements of dv are symmetrized. The argument ev is interpreted as the superdiagonal. Blocks from the subdiagonal are (materialized) transpose of the corresponding superdiagonal blocks.

Examples

```

julia> dv = [1, 2, 3, 4]
4-element Vector{Int64}:
 1
 2
 3
 4

julia> ev = [7, 8, 9]
3-element Vector{Int64}:
 7
 8
 9

julia> SymTridiagonal(dv, ev)
4×4 SymTridiagonal{Int64, Vector{Int64}}:
 1  7  .  .
 7  2  8  .
 .  8  3  9
 .  .  9  4

```

```
julia> A = SymTridiagonal(fill([1 2; 3 4], 3), fill([1 2; 3 4], 2));
```

```
julia> A[1,1]
2×2 Symmetric{Int64, Matrix{Int64}}:
 1  2
 2  4
```

```
julia> A[1,2]
2×2 Matrix{Int64}:
 1  2
 3  4
```

```
julia> A[2,1]
2×2 Matrix{Int64}:
 1  3
 2  4
```

```
SymTridiagonal(A::AbstractMatrix)
```

Construct a symmetric tridiagonal matrix from the diagonal and first superdiagonal of the symmetric matrix A.

Examples

```
julia> A = [1 2 3; 2 4 5; 3 5 6]
3×3 Matrix{Int64}:
 1  2  3
 2  4  5
 3  5  6
```

```
julia> SymTridiagonal(A)
3×3 SymTridiagonal{Int64, Vector{Int64}}:
 1  2  .
 2  4  5
 .  5  6
```

```
julia> B = reshape([1 2; 2 3], [1 2; 3 4], [1 3; 2 4], [1 2; 2 3]), 2, 2);
```

```
julia> SymTridiagonal(B)
2×2 SymTridiagonal{Matrix{Int64}, Vector{Matrix{Int64}}}:
 [1 2; 2 3]  [1 3; 2 4]
 [1 2; 3 4]  [1 2; 2 3]
```

LinearAlgebra.Tridiagonal – Type.

```
Tridiagonal{dl::V, d::V, du::V} where V <: AbstractVector
```

Construct a tridiagonal matrix from the first subdiagonal, diagonal, and first superdiagonal, respectively. The result is of type `Tridiagonal` and provides efficient specialized linear solvers, but may be converted into a regular matrix with `convert(Array, _)` (or `Array(_)` for short). The lengths of `dl` and `du` must be one less than the length of `d`.

Examples

```
julia> dl = [1, 2, 3];
julia> du = [4, 5, 6];
julia> d = [7, 8, 9, 0];
julia> Tridiagonal(dl, d, du)
4×4 Tridiagonal{Int64, Vector{Int64}}:
 7  4  .  .
 1  8  5  .
 .  2  9  6
 .  .  3  0
```

```
| Tridiagonal(A)
```

Construct a tridiagonal matrix from the first sub-diagonal, diagonal and first super-diagonal of the matrix A.

Examples

```
julia> A = [1 2 3 4; 1 2 3 4; 1 2 3 4; 1 2 3 4]
4×4 Matrix{Int64}:
 1  2  3  4
 1  2  3  4
 1  2  3  4
 1  2  3  4

julia> Tridiagonal(A)
4×4 Tridiagonal{Int64, Vector{Int64}}:
 1  2  .  .
 1  2  3  .
 .  2  3  4
 .  .  3  4
```

LinearAlgebra.Symmetric - Type.

```
| Symmetric(A, uplo=:U)
```

Construct a Symmetric view of the upper (if uplo = :U) or lower (if uplo = :L) triangle of the matrix A.

Symmetric views are mainly useful for real-symmetric matrices, for which specialized algorithms (e.g. for eigenproblems) are enabled for Symmetric types. More generally, see also [Hermitian\(A\)](#) for Hermitian matrices $A == A'$, which is effectively equivalent to Symmetric for real matrices but is also useful for complex matrices. (Whereas complex Symmetric matrices are supported but have few if any specialized algorithms.)

To compute the symmetric part of a real matrix, or more generally the Hermitian part $(A + A') / 2$ of a real or complex matrix A, use [hermitianpart](#).

Examples

```
julia> A = [1 2 3; 4 5 6; 7 8 9]
3×3 Matrix{Int64}:
```

```

1 2 3
4 5 6
7 8 9

julia> Supper = Symmetric(A)
3×3 Symmetric{Int64, Matrix{Int64}}:
 1 2 3
 2 5 6
 3 6 9

julia> Slower = Symmetric(A, :L)
3×3 Symmetric{Int64, Matrix{Int64}}:
 1 4 7
 4 5 8
 7 8 9

julia> hermitianpart(A)
3×3 Hermitian{Float64, Matrix{Float64}}:
 1.0 3.0 5.0
 3.0 5.0 7.0
 5.0 7.0 9.0

```

Note that `Supper` will not be equal to `Slower` unless `A` is itself symmetric (e.g. if `A == transpose(A)`).

`LinearAlgebra.Hermitian` - Type.

```
| Hermitian(A, uplo=:U)
```

Construct a Hermitian view of the upper (if `uplo = :U`) or lower (if `uplo = :L`) triangle of the matrix `A`.

To compute the Hermitian part of `A`, use `hermitianpart`.

Examples

```

julia> A = [1 2+2im 3-3im; 4 5 6-6im; 7 8+8im 9]
3×3 Matrix{Complex{Int64}}:
 1+0im 2+2im 3-3im
 4+0im 5+0im 6-6im
 7+0im 8+8im 9+0im

julia> Hupper = Hermitian(A)
3×3 Hermitian{Complex{Int64}, Matrix{Complex{Int64}}}:
 1+0im 2+2im 3-3im
 2-2im 5+0im 6-6im
 3+3im 6+6im 9+0im

julia> Hlower = Hermitian(A, :L)
3×3 Hermitian{Complex{Int64}, Matrix{Complex{Int64}}}:
 1+0im 4+0im 7+0im
 4+0im 5+0im 8-8im
 7+0im 8+8im 9+0im

julia> hermitianpart(A)

```

```
3×3 Hermitian{ComplexF64, Matrix{ComplexF64}}:
 1.0+0.0im  3.0+1.0im  5.0-1.5im
 3.0-1.0im  5.0+0.0im  7.0-7.0im
 5.0+1.5im  7.0+7.0im  9.0+0.0im
```

Note that `Hupper` will not be equal to `Hlower` unless `A` is itself Hermitian (e.g. if `A == adjoint(A)`).

All non-real parts of the diagonal will be ignored.

```
| Hermitian(fill(complex(1,1), 1, 1)) == fill(1, 1, 1)
```

`LinearAlgebra.LowerTriangular` – Type.

```
| LowerTriangular(A::AbstractMatrix)
```

Construct a `LowerTriangular` view of the matrix `A`.

Examples

```
julia> A = [1.0 2.0 3.0; 4.0 5.0 6.0; 7.0 8.0 9.0]
3×3 Matrix{Float64}:
 1.0  2.0  3.0
 4.0  5.0  6.0
 7.0  8.0  9.0

julia> LowerTriangular(A)
3×3 LowerTriangular{Float64, Matrix{Float64}}:
 1.0  .  .
 4.0  5.0  .
 7.0  8.0  9.0
```

`LinearAlgebra.UpperTriangular` – Type.

```
| UpperTriangular(A::AbstractMatrix)
```

Construct an `UpperTriangular` view of the matrix `A`.

Examples

```
julia> A = [1.0 2.0 3.0; 4.0 5.0 6.0; 7.0 8.0 9.0]
3×3 Matrix{Float64}:
 1.0  2.0  3.0
 4.0  5.0  6.0
 7.0  8.0  9.0

julia> UpperTriangular(A)
3×3 UpperTriangular{Float64, Matrix{Float64}}:
 1.0  2.0  3.0
 .  5.0  6.0
 .  .  9.0
```

`LinearAlgebra.UnitLowerTriangular` – Type.

```
| UnitLowerTriangular(A::AbstractMatrix)
```

Construct a `UnitLowerTriangular` view of the matrix `A`. Such a view has the `oneunit` of the `eltype` of `A` on its diagonal.

Examples

```
julia> A = [1.0 2.0 3.0; 4.0 5.0 6.0; 7.0 8.0 9.0]
3×3 Matrix{Float64}:
 1.0  2.0  3.0
 4.0  5.0  6.0
 7.0  8.0  9.0

julia> UnitLowerTriangular(A)
3×3 UnitLowerTriangular{Float64, Matrix{Float64}}:
 1.0  .  .
 4.0  1.0 .
 7.0  8.0 1.0
```

`LinearAlgebra.UnitUpperTriangular` – Type.

```
UnitUpperTriangular(A::AbstractMatrix)
```

Construct an `UnitUpperTriangular` view of the matrix `A`. Such a view has the `oneunit` of the `eltype` of `A` on its diagonal.

Examples

```
julia> A = [1.0 2.0 3.0; 4.0 5.0 6.0; 7.0 8.0 9.0]
3×3 Matrix{Float64}:
 1.0  2.0  3.0
 4.0  5.0  6.0
 7.0  8.0  9.0

julia> UnitUpperTriangular(A)
3×3 UnitUpperTriangular{Float64, Matrix{Float64}}:
 1.0  2.0  3.0
 .  1.0  6.0
 .  .  1.0
```

`LinearAlgebra.UpperHessenberg` – Type.

```
UpperHessenberg(A::AbstractMatrix)
```

Construct an `UpperHessenberg` view of the matrix `A`. Entries of `A` below the first subdiagonal are ignored.

Julia 1.3

This type was added in Julia 1.3.

Efficient algorithms are implemented for $H \setminus b$, $\det(H)$, and similar.

See also the `hessenberg` function to factor any matrix into a similar upper-Hessenberg matrix.

If `F::Hessenberg` is the factorization object, the unitary matrix can be accessed with `F.Q` and the Hessenberg matrix with `F.H`. When `Q` is extracted, the resulting type is the `HessenbergQ` object, and may be converted to a regular matrix with `convert(Array, _)` (or `Array(_)` for short).

Iterating the decomposition produces the factors $F.Q$ and $F.H$.

Examples

```
julia> A = [1 2 3 4; 5 6 7 8; 9 10 11 12; 13 14 15 16]
4×4 Matrix{Int64}:
 1  2  3  4
 5  6  7  8
 9 10 11 12
13 14 15 16

julia> UpperHessenberg(A)
4×4 UpperHessenberg{Int64, Matrix{Int64}}:
 1  2  3  4
 5  6  7  8
 · 10 11 12
 ·   · 15 16
```

LinearAlgebra.UniformScaling - Type.

```
| UniformScaling{T<:Number}
```

Generically sized uniform scaling operator defined as a scalar times the identity operator, $\lambda * I$. Although without an explicit size, it acts similarly to a matrix in many cases and includes support for some indexing. See also [I](#).

Julia 1.6

Indexing using ranges is available as of Julia 1.6.

Examples

```
julia> J = UniformScaling(2.)
UniformScaling{Float64}
2.0*I

julia> A = [1. 2.; 3. 4.]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> J*A
2×2 Matrix{Float64}:
 2.0  4.0
 6.0  8.0

julia> J[1:2, 1:2]
2×2 Matrix{Float64}:
 2.0  0.0
 0.0  2.0
```

LinearAlgebra.I - Constant.

```
| I
```

An object of type `UniformScaling`, representing an identity matrix of any size.

Examples

```
julia> fill(1, (5,6)) * I == fill(1, (5,6))
true

julia> [1 2im 3; 1im 2 3] * I
2×3 Matrix{Complex{Int64}}:
 1+0im  0+2im  3+0im
 0+1im  2+0im  3+0im
```

`LinearAlgebra.UniformScaling` – Method.

```
(I::UniformScaling)(n::Integer)
```

Construct a Diagonal matrix from a `UniformScaling`.

Julia 1.2

This method is available as of Julia 1.2.

Examples

```
julia> I(3)
3×3 Diagonal{Bool, Vector{Bool}}:
 1  .  .
 .  1  .
 .  .  1

julia> (0.7*I)(3)
3×3 Diagonal{Float64, Vector{Float64}}:
 0.7  .  .
 .  0.7  .
 .  .  0.7
```

`LinearAlgebra.Factorization` – Type.

```
LinearAlgebra.Factorization
```

Abstract type for [matrix factorizations](#) a.k.a. matrix decompositions. See [online documentation](#) for a list of available matrix factorizations.

`LinearAlgebra.LU` – Type.

```
LU <: Factorization
```

Matrix factorization type of the LU factorization of a square matrix A. This is the return type of `lu`, the corresponding matrix factorization function.

The individual components of the factorization `F::LU` can be accessed via [getproperty](#):

Iterating the factorization produces the components `F.L`, `F.U`, and `F.p`.

Examples

| Component | Description |
|-----------|--------------------------------------|
| F.L | L (unit lower triangular) part of LU |
| F.U | U (upper triangular) part of LU |
| F.p | (right) permutation Vector |
| F.P | (right) permutation Matrix |

```
julia> A = [4 3; 6 3]
2×2 Matrix{Int64}:
 4  3
 6  3

julia> F = lu(A)

julia> F.L * F.U == A[F.p, :]
true

julia> l, u, p = lu(A); # destructuring via iteration

julia> l == F.L && u == F.U && p == F.p
true
```

LinearAlgebra.lu - Function.

```
lu(A::AbstractSparseMatrixCSC; check = true, q = nothing, control = get_umfpack_control()) ->
↳ F::UmfpackLU
```

Compute the LU factorization of a sparse matrix A.

For sparse A with real or complex element type, the return type of F is UmfpackLU{Tv, Ti}, with Tv = `Float64` or `ComplexF64` respectively and Ti is an integer type (`Int32` or `Int64`).

When check = true, an error is thrown if the decomposition fails. When check = false, responsibility for checking the decomposition's validity (via `issuccess`) lies with the user.

The permutation q can either be a permutation vector or nothing. If no permutation vector is provided or q is nothing, UMFPACK's default is used. If the permutation is not zero-based, a zero-based copy is made.

The control vector defaults to the package's default configuration for UMFPACK, but can be changed by passing a vector of length UMFPACK_CONTROL. See the UMFPACK manual for possible configurations. The corresponding variables are named JL_UMFPACK_ since Julia uses one-based indexing.

The individual components of the factorization F can be accessed by indexing:

The relation between F and A is

| Component | Description |
|-----------|---------------------------------|
| L | L (lower triangular) part of LU |
| U | U (upper triangular) part of LU |
| p | right permutation Vector |
| q | left permutation Vector |
| Rs | Vector of scaling factors |
| : | (L,U,p,q,Rs) components |

$F.L * F.U == (F.Rs .* A)[F.p, F.q]$

F further supports the following functions:

- `\`
- `det`

See also [lu!](#)

Note

`lu(A::AbstractSparseMatrixCSC)` uses the UMFPACK¹ library that is part of [SuiteSparse](#). As this library only supports sparse matrices with [Float64](#) or `ComplexF64` elements, `lu` converts A into a copy that is of type `SparseMatrixCSC{Float64}` or `SparseMatrixCSC{ComplexF64}` as appropriate.

source

```
| lu(A, pivot = RowMaximum(); check = true) -> F::LU
```

Compute the LU factorization of A.

When `check = true`, an error is thrown if the decomposition fails. When `check = false`, responsibility for checking the decomposition's validity (via [issuccess](#)) lies with the user.

In most cases, if A is a subtype S of `AbstractMatrix{T}` with an element type T supporting `+`, `-`, `*` and `/`, the return type is `LU{T,S{T}}`.

In general, LU factorization involves a permutation of the rows of the matrix (corresponding to the `F.p` output described below), known as "pivoting" (because it corresponds to choosing which row contains the "pivot", the diagonal entry of `F.U`). One of the following pivoting strategies can be selected via the optional `pivot` argument:

- `RowMaximum()` (default): the standard pivoting strategy; the pivot corresponds to the element of maximum absolute value among the remaining, to be factorized rows. This pivoting strategy requires the element type to also support [abs](#) and `<`. (This is generally the only numerically stable option for floating-point matrices.)
- `RowNonZero()`: the pivot corresponds to the first non-zero element among the remaining, to be factorized rows. (This corresponds to the typical choice in hand calculations, and is also useful for more general algebraic number types that support [iszero](#) but not `abs` or `<`.)

¹Davis, Timothy A. (2004b). Algorithm 832: UMFPACK V4.3--an Unsymmetric-Pattern Multifrontal Method. ACM Trans. Math. Softw., 30(2), 196-199. doi:10.1145/992200.992206

- `NoPivot()`: pivoting turned off (may fail if a zero entry is encountered).

The individual components of the factorization `F` can be accessed via [getproperty](#):

| Component | Description |
|------------------|---------------------------------|
| <code>F.L</code> | L (lower triangular) part of LU |
| <code>F.U</code> | U (upper triangular) part of LU |
| <code>F.p</code> | (right) permutation Vector |
| <code>F.P</code> | (right) permutation Matrix |

Iterating the factorization produces the components `F.L`, `F.U`, and `F.p`.

The relationship between `F` and `A` is

$$F.L * F.U == A[F.p, :]$$

`F` further supports the following functions:

| Supported function | LU | LU{T,Tridiagonal{T}} |
|------------------------|----|----------------------|
| <code>/</code> | ✓ | |
| <code>\</code> | ✓ | ✓ |
| <code>inv</code> | ✓ | ✓ |
| <code>det</code> | ✓ | ✓ |
| <code>logdet</code> | ✓ | ✓ |
| <code>logabsdet</code> | ✓ | ✓ |
| <code>size</code> | ✓ | ✓ |

Examples

```
julia> A = [4 3; 6 3]
2×2 Matrix{Int64}:
 4  3
 6  3

julia> F = lu(A)
LU{Float64, Matrix{Float64}, Vector{Int64}}
L factor:
2×2 Matrix{Float64}:
 1.0  0.0
 0.666667  1.0
U factor:
2×2 Matrix{Float64}:
 6.0  3.0
 0.0  1.0

julia> F.L * F.U == A[F.p, :]
true

julia> l, u, p = lu(A); # destructuring via iteration

julia> l == F.L && u == F.U && p == F.p
true
```

`LinearAlgebra.lu!` – Function.

```
lu!(F::UmfpackLU, A::AbstractSparseMatrixCSC; check=true, reuse_symbolic=true, q=nothing) ->
↳ F::UmfpackLU
```

Compute the LU factorization of a sparse matrix `A`, reusing the symbolic factorization of an already existing LU factorization stored in `F`. Unless `reuse_symbolic` is set to `false`, the sparse matrix `A` must have an identical nonzero pattern as the matrix used to create the LU factorization `F`, otherwise an error is thrown. If the size of `A` and `F` differ, all vectors will be resized accordingly.

When `check = true`, an error is thrown if the decomposition fails. When `check = false`, responsibility for checking the decomposition's validity (via `issuccess`) lies with the user.

The permutation `q` can either be a permutation vector or nothing. If no permutation vector is provided or `q` is nothing, UMFPACK's default is used. If the permutation is not zero based, a zero based copy is made.

See also [lu](#)

Note

`lu!(F::UmfpackLU, A::AbstractSparseMatrixCSC)` uses the UMFPACK library that is part of SuiteSparse. As this library only supports sparse matrices with `Float64` or `ComplexF64` elements, `lu!` will automatically convert the types to those set by the LU factorization or `SparseMatrixCSC{ComplexF64}` as appropriate.

Julia 1.5

`lu!` for `UmfpackLU` requires at least Julia 1.5.

Examples

```
julia> A = sparse(Float64[1.0 2.0; 0.0 3.0]);
julia> F = lu(A);
julia> B = sparse(Float64[1.0 1.0; 0.0 1.0]);
julia> lu!(F, B);
julia> F \ ones(2)
2-element Vector{Float64}:
 0.0
 1.0
```

source

```
lu!(A, pivot = RowMaximum(); check = true) -> LU
```

`lu!` is the same as [lu](#), but saves space by overwriting the input `A`, instead of creating a copy. An `InexactError` exception is thrown if the factorization produces a number not representable by the element type of `A`, e.g. for integer types.

Examples

```

julia> A = [4. 3.; 6. 3.]
2×2 Matrix{Float64}:
 4.0  3.0
 6.0  3.0

julia> F = lu!(A)
LU{Float64, Matrix{Float64}, Vector{Int64}}
L factor:
2×2 Matrix{Float64}:
 1.0      0.0
 0.666667  1.0
U factor:
2×2 Matrix{Float64}:
 6.0  3.0
 0.0  1.0

julia> iA = [4 3; 6 3]
2×2 Matrix{Int64}:
 4  3
 6  3

julia> lu!(iA)
ERROR: InexactError: Int64(0.6666666666666666)
Stacktrace:

```

LinearAlgebra.Cholesky - Type.

Cholesky <: **Factorization**

Matrix factorization type of the Cholesky factorization of a dense symmetric/Hermitian positive definite matrix A . This is the return type of `cholesky`, the corresponding matrix factorization function.

The triangular Cholesky factor can be obtained from the factorization $F::\text{Cholesky}$ via $F.L$ and $F.U$, where $A \approx F.U' * F.U \approx F.L * F.L'$.

The following functions are available for Cholesky objects: `size`, `\`, `inv`, `det`, `logdet` and `isposdef`.

Iterating the decomposition produces the components L and U .

Examples

```

julia> A = [4. 12. -16.; 12. 37. -43.; -16. -43. 98.]
3×3 Matrix{Float64}:
 4.0  12.0 -16.0
 12.0  37.0 -43.0
-16.0 -43.0  98.0

julia> C = cholesky(A)
Cholesky{Float64, Matrix{Float64}}
U factor:
3×3 UpperTriangular{Float64, Matrix{Float64}}:
 2.0  6.0 -8.0
  .  1.0  5.0
  .  .   3.0

julia> l, u = C; # destructuring via iteration

julia> l == C.L && u == C.U
true

```

LinearAlgebra.CholeskyPivoted – Type.

CholeskyPivoted

Matrix factorization type of the pivoted Cholesky factorization of a dense symmetric/Hermitian positive semi-definite matrix A . This is the return type of `cholesky(_, ::RowMaximum)`, the corresponding matrix factorization function.

The triangular Cholesky factor can be obtained from the factorization $F::\text{CholeskyPivoted}$ via $F.L$ and $F.U$, and the permutation via $F.p$, where $A[F.p, F.p] \approx U_r' * U_r \approx L_r * L_r'$ with $U_r = F.U[1:F.rank, :]$ and $L_r = F.L[:, 1:F.rank]$, or alternatively $A \approx U_p' * U_p \approx L_p * L_p'$ with $U_p = F.U[1:F.rank, \text{invperm}(F.p)]$ and $L_p = F.L[\text{invperm}(F.p), 1:F.rank]$.

The following functions are available for CholeskyPivoted objects: `size`, `\`, `inv`, `det`, and `rank`.

Iterating the decomposition produces the components L and U .

Examples

```

julia> X = [1.0, 2.0, 3.0, 4.0];

julia> A = X * X';

julia> C = cholesky(A, RowMaximum(), check = false)
CholeskyPivoted{Float64, Matrix{Float64}, Vector{Int64}}
U factor with rank 1:
4×4 UpperTriangular{Float64, Matrix{Float64}}:
 4.0  2.0  3.0  1.0
  .   0.0  6.0  2.0
  .   .   9.0  3.0
  .   .   .   1.0

permutation:
4-element Vector{Int64}:
 4

```

```

2
3
1

julia> C.U[1:C.rank, :]' * C.U[1:C.rank, :] ≈ A[C.p, C.p]
true

julia> l, u = C; # destructuring via iteration

julia> l == C.L && u == C.U
true

```

LinearAlgebra.cholesky – Function.

```
cholesky(A, NoPivot(); check = true) -> Cholesky
```

Compute the Cholesky factorization of a dense symmetric positive definite matrix A and return a [Cholesky](#) factorization. The matrix A can either be a [Symmetric](#) or [Hermitian AbstractMatrix](#) or a perfectly symmetric or Hermitian AbstractMatrix.

The triangular Cholesky factor can be obtained from the factorization F via $F.L$ and $F.U$, where $A \approx F.U' * F.U \approx F.L * F.L'$.

The following functions are available for Cholesky objects: [size](#), [\](#), [inv](#), [det](#), [logdet](#) and [isposdef](#).

If you have a matrix A that is slightly non-Hermitian due to roundoff errors in its construction, wrap it in [Hermitian\(A\)](#) before passing it to [cholesky](#) in order to treat it as perfectly Hermitian.

When `check = true`, an error is thrown if the decomposition fails. When `check = false`, responsibility for checking the decomposition's validity (via [issuccess](#)) lies with the user.

Examples

```

julia> A = [4. 12. -16.; 12. 37. -43.; -16. -43. 98.]
3×3 Matrix{Float64}:
 4.0  12.0 -16.0
 12.0  37.0 -43.0
-16.0 -43.0  98.0

julia> C = cholesky(A)
Cholesky{Float64, Matrix{Float64}}
U factor:
3×3 UpperTriangular{Float64, Matrix{Float64}}:
 2.0  6.0 -8.0
  .  1.0  5.0
  .  .   3.0

julia> C.U
3×3 UpperTriangular{Float64, Matrix{Float64}}:
 2.0  6.0 -8.0
  .  1.0  5.0
  .  .   3.0

julia> C.L
3×3 LowerTriangular{Float64, Matrix{Float64}}:

```

```

2.0  .  .
6.0  1.0 .
-8.0  5.0 3.0

```

```

julia> C.L * C.U == A
true

```

```

cholesky(A, RowMaximum(); tol = 0.0, check = true) -> CholeskyPivoted

```

Compute the pivoted Cholesky factorization of a dense symmetric positive semi-definite matrix A and return a `CholeskyPivoted` factorization. The matrix A can either be a `Symmetric` or `Hermitian AbstractMatrix` or a perfectly symmetric or Hermitian `AbstractMatrix`.

The triangular Cholesky factor can be obtained from the factorization F via $F.L$ and $F.U$, and the permutation via $F.p$, where $A[F.p, F.p] \approx U_r' * U_r \approx L_r * L_r'$ with $U_r = F.U[1:F.rank, :]$ and $L_r = F.L[:, 1:F.rank]$, or alternatively $A \approx U_p' * U_p \approx L_p * L_p'$ with $U_p = F.U[1:F.rank, invperm(F.p)]$ and $L_p = F.L[invperm(F.p), 1:F.rank]$.

The following functions are available for `CholeskyPivoted` objects: `size`, `\`, `inv`, `det`, and `rank`.

The argument `tol` determines the tolerance for determining the rank. For negative values, the tolerance is the machine precision.

If you have a matrix A that is slightly non-Hermitian due to roundoff errors in its construction, wrap it in `Hermitian(A)` before passing it to `cholesky` in order to treat it as perfectly Hermitian.

When `check = true`, an error is thrown if the decomposition fails. When `check = false`, responsibility for checking the decomposition's validity (via `issuccess`) lies with the user.

Examples

```

julia> X = [1.0, 2.0, 3.0, 4.0];

julia> A = X * X';

julia> C = cholesky(A, RowMaximum(), check = false)
CholeskyPivoted{Float64, Matrix{Float64}, Vector{Int64}}
U factor with rank 1:
4×4 UpperTriangular{Float64, Matrix{Float64}}:
 4.0  2.0  3.0  1.0
 .   0.0  6.0  2.0
 .   .   9.0  3.0
 .   .   .   1.0
permutation:
4-element Vector{Int64}:
 4
 2
 3
 1

julia> C.U[1:C.rank, :]' * C.U[1:C.rank, :] ≈ A[C.p, C.p]
true

julia> l, u = C; # destructuring via iteration

```

```
julia> l == C.L && u == C.U
true
```

```
cholesky(A::SparseMatrixCSC; shift = 0.0, check = true, perm = nothing) -> CHOLMOD.Factor
```

Compute the Cholesky factorization of a sparse positive definite matrix A . A must be a `SparseMatrixCSC` or a `Symmetric/Hermitian` view of a `SparseMatrixCSC`. Note that even if A doesn't have the type tag, it must still be symmetric or Hermitian. If `perm` is not given, a fill-reducing permutation is used. $F = \text{cholesky}(A)$ is most frequently used to solve systems of equations with $F \backslash b$, but also the methods `diag`, `det`, and `logdet` are defined for F . You can also extract individual factors from F , using $F.L$. However, since pivoting is on by default, the factorization is internally represented as $A == P' * L * L' * P$ with a permutation matrix P ; using just L without accounting for P will give incorrect answers. To include the effects of permutation, it's typically preferable to extract "combined" factors like $PtL = F.PtL$ (the equivalent of $P' * L$) and $LtP = F.UP$ (the equivalent of $L' * P$).

When `check = true`, an error is thrown if the decomposition fails. When `check = false`, responsibility for checking the decomposition's validity (via `issuccess`) lies with the user.

Setting the optional `shift` keyword argument computes the factorization of $A + \text{shift} * I$ instead of A . If the `perm` argument is provided, it should be a permutation of $1:\text{size}(A,1)$ giving the ordering to use (instead of `CHOLMOD`'s default AMD ordering).

Examples

In the following example, the fill-reducing permutation used is $[3, 2, 1]$. If `perm` is set to $1:3$ to enforce no permutation, the number of nonzero elements in the factor is 6.

```
julia> A = [2 1 1; 1 2 0; 1 0 2]
3×3 Matrix{Int64}:
 2  1  1
 1  2  0
 1  0  2

julia> C = cholesky(sparse(A))
SparseArrays.CHOLMOD.Factor{Float64, Int64}
type:      LLt
method:    simplicial
maxnnz:    5
nnz:       5
success:    true

julia> C.p
3-element Vector{Int64}:
 3
 2
 1

julia> L = sparse(C.L);

julia> Matrix(L)
3×3 Matrix{Float64}:
 1.41421  0.0  0.0
 0.0      1.41421  0.0
 0.707107 0.707107 1.0
```

```

julia> L * L' ≈ A[C.p, C.p]
true

julia> P = sparse(1:3, C.p, ones(3))
3×3 SparseMatrixCSC{Float64, Int64} with 3 stored entries:
 .   .   1.0
 .  1.0   .
 1.0   .   .

julia> P' * L * L' * P ≈ A
true

julia> C = cholesky(sparse(A), perm=1:3)
SparseArrays.CHOLMOD.Factor{Float64, Int64}
type:      LLt
method:    simplicial
maxnnz:    6
nnz:       6
success:   true

julia> L = sparse(C.L);

julia> Matrix(L)
3×3 Matrix{Float64}:
 1.41421   0.0   0.0
 0.707107  1.22474  0.0
 0.707107 -0.408248  1.1547

julia> L * L' ≈ A
true

```

Note

This method uses the CHOLMOD^{2,3} library from [SuiteSparse](#). CHOLMOD only supports double or complex double element types. Input matrices not of those element types will be converted to `SparseMatrixCSC{Float64}` or `SparseMatrixCSC{ComplexF64}` as appropriate.

Many other functions from CHOLMOD are wrapped but not exported from the `Base.SparseArrays.CHOLMOD` module.

[source](#)

LinearAlgebra.lowrankdowndate! – Function.

```
| lowrankdowndate!(C::Cholesky, v::AbstractVector) -> CC::Cholesky
```

Downdate a Cholesky factorization C with the vector v. If $A = C.U'C.U$ then $CC = \text{cholesky}(C.U'C.U - v*v')$ but the computation of CC only uses $O(n^2)$ operations. The input factorization C is updated in place such that on exit $C == CC$. The vector v is destroyed during the computation.

```
| lowrankdowndate!(F::CHOLMOD.Factor, C::AbstractArray)
```

Update an LDLt or LLt Factorization F of A to a factorization of $A - C*C'$.

LLt factorizations are converted to LDLt.

See also [lowrankdowndate](#), [lowrankupdate](#), [lowrankupdate!](#).

[source](#)

LinearAlgebra.LDLt – Type.

```
| LDLt <: Factorization
```

Matrix factorization type of the LDLt factorization of a real [SymTridiagonal](#) matrix S such that $S = L*Diagonal(d)*L'$, where L is a [UnitLowerTriangular](#) matrix and d is a vector. The main use of an

| Component | Description |
|-----------|---|
| F.L | L (unit lower triangular) part of LDLt |
| F.D | D (diagonal) part of LDLt |
| F.Lt | Lt (unit upper triangular) part of LDLt |
| F.d | diagonal values of D as a Vector |

LDLt factorization $F = \text{ldlt}(S)$ is to solve the linear system of equations $Sx = b$ with $F \backslash b$. This is the return type of `ldlt`, the corresponding matrix factorization function.

The individual components of the factorization $F::\text{LDLt}$ can be accessed via `getproperty`:

Examples

```
julia> S = SymTridiagonal([3., 4., 5.], [1., 2.])
3×3 SymTridiagonal{Float64, Vector{Float64}}:
 3.0  1.0   .
 1.0  4.0  2.0
   .  2.0  5.0

julia> F = ldlt(S)
LDLt{Float64, SymTridiagonal{Float64, Vector{Float64}}}
L factor:
3×3 UnitLowerTriangular{Float64, SymTridiagonal{Float64, Vector{Float64}}}:
 1.0   .   .
 0.333333  1.0   .
 0.0      0.545455  1.0
D factor:
3×3 Diagonal{Float64, Vector{Float64}}:
 3.0   .   .
   .  3.66667   .
   .   .  3.90909
```

`LinearAlgebra.ldlt` – Function.

```
| ldlt(S::SymTridiagonal) -> LDLt
```

Compute an LDLt (i.e., LDL^T) factorization of the real symmetric tridiagonal matrix S such that $S = L \cdot \text{Diagonal}(d) \cdot L'$ where L is a unit lower triangular matrix and d is a vector. The main use of an LDLt factorization $F = \text{ldlt}(S)$ is to solve the linear system of equations $Sx = b$ with $F \backslash b$.

See also `bunchkaufman` for a similar, but pivoted, factorization of arbitrary symmetric or Hermitian matrices.

Examples

```
julia> S = SymTridiagonal([3., 4., 5.], [1., 2.])
3×3 SymTridiagonal{Float64, Vector{Float64}}:
 3.0  1.0   .
 1.0  4.0  2.0
   .  2.0  5.0

julia> ldltS = ldlt(S);
```

```
julia> b = [6., 7., 8.];

julia> ldltS \ b
3-element Vector{Float64}:
 1.7906976744186047
 0.627906976744186
 1.3488372093023255

julia> S \ b
3-element Vector{Float64}:
 1.7906976744186047
 0.627906976744186
 1.3488372093023255
```

```
ldlt(A::SparseMatrixCSC; shift = 0.0, check = true, perm=nothing) -> CHOLMOD.Factor
```

Compute the LDL' factorization of a sparse matrix A . A must be a [SparseMatrixCSC](#) or a [Symmetric/Hermitian](#) view of a [SparseMatrixCSC](#). Note that even if A doesn't have the type tag, it must still be symmetric or Hermitian. A fill-reducing permutation is used. $F = \text{ldlt}(A)$ is most frequently used to solve systems of equations $Ax = b$ with $F \backslash b$. The returned factorization object F also supports the methods [diag](#), [det](#), [logdet](#), and [inv](#). You can extract individual factors from F using $F.L$. However, since pivoting is on by default, the factorization is internally represented as $A == P' * L * D * L' * P$ with a permutation matrix P ; using just L without accounting for P will give incorrect answers. To include the effects of permutation, it is typically preferable to extract "combined" factors like $PtL = F.PtL$ (the equivalent of $P' * L$) and $LtP = F.UP$ (the equivalent of $L' * P$). The complete list of supported factors is `:L`, `:PtL`, `:D`, `:UP`, `:U`, `:LD`, `:DU`, `:PtLD`, `:DUP`.

When `check = true`, an error is thrown if the decomposition fails. When `check = false`, responsibility for checking the decomposition's validity (via [issuccess](#)) lies with the user.

Setting the optional `shift` keyword argument computes the factorization of $A + \text{shift} * I$ instead of A . If the `perm` argument is provided, it should be a permutation of $1:\text{size}(A,1)$ giving the ordering to use (instead of CHOLMOD's default AMD ordering).

Note

This method uses the CHOLMOD^{2,3} library from [SuiteSparse](#). CHOLMOD only supports double or complex double element types. Input matrices not of those element types will be converted to `SparseMatrixCSC{Float64}` or `SparseMatrixCSC{ComplexF64}` as appropriate.

Many other functions from CHOLMOD are wrapped but not exported from the `Base.SparseArrays.CHOLMOD` module.

source

`LinearAlgebra.ldlt!` – Function.

```
ldlt!(S::SymTridiagonal) -> LDLt
```

Same as [ldlt](#), but saves space by overwriting the input S , instead of creating a copy.

Examples

```
julia> S = SymTridiagonal([3., 4., 5.], [1., 2.])
3×3 SymTridiagonal{Float64, Vector{Float64}}:
 3.0  1.0   .
 1.0  4.0  2.0
  .   2.0  5.0

julia> ldltS = ldlt!(S);

julia> ldltS === S
false

julia> S
3×3 SymTridiagonal{Float64, Vector{Float64}}:
 3.0      0.333333   .
 0.333333  3.66667  0.545455
  .        0.545455  3.90909
```

```
ldlt!(F::CHOLMOD.Factor, A::SparseMatrixCSC; shift = 0.0, check = true) -> CHOLMOD.Factor
```

Compute the LDL' factorization of A , reusing the symbolic factorization F . A must be a [SparseMatrixCSC](#) or a [Symmetric/Hermitian](#) view of a [SparseMatrixCSC](#). Note that even if A doesn't have the type tag, it must still be symmetric or Hermitian.

See also [ldlt](#).

Note

This method uses the CHOLMOD library from [SuiteSparse](#), which only supports doubles or complex doubles. Input matrices not of those element types will be converted to `SparseMatrixCSC{Float64}` or `SparseMatrixCSC{ComplexF64}` as appropriate.

source

`LinearAlgebra.QR` – Type.

```
QR <: Factorization
```

A QR matrix factorization stored in a packed format, typically obtained from [qr](#). If A is an $m \times n$ matrix, then

$$A = QR$$

where Q is an orthogonal/unitary matrix and R is upper triangular. The matrix Q is stored as a sequence of Householder reflectors v_i and coefficients τ_i where:

$$Q = \prod_{i=1}^{\min(m,n)} (I - \tau_i v_i v_i^T).$$

Iterating the decomposition produces the components Q and R .

The object has two fields:

- `factors` is an $m \times n$ matrix.
 - The upper triangular part contains the elements of R , that is $R = \text{triu}(F.\text{factors})$ for a QR object F .
 - The subdiagonal part contains the reflectors v_i stored in a packed format where v_i is the i th column of the matrix $V = I + \text{tril}(F.\text{factors}, -1)$.
- τ is a vector of length $\min(m, n)$ containing the coefficients αu_i .

`LinearAlgebra.QRCompactWY` – Type.

| `QRCompactWY` <: **Factorization**

A QR matrix factorization stored in a compact blocked format, typically obtained from `qr`. If A is an $m \times n$ matrix, then

$$A = QR$$

where Q is an orthogonal/unitary matrix and R is upper triangular. It is similar to the `QR` format except that the orthogonal/unitary matrix Q is stored in Compact WY format ⁴. For the block size n_b , it is stored as a $m \times n$ lower trapezoidal matrix V and a matrix $T = (T_1 \ T_2 \ \dots \ T_{b-1} \ T'_b)$ composed of $b = \lceil \min(m, n)/n_b \rceil$ upper triangular matrices T_j of size $n_b \times n_b$ ($j = 1, \dots, b-1$) and an upper trapezoidal $n_b \times \min(m, n) - (b-1)n_b$ matrix T'_b ($j = b$) whose upper square part denoted with T_b satisfying

$$Q = \prod_{i=1}^{\min(m, n)} (I - \tau_i v_i v_i^T) = \prod_{j=1}^b (I - V_j T_j V_j^T)$$

such that v_i is the i th column of V , τ_i is the i th element of $[\text{diag}(T_1); \text{diag}(T_2); \dots; \text{diag}(T_b)]$, and $(V_1 \ V_2 \ \dots \ V_b)$ is the left $m \times \min(m, n)$ block of V . When constructed using `qr`, the block size is given by $n_b = \min(m, n, 36)$.

Iterating the decomposition produces the components Q and R .

The object has two fields:

- `factors`, as in the `QR` type, is an $m \times n$ matrix.
 - The upper triangular part contains the elements of R , that is $R = \text{triu}(F.\text{factors})$ for a QR object F .
 - The subdiagonal part contains the reflectors v_i stored in a packed format such that $V = I + \text{tril}(F.\text{factors}, -1)$.
- T is a n_b -by- $\min(m, n)$ matrix as described above. The subdiagonal elements for each triangular matrix T_j are ignored.

Note

This format should not to be confused with the older WY representation ⁵.

LinearAlgebra.QRPivoted - Type.

| QRPivoted <: **Factorization**

A QR matrix factorization with column pivoting in a packed format, typically obtained from `qr`. If A is an $m \times n$ matrix, then

$$AP = QR$$

where P is a permutation matrix, Q is an orthogonal/unitary matrix and R is upper triangular. The matrix Q is stored as a sequence of Householder reflectors:

$$Q = \prod_{i=1}^{\min(m,n)} (I - \tau_i v_i v_i^T).$$

Iterating the decomposition produces the components Q , R , and p .

The object has three fields:

- `factors` is an $m \times n$ matrix.
 - The upper triangular part contains the elements of R , that is $R = \text{triu}(F.\text{factors})$ for a QR object F .
 - The subdiagonal part contains the reflectors v_i stored in a packed format where v_i is the i th column of the matrix $V = I + \text{tril}(F.\text{factors}, -1)$.
- τ is a vector of length $\min(m, n)$ containing the coefficients αu_i .
- `jpvt` is an integer vector of length n corresponding to the permutation P .

LinearAlgebra.qr - Function.

| `qr(A::SparseMatrixCSC; tol=_default_tol(A), ordering=ORDERING_DEFAULT) -> QRSparse`

Compute the QR factorization of a sparse matrix A . Fill-reducing row and column permutations are used such that $F.R = F.Q' * A[F.prow, F.pcol]$. The main application of this type is to solve least squares or underdetermined problems with `\`. The function calls the C library SPQR⁶.

Note

`qr(A::SparseMatrixCSC)` uses the SPQR library that is part of `SuiteSparse`. As this library only supports sparse matrices with `Float64` or `ComplexF64` elements, as of Julia v1.4 `qr` converts A into a copy that is of type `SparseMatrixCSC{Float64}` or `SparseMatrixCSC{ComplexF64}` as appropriate.

⁴R Schreiber and C Van Loan, "A storage-efficient WY representation for products of Householder transformations", SIAM J Sci Stat Comput 10 (1989), 53-57. doi:10.1137/0910005

Examples

```
julia> A = sparse([1,2,3,4], [1,1,2,2], [1.0,1.0,1.0,1.0])
4×2 SparseMatrixCSC{Float64, Int64} with 4 stored entries:
 1.0  .
 1.0  .
  .  1.0
  .  1.0

julia> qr(A)
SparseArrays.SPQR.QRSparse{Float64, Int64}
Q factor:
4×4 SparseArrays.SPQR.QRSparseQ{Float64, Int64}
R factor:
2×2 SparseMatrixCSC{Float64, Int64} with 2 stored entries:
-1.41421  .
 .      -1.41421
Row permutation:
4-element Vector{Int64}:
 1
 3
 4
 2
Column permutation:
2-element Vector{Int64}:
 1
 2
```

source

```
| qr(A, pivot = NoPivot(); blocksize) -> F
```

Compute the QR factorization of the matrix A: an orthogonal (or unitary if A is complex-valued) matrix Q, and an upper triangular matrix R such that

$$A = QR$$

The returned object F stores the factorization in a packed format:

- if `pivot == ColumnNorm()` then F is a `QRPivoted` object,
- otherwise if the element type of A is a BLAS type (`Float32`, `Float64`, `ComplexF32` or `ComplexF64`), then F is a `QRCompactWY` object,
- otherwise F is a `QR` object.

The individual components of the decomposition F can be retrieved via property accessors:

- `F.Q`: the orthogonal/unitary matrix Q

⁶Foster, L. V., & Davis, T. A. (2013). Algorithm 933: Reliable Calculation of Numerical Rank, Null Space Bases, Pseudoinverse Solutions, and Basic Solutions Using SuitesparseQR. ACM Trans. Math. Softw., 40(1). doi:10.1145/2513109.2513116

- $F.R$: the upper triangular matrix R
- $F.p$: the permutation vector of the pivot ([QRPivoted](#) only)
- $F.P$: the permutation matrix of the pivot ([QRPivoted](#) only)

Iterating the decomposition produces the components Q , R , and if extant p .

The following functions are available for the QR objects: [inv](#), [size](#), and [\](#). When A is rectangular, [\](#) will return a least squares solution and if the solution is not unique, the one with smallest norm is returned. When A is not full rank, factorization with (column) pivoting is required to obtain a minimum norm solution.

Multiplication with respect to either full/square or non-full/square Q is allowed, i.e. both $F.Q * F.R$ and $F.Q * A$ are supported. A Q matrix can be converted into a regular matrix with [Matrix](#). This operation returns the "thin" Q factor, i.e., if A is $m \times n$ with $m \geq n$, then [Matrix\(F.Q\)](#) yields an $m \times n$ matrix with orthonormal columns. To retrieve the "full" Q factor, an $m \times m$ orthogonal matrix, use $F.Q * I$ or [collect\(F.Q\)](#). If $m \leq n$, then [Matrix\(F.Q\)](#) yields an $m \times m$ orthogonal matrix.

The block size for QR decomposition can be specified by keyword argument `blocksize :: Integer` when `pivot == NoPivot()` and A is a `StridedMatrix{<:BlasFloat}`. It is ignored when `blocksize > minimum(size(A))`. See [QRCompactWY](#).

Julia 1.4

The `blocksize` keyword argument requires Julia 1.4 or later.

Examples

```
julia> A = [3.0 -6.0; 4.0 -8.0; 0.0 1.0]
3x2 Matrix{Float64}:
 3.0  -6.0
 4.0  -8.0
 0.0   1.0

julia> F = qr(A)
LinearAlgebra.QRCompactWY{Float64, Matrix{Float64}, Matrix{Float64}}
Q factor: 3x3 LinearAlgebra.QRCompactWYQ{Float64, Matrix{Float64}, Matrix{Float64}}
R factor:
2x2 Matrix{Float64}:
-5.0  10.0
 0.0  -1.0

julia> F.Q * F.R == A
true
```

Note

`qr` returns multiple types because LAPACK uses several representations that minimize the memory storage requirements of products of Householder elementary reflectors, so that the Q and R matrices can be stored compactly rather as two separate dense matrices.

`LinearAlgebra.qr!` – Function.

```
| qr!(A, pivot = NoPivot(); blocksize)
```

`qr!` is the same as `qr` when `A` is a subtype of `AbstractMatrix`, but saves space by overwriting the input `A`, instead of creating a copy. An `InexactError` exception is thrown if the factorization produces a number not representable by the element type of `A`, e.g. for integer types.

Julia 1.4

The `blocksize` keyword argument requires Julia 1.4 or later.

Examples

```
julia> a = [1. 2.; 3. 4.]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> qr!(a)
LinearAlgebra.QRCompactWY{Float64, Matrix{Float64}, Matrix{Float64}}
Q factor: 2×2 LinearAlgebra.QRCompactWYQ{Float64, Matrix{Float64}, Matrix{Float64}}
R factor:
2×2 Matrix{Float64}:
-3.16228 -4.42719
 0.0      -0.632456

julia> a = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> qr!(a)
ERROR: InexactError: Int64(3.1622776601683795)
Stacktrace:
[...]
```

LinearAlgebra.LQ – Type.

LQ <: **Factorization**

Matrix factorization type of the LQ factorization of a matrix `A`. The LQ decomposition is the `QR` decomposition of `transpose(A)`. This is the return type of `lq`, the corresponding matrix factorization function.

If `S::LQ` is the factorization object, the lower triangular component can be obtained via `S.L`, and the orthogonal/unitary component via `S.Q`, such that $A \approx S.L * S.Q$.

Iterating the decomposition produces the components `S.L` and `S.Q`.

Examples

```
julia> A = [5. 7.; -2. -4.]
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

julia> S = lq(A)
LQ{Float64, Matrix{Float64}, Vector{Float64}}
```

```

L factor:
2×2 Matrix{Float64}:
 -8.60233  0.0
  4.41741 -0.697486
Q factor: 2×2 LinearAlgebra.LQPackedQ{Float64, Matrix{Float64}, Vector{Float64}}

julia> S.L * S.Q
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

julia> l, q = S; # destructuring via iteration

julia> l == S.L && q == S.Q
true

```

LinearAlgebra.lq – Function.

```
lq(A) -> S::LQ
```

Compute the LQ decomposition of A . The decomposition's lower triangular component can be obtained from the `LQ` object S via $S.L$, and the orthogonal/unitary component via $S.Q$, such that $A \approx S.L * S.Q$.

Iterating the decomposition produces the components $S.L$ and $S.Q$.

The LQ decomposition is the QR decomposition of $\text{transpose}(A)$, and it is useful in order to compute the minimum-norm solution $\text{lq}(A) \setminus b$ to an underdetermined system of equations (A has more columns than rows, but has full row rank).

Examples

```

julia> A = [5. 7.; -2. -4.]
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

julia> S = lq(A)
LQ{Float64, Matrix{Float64}, Vector{Float64}}
L factor:
2×2 Matrix{Float64}:
 -8.60233  0.0
  4.41741 -0.697486
Q factor: 2×2 LinearAlgebra.LQPackedQ{Float64, Matrix{Float64}, Vector{Float64}}

julia> S.L * S.Q
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

julia> l, q = S; # destructuring via iteration

julia> l == S.L && q == S.Q
true

```

LinearAlgebra.lq! – Function.

```
| lq!(A) -> LQ
```

Compute the [LQ](#) factorization of A, using the input matrix as a workspace. See also [lq](#).

`LinearAlgebra.BunchKaufman` – Type.

```
| BunchKaufman <: Factorization
```

Matrix factorization type of the Bunch-Kaufman factorization of a symmetric or Hermitian matrix A as $P'UDU'P$ or $P'LDL'P$, depending on whether the upper (the default) or the lower triangle is stored in A. If A is complex symmetric then U' and L' denote the unconjugated transposes, i.e. `transpose(U)` and `transpose(L)`, respectively. This is the return type of [bunchkaufman](#), the corresponding matrix factorization function.

If `S::BunchKaufman` is the factorization object, the components can be obtained via `S.D`, `S.U` or `S.L` as appropriate given `S.uplo`, and `S.p`.

Iterating the decomposition produces the components `S.D`, `S.U` or `S.L` as appropriate given `S.uplo`, and `S.p`.

Examples

```
julia> A = [1 2; 2 3]
2×2 Matrix{Int64}:
 1  2
 2  3

julia> S = bunchkaufman(A) # A gets wrapped internally by Symmetric(A)
BunchKaufman{Float64, Matrix{Float64}, Vector{Int64}}
D factor:
2×2 Tridiagonal{Float64, Vector{Float64}}:
-0.333333  0.0
 0.0      3.0
U factor:
2×2 UnitUpperTriangular{Float64, Matrix{Float64}}:
 1.0  0.666667
  .   1.0
permutation:
2-element Vector{Int64}:
 1
 2

julia> d, u, p = S; # destructuring via iteration

julia> d == S.D && u == S.U && p == S.p
true

julia> S = bunchkaufman(Symmetric(A, :L))
BunchKaufman{Float64, Matrix{Float64}, Vector{Int64}}
D factor:
2×2 Tridiagonal{Float64, Vector{Float64}}:
 3.0  0.0
 0.0 -0.333333
L factor:
```

```

2×2 UnitLowerTriangular{Float64, Matrix{Float64}}:
 1.0      .
 0.666667  1.0
permutation:
2-element Vector{Int64}:
 2
 1

```

`LinearAlgebra.bunchkaufman` – Function.

```
bunchkaufman(A, rook::Bool=false; check = true) -> S::BunchKaufman
```

Compute the Bunch-Kaufman⁷ factorization of a symmetric or Hermitian matrix A as $P' * U * D * U' * P$ or $P' * L * D * L' * P$, depending on which triangle is stored in A , and return a `BunchKaufman` object. Note that if A is complex symmetric then U' and L' denote the unconjugated transposes, i.e. `transpose(U)` and `transpose(L)`.

Iterating the decomposition produces the components $S.D$, $S.U$ or $S.L$ as appropriate given `S.uplo`, and `S.p`.

If `rook` is `true`, rook pivoting is used. If `rook` is `false`, rook pivoting is not used.

When `check = true`, an error is thrown if the decomposition fails. When `check = false`, responsibility for checking the decomposition's validity (via `issuccess`) lies with the user.

The following functions are available for `BunchKaufman` objects: `size`, `\`, `inv`, `issymmetric`, `ishermitian`, `getindex`.

Examples

```

julia> A = [1 2; 2 3]
2×2 Matrix{Int64}:
 1  2
 2  3

julia> S = bunchkaufman(A) # A gets wrapped internally by Symmetric(A)
BunchKaufman{Float64, Matrix{Float64}, Vector{Int64}}
D factor:
2×2 Tridiagonal{Float64, Vector{Float64}}:
 -0.333333  0.0
  0.0      3.0
U factor:
2×2 UnitUpperTriangular{Float64, Matrix{Float64}}:
 1.0  0.666667
 .   1.0
permutation:
2-element Vector{Int64}:
 1
 2

julia> d, u, p = S; # destructuring via iteration

```

⁷J R Bunch and L Kaufman, Some stable methods for calculating inertia and solving symmetric linear systems, *Mathematics of Computation* 31:137 (1977), 163-179. [url](#).

```

julia> d == S.D && u == S.U && p == S.p
true

julia> S.U*S.D*S.U' - S.P*A*S.P'
2×2 Matrix{Float64}:
 0.0  0.0
 0.0  0.0

julia> S = bunchkaufman(Symmetric(A, :L))
BunchKaufman{Float64, Matrix{Float64}, Vector{Int64}}
D factor:
2×2 Tridiagonal{Float64, Vector{Float64}}:
 3.0  0.0
 0.0 -0.333333
L factor:
2×2 UnitLowerTriangular{Float64, Matrix{Float64}}:
 1.0      .
 0.666667  1.0
permutation:
2-element Vector{Int64}:
 2
 1

julia> S.L*S.D*S.L' - A[S.p, S.p]
2×2 Matrix{Float64}:
 0.0  0.0
 0.0  0.0

```

LinearAlgebra.bunchkaufman! – Function.

```
bunchkaufman!(A, rook::Bool=false; check = true) -> BunchKaufman
```

bunchkaufman! is the same as `bunchkaufman`, but saves space by overwriting the input A, instead of creating a copy.

LinearAlgebra.Eigen – Type.

```
Eigen <: Factorization
```

Matrix factorization type of the eigenvalue/spectral decomposition of a square matrix A. This is the return type of `eigen`, the corresponding matrix factorization function.

If `F::Eigen` is the factorization object, the eigenvalues can be obtained via `F.values` and the eigenvectors as the columns of the matrix `F.vectors`. (The kth eigenvector can be obtained from the slice `F.vectors[:, k]`.)

Iterating the decomposition produces the components `F.values` and `F.vectors`.

Examples

```

julia> F = eigen([1.0 0.0 0.0; 0.0 3.0 0.0; 0.0 0.0 18.0])
Eigen{Float64, Float64, Matrix{Float64}, Vector{Float64}}
values:

```

```

3-element Vector{Float64}:
 1.0
 3.0
18.0
vectors:
3×3 Matrix{Float64}:
 1.0  0.0  0.0
 0.0  1.0  0.0
 0.0  0.0  1.0

julia> F.values
3-element Vector{Float64}:
 1.0
 3.0
18.0

julia> F.vectors
3×3 Matrix{Float64}:
 1.0  0.0  0.0
 0.0  1.0  0.0
 0.0  0.0  1.0

julia> vals, vecs = F; # destructuring via iteration

julia> vals == F.values && vecs == F.vectors
true

```

LinearAlgebra.GeneralizedEigen – Type.

GeneralizedEigen <: **Factorization**

Matrix factorization type of the generalized eigenvalue/spectral decomposition of A and B. This is the return type of `eigen`, the corresponding matrix factorization function, when called with two matrix arguments.

If `F::GeneralizedEigen` is the factorization object, the eigenvalues can be obtained via `F.values` and the eigenvectors as the columns of the matrix `F.vectors`. (The *k*th eigenvector can be obtained from the slice `F.vectors[:, k]`.)

Iterating the decomposition produces the components `F.values` and `F.vectors`.

Examples

```

julia> A = [1 0; 0 -1]
2×2 Matrix{Int64}:
 1  0
 0 -1

julia> B = [0 1; 1 0]
2×2 Matrix{Int64}:
 0  1
 1  0

julia> F = eigen(A, B)

```

```

GeneralizedEigen{ComplexF64, ComplexF64, Matrix{ComplexF64}, Vector{ComplexF64}}
values:
2-element Vector{ComplexF64}:
 0.0 - 1.0im
 0.0 + 1.0im
vectors:
2×2 Matrix{ComplexF64}:
 0.0+1.0im  0.0-1.0im
 -1.0+0.0im -1.0-0.0im

julia> F.values
2-element Vector{ComplexF64}:
 0.0 - 1.0im
 0.0 + 1.0im

julia> F.vectors
2×2 Matrix{ComplexF64}:
 0.0+1.0im  0.0-1.0im

julia> vals, vecs = F; # destructuring via iteration

julia> vals == F.values && vecs == F.vectors
true

```

`LinearAlgebra.eigvals` – Function.

```
eigvals(A; permute::Bool=true, scale::Bool=true, sortby) -> values
```

Return the eigenvalues of A.

For general non-symmetric matrices it is possible to specify how the matrix is balanced before the eigenvalue calculation. The `permute`, `scale`, and `sortby` keywords are the same as for [eigen](#).

Examples

```

julia> diag_matrix = [1 0; 0 4]
2×2 Matrix{Int64}:
 1  0
 0  4

julia> eigvals(diag_matrix)
2-element Vector{Float64}:
 1.0
 4.0

```

For a scalar input, `eigvals` will return a scalar.

Example

```
julia> eigvals(-2)
-2
```

```
eigvals(A, B) -> values
```

Compute the generalized eigenvalues of A and B.

Examples

```
julia> A = [1 0; 0 -1]
2×2 Matrix{Int64}:
 1  0
 0 -1

julia> B = [0 1; 1 0]
2×2 Matrix{Int64}:
 0  1
 1  0

julia> eigvals(A,B)
2-element Vector{ComplexF64}:
 0.0 - 1.0im
 0.0 + 1.0im
```

```
| eigvals(A::Union{SymTridiagonal, Hermitian, Symmetric}, irange::UnitRange) -> values
```

Return the eigenvalues of A. It is possible to calculate only a subset of the eigenvalues by specifying a [UnitRange](#) `irange` covering indices of the sorted eigenvalues, e.g. the 2nd to 8th eigenvalues.

Examples

```
julia> A = SymTridiagonal([1.; 2.; 1.], [2.; 3.])
3×3 SymTridiagonal{Float64, Vector{Float64}}:
 1.0  2.0  .
 2.0  2.0  3.0
 .    3.0  1.0

julia> eigvals(A, 2:2)
1-element Vector{Float64}:
 0.9999999999999996

julia> eigvals(A)
3-element Vector{Float64}:
 -2.1400549446402604
  1.0000000000000002
  5.140054944640259
```

```
| eigvals(A::Union{SymTridiagonal, Hermitian, Symmetric}, vl::Real, vu::Real) -> values
```

Return the eigenvalues of A. It is possible to calculate only a subset of the eigenvalues by specifying a pair `vl` and `vu` for the lower and upper boundaries of the eigenvalues.

Examples

```
julia> A = SymTridiagonal([1.; 2.; 1.], [2.; 3.])
3×3 SymTridiagonal{Float64, Vector{Float64}}:
 1.0  2.0  .
 2.0  2.0  3.0
 .    3.0  1.0
```

```
julia> eigvals(A, -1, 2)
1-element Vector{Float64}:
 1.0000000000000009

julia> eigvals(A)
3-element Vector{Float64}:
-2.1400549446402604
 1.0000000000000002
 5.140054944640259
```

`LinearAlgebra.eigvals!` – Function.

```
eigvals!(A; permute::Bool=true, scale::Bool=true, sortby) -> values
```

Same as `eigvals`, but saves space by overwriting the input `A`, instead of creating a copy. The `permute`, `scale`, and `sortby` keywords are the same as for `eigen`.

Note

The input matrix `A` will not contain its eigenvalues after `eigvals!` is called on it - `A` is used as a workspace.

Examples

```
julia> A = [1. 2.; 3. 4.]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> eigvals!(A)
2-element Vector{Float64}:
-0.3722813232690143
 5.372281323269014

julia> A
2×2 Matrix{Float64}:
-0.372281 -1.0
 0.0      5.37228
```

```
eigvals!(A, B; sortby) -> values
```

Same as `eigvals`, but saves space by overwriting the input `A` (and `B`), instead of creating copies.

Note

The input matrices `A` and `B` will not contain their eigenvalues after `eigvals!` is called. They are used as workspaces.

Examples

```
julia> A = [1. 0.; 0. -1.]
2×2 Matrix{Float64}:
 1.0  0.0
```

```

0.0  -1.0

julia> B = [0. 1.; 1. 0.]
2×2 Matrix{Float64}:
 0.0  1.0
 1.0  0.0

julia> eigvals!(A, B)
2-element Vector{ComplexF64}:
 0.0 - 1.0im
 0.0 + 1.0im

julia> A
2×2 Matrix{Float64}:
-0.0  -1.0
 1.0   -0.0

julia> B
2×2 Matrix{Float64}:
 1.0  0.0
 0.0  1.0

```

```
eigvals!(A::Union{SymTridiagonal, Hermitian, Symmetric}, irange::UnitRange) -> values
```

Same as `eigvals`, but saves space by overwriting the input A, instead of creating a copy. `irange` is a range of eigenvalue indices to search for - for instance, the 2nd to 8th eigenvalues.

```
eigvals!(A::Union{SymTridiagonal, Hermitian, Symmetric}, vl::Real, vu::Real) -> values
```

Same as `eigvals`, but saves space by overwriting the input A, instead of creating a copy. `vl` is the lower bound of the interval to search for eigenvalues, and `vu` is the upper bound.

`LinearAlgebra.eigmax` - Function.

```
eigmax(A; permute::Bool=true, scale::Bool=true)
```

Return the largest eigenvalue of A. The option `permute=true` permutes the matrix to become closer to upper triangular, and `scale=true` scales the matrix by its diagonal elements to make rows and columns more equal in norm. Note that if the eigenvalues of A are complex, this method will fail, since complex numbers cannot be sorted.

Examples

```

julia> A = [0 im; -im 0]
2×2 Matrix{Complex{Int64}}:
 0+0im  0+1im
 0-1im  0+0im

julia> eigmax(A)
1.0

julia> A = [0 im; -1 0]
2×2 Matrix{Complex{Int64}}:
 0+0im  0+1im

```

```

-1+0im  0+0im

julia> eigmax(A)
ERROR: DomainError with Complex{Int64}[0+0im 0+1im; -1+0im 0+0im]:
`A` cannot have complex eigenvalues.
Stacktrace:
[...]

```

LinearAlgebra.eigmin – Function.

```

eigmin(A; permute::Bool=true, scale::Bool=true)

```

Return the smallest eigenvalue of A. The option permute=true permutes the matrix to become closer to upper triangular, and scale=true scales the matrix by its diagonal elements to make rows and columns more equal in norm. Note that if the eigenvalues of A are complex, this method will fail, since complex numbers cannot be sorted.

Examples

```

julia> A = [0 im; -im 0]
2×2 Matrix{Complex{Int64}}:
 0+0im  0+1im
 0-1im  0+0im

julia> eigmin(A)
-1.0

julia> A = [0 im; -1 0]
2×2 Matrix{Complex{Int64}}:
 0+0im  0+1im
-1+0im  0+0im

julia> eigmin(A)
ERROR: DomainError with Complex{Int64}[0+0im 0+1im; -1+0im 0+0im]:
`A` cannot have complex eigenvalues.
Stacktrace:
[...]

```

LinearAlgebra.eigvecs – Function.

```

eigvecs(A::SymTridiagonal[, eigvals]) -> Matrix

```

Return a matrix M whose columns are the eigenvectors of A. (The kth eigenvector can be obtained from the slice M[:, k].)

If the optional vector of eigenvalues eigvals is specified, eigvecs returns the specific corresponding eigenvectors.

Examples

```

julia> A = SymTridiagonal([1.; 2.; 1.], [2.; 3.])
3×3 SymTridiagonal{Float64, Vector{Float64}}:
 1.0  2.0   .
 2.0  2.0  3.0

```

```
· 3.0 1.0

```
-1.0+0.0im -1.0-0.0im
```

LinearAlgebra.eigen – Function.

```
| eigen(A; permute::Bool=true, scale::Bool=true, sortby) -> Eigen
```

Compute the eigenvalue decomposition of A, returning an [Eigen](#) factorization object F which contains the eigenvalues in F.values and the eigenvectors in the columns of the matrix F.vectors. This corresponds to solving an eigenvalue problem of the form $Ax = \lambda x$, where A is a matrix, x is an eigenvector, and λ is an eigenvalue. (The kth eigenvector can be obtained from the slice F.vectors[:, k].)

Iterating the decomposition produces the components F.values and F.vectors.

The following functions are available for Eigen objects: [inv](#), [det](#), and [isposdef](#).

For general nonsymmetric matrices it is possible to specify how the matrix is balanced before the eigenvector calculation. The option permute=true permutes the matrix to become closer to upper triangular, and scale=true scales the matrix by its diagonal elements to make rows and columns more equal in norm. The default is true for both options.

By default, the eigenvalues and vectors are sorted lexicographically by $(\text{real}(\lambda), \text{imag}(\lambda))$. A different comparison function $\text{by}(\lambda)$ can be passed to sortby, or you can pass sortby=nothing to leave the eigenvalues in an arbitrary order. Some special matrix types (e.g. [Diagonal](#) or [SymTridiagonal](#)) may implement their own sorting convention and not accept a sortby keyword.

Examples

```
julia> F = eigen([1.0 0.0 0.0; 0.0 3.0 0.0; 0.0 0.0 18.0])
Eigen{Float64, Float64, Matrix{Float64}, Vector{Float64}}
values:
3-element Vector{Float64}:
 1.0
 3.0
18.0
vectors:
3×3 Matrix{Float64}:
 1.0  0.0  0.0
 0.0  1.0  0.0
 0.0  0.0  1.0

julia> F.values
3-element Vector{Float64}:
 1.0
 3.0
18.0

julia> F.vectors
3×3 Matrix{Float64}:
 1.0  0.0  0.0
 0.0  1.0  0.0
 0.0  0.0  1.0

julia> vals, vecs = F; # destructuring via iteration

julia> vals == F.values && vecs == F.vectors
true
```

```
| eigen(A, B; sortby) -> GeneralizedEigen
```

Compute the generalized eigenvalue decomposition of A and B , returning a [GeneralizedEigen](#) factorization object F which contains the generalized eigenvalues in $F.values$ and the generalized eigenvectors in the columns of the matrix $F.vectors$. This corresponds to solving a generalized eigenvalue problem of the form $Ax = \lambda Bx$, where A , B are matrices, x is an eigenvector, and λ is an eigenvalue. (The k th generalized eigenvector can be obtained from the slice $F.vectors[:, k]$.)

Iterating the decomposition produces the components $F.values$ and $F.vectors$.

By default, the eigenvalues and vectors are sorted lexicographically by $(\text{real}(\lambda), \text{imag}(\lambda))$. A different comparison function $\text{by}(\lambda)$ can be passed to `sortby`, or you can pass `sortby=nothing` to leave the eigenvalues in an arbitrary order.

Examples

```
julia> A = [1 0; 0 -1]
2×2 Matrix{Int64}:
 1  0
 0 -1

julia> B = [0 1; 1 0]
2×2 Matrix{Int64}:
 0  1
 1  0

julia> F = eigen(A, B);

julia> F.values
2-element Vector{ComplexF64}:
 0.0 - 1.0im
 0.0 + 1.0im

julia> F.vectors
2×2 Matrix{ComplexF64}:
 0.0+1.0im  0.0-1.0im
-1.0+0.0im -1.0-0.0im

julia> vals, vecs = F; # destructuring via iteration

julia> vals == F.values && vecs == F.vectors
true
```

```
| eigen(A::Union{SymTridiagonal, Hermitian, Symmetric}, irange::UnitRange) -> Eigen
```

Compute the eigenvalue decomposition of A , returning an [Eigen](#) factorization object F which contains the eigenvalues in $F.values$ and the eigenvectors in the columns of the matrix $F.vectors$. (The k th eigenvector can be obtained from the slice $F.vectors[:, k]$.)

Iterating the decomposition produces the components $F.values$ and $F.vectors$.

The following functions are available for Eigen objects: [inv](#), [det](#), and [isposdef](#).

The [UnitRange](#) `irange` specifies indices of the sorted eigenvalues to search for.

Note

If `irange` is not `1:n`, where `n` is the dimension of `A`, then the returned factorization will be a truncated factorization.

```
| eigen(A::Union{SymTridiagonal, Hermitian, Symmetric}, vl::Real, vu::Real) -> Eigen
```

Compute the eigenvalue decomposition of `A`, returning an [Eigen](#) factorization object `F` which contains the eigenvalues in `F.values` and the eigenvectors in the columns of the matrix `F.vectors`. (The `k`th eigenvector can be obtained from the slice `F.vectors[:, k]`.)

Iterating the decomposition produces the components `F.values` and `F.vectors`.

The following functions are available for Eigen objects: [inv](#), [det](#), and [isposdef](#).

`vl` is the lower bound of the window of eigenvalues to search for, and `vu` is the upper bound.

Note

If `[vl, vu]` does not contain all eigenvalues of `A`, then the returned factorization will be a truncated factorization.

`LinearAlgebra.eigen!` – Function.

```
| eigen!(A; permute, scale, sortby)
| eigen!(A, B; sortby)
```

Same as [eigen](#), but saves space by overwriting the input `A` (and `B`), instead of creating a copy.

`LinearAlgebra.Hessenberg` – Type.

```
| Hessenberg <: Factorization
```

A Hessenberg object represents the Hessenberg factorization QHQ' of a square matrix, or a shift $Q(H+\mu I)Q'$ thereof, which is produced by the [hessenberg](#) function.

`LinearAlgebra.hessenberg` – Function.

```
| hessenberg(A) -> Hessenberg
```

Compute the Hessenberg decomposition of `A` and return a Hessenberg object. If `F` is the factorization object, the unitary matrix can be accessed with `F.Q` (of type `LinearAlgebra.HessenbergQ`) and the Hessenberg matrix with `F.H` (of type [UpperHessenberg](#)), either of which may be converted to a regular matrix with `Matrix(F.H)` or `Matrix(F.Q)`.

If `A` is [Hermitian](#) or real-[Symmetric](#), then the Hessenberg decomposition produces a real-symmetric tridiagonal matrix and `F.H` is of type [SymTridiagonal](#).

Note that the shifted factorization $A+\mu I = Q(H+\mu I)Q'$ can be constructed efficiently by $F + \mu I$ using the [UniformScaling](#) object `I`, which creates a new Hessenberg object with shared storage and a modified shift. The shift of a given `F` is obtained by `F.μ`. This is useful because multiple shifted solves $(F + \mu I) \setminus b$ (for different μ and/or b) can be performed efficiently once `F` is created.

Iterating the decomposition produces the factors `F.Q`, `F.H`, `F.μ`.

Examples

```

julia> A = [4. 9. 7.; 4. 4. 1.; 4. 3. 2.]
3×3 Matrix{Float64}:
 4.0  9.0  7.0
 4.0  4.0  1.0
 4.0  3.0  2.0

julia> F = hessenberg(A)
Hessenberg{Float64, UpperHessenberg{Float64, Matrix{Float64}}, Matrix{Float64},
↪ Vector{Float64}, Bool}
Q factor: 3×3 LinearAlgebra.HessenbergQ{Float64, Matrix{Float64}, Vector{Float64}, false}
H factor:
3×3 UpperHessenberg{Float64, Matrix{Float64}}:
 4.0      -11.3137      -1.41421
-5.65685    5.0         2.0
 .          -8.88178e-16  1.0

julia> F.Q * F.H * F.Q'
3×3 Matrix{Float64}:
 4.0  9.0  7.0
 4.0  4.0  1.0
 4.0  3.0  2.0

julia> q, h = F; # destructuring via iteration

julia> q == F.Q && h == F.H
true

```

LinearAlgebra.hessenberg! – Function.

```
hessenberg!(A) -> Hessenberg
```

hessenberg! is the same as [hessenberg](#), but saves space by overwriting the input A, instead of creating a copy.

LinearAlgebra.Schur – Type.

```
Schur <: Factorization
```

Matrix factorization type of the Schur factorization of a matrix A. This is the return type of [schur\(_\)](#), the corresponding matrix factorization function.

If `F::Schur` is the factorization object, the (quasi) triangular Schur factor can be obtained via either `F.Schur` or `F.T` and the orthogonal/unitary Schur vectors via `F.vectors` or `F.Z` such that $A = F.vectors * F.Schur * F.vectors'$. The eigenvalues of A can be obtained with `F.values`.

Iterating the decomposition produces the components `F.T`, `F.Z`, and `F.values`.

Examples

```

julia> A = [5. 7.; -2. -4.]
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

```

```

julia> F = schur(A)
Schur{Float64, Matrix{Float64}, Vector{Float64}}
T factor:
2×2 Matrix{Float64}:
 3.0  9.0
 0.0 -2.0
Z factor:
2×2 Matrix{Float64}:
 0.961524  0.274721
-0.274721  0.961524
eigenvalues:
2-element Vector{Float64}:
 3.0
-2.0

julia> F.vectors * F.Schur * F.vectors'
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

julia> t, z, vals = F; # destructuring via iteration

julia> t == F.T && z == F.Z && vals == F.values
true

```

LinearAlgebra.GeneralizedSchur – Type.

| GeneralizedSchur <: **Factorization**

Matrix factorization type of the generalized Schur factorization of two matrices A and B. This is the return type of `schur(,)`, the corresponding matrix factorization function.

If `F::GeneralizedSchur` is the factorization object, the (quasi) triangular Schur factors can be obtained via `F.S` and `F.T`, the left unitary/orthogonal Schur vectors via `F.left` or `F.Q`, and the right unitary/orthogonal Schur vectors can be obtained with `F.right` or `F.Z` such that $A = F.left * F.S * F.right'$ and $B = F.left * F.T * F.right'$. The generalized eigenvalues of A and B can be obtained with `F.α./F.β`.

Iterating the decomposition produces the components `F.S`, `F.T`, `F.Q`, `F.Z`, `F.α`, and `F.β`.

LinearAlgebra.schur – Function.

| `schur(A) -> F::Schur`

Computes the Schur factorization of the matrix A. The (quasi) triangular Schur factor can be obtained from the Schur object F with either `F.Schur` or `F.T` and the orthogonal/unitary Schur vectors can be obtained with `F.vectors` or `F.Z` such that $A = F.vectors * F.Schur * F.vectors'$. The eigenvalues of A can be obtained with `F.values`.

For real A, the Schur factorization is "quasitriangular", which means that it is upper-triangular except with 2×2 diagonal blocks for any conjugate pair of complex eigenvalues; this allows the factorization to be purely real even when there are complex eigenvalues. To obtain the (complex) purely upper-triangular Schur factorization from a real quasitriangular factorization, you can use `Schur{Complex}(schur(A))`.

Iterating the decomposition produces the components `F.T`, `F.Z`, and `F.values`.

Examples

```

julia> A = [5. 7.; -2. -4.]
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

julia> F = schur(A)
Schur{Float64, Matrix{Float64}, Vector{Float64}}
T factor:
2×2 Matrix{Float64}:
 3.0  9.0
 0.0 -2.0
Z factor:
2×2 Matrix{Float64}:
 0.961524  0.274721
-0.274721  0.961524
eigenvalues:
2-element Vector{Float64}:
 3.0
-2.0

julia> F.vectors * F.Schur * F.vectors'
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

julia> t, z, vals = F; # destructuring via iteration

julia> t == F.T && z == F.Z && vals == F.values
true

schur(A, B) -> F::GeneralizedSchur

```

Computes the Generalized Schur (or QZ) factorization of the matrices A and B. The (quasi) triangular Schur factors can be obtained from the Schur object F with F.S and F.T, the left unitary/orthogonal Schur vectors can be obtained with F.left or F.Q and the right unitary/orthogonal Schur vectors can be obtained with F.right or F.Z such that $A=F.\text{left}*F.S*F.\text{right}'$ and $B=F.\text{left}*F.T*F.\text{right}'$. The generalized eigenvalues of A and B can be obtained with $F.\alpha./F.\beta$.

Iterating the decomposition produces the components F.S, F.T, F.Q, F.Z, F. α , and F. β .

LinearAlgebra.schur! – Function.

```
schur!(A) -> F::Schur
```

Same as `schur` but uses the input argument A as workspace.

Examples

```

julia> A = [5. 7.; -2. -4.]
2×2 Matrix{Float64}:
 5.0  7.0
-2.0 -4.0

julia> F = schur!(A)

```

```

Schur{Float64, Matrix{Float64}, Vector{Float64}}
T factor:
2×2 Matrix{Float64}:
 3.0  9.0
 0.0 -2.0
Z factor:
2×2 Matrix{Float64}:
 0.961524  0.274721
-0.274721  0.961524
eigenvalues:
2-element Vector{Float64}:
 3.0
-2.0

julia> A
2×2 Matrix{Float64}:
 3.0  9.0
 0.0 -2.0

schur!(A::StridedMatrix, B::StridedMatrix) -> F::GeneralizedSchur

```

Same as `schur` but uses the input matrices A and B as workspace.

`LinearAlgebra.ordschur` – Function.

```
ordschur(F::Schur, select::Union{Vector{Bool}, BitVector}) -> F::Schur
```

Reorders the Schur factorization F of a matrix $A = Z^*T^*Z'$ according to the logical array `select` returning the reordered factorization F object. The selected eigenvalues appear in the leading diagonal of $F.Schur$ and the corresponding leading columns of $F.vectors$ form an orthogonal/unitary basis of the corresponding right invariant subspace. In the real case, a complex conjugate pair of eigenvalues must be either both included or both excluded via `select`.

```
ordschur(F::GeneralizedSchur, select::Union{Vector{Bool}, BitVector}) -> F::GeneralizedSchur
```

Reorders the Generalized Schur factorization F of a matrix pair $(A, B) = (Q^*S^*Z', Q^*T^*Z')$ according to the logical array `select` and returns a `GeneralizedSchur` object F . The selected eigenvalues appear in the leading diagonal of both $F.S$ and $F.T$, and the left and right orthogonal/unitary Schur vectors are also reordered such that $(A, B) = F.Q^*(F.S, F.T)^*F.Z'$ still holds and the generalized eigenvalues of A and B can still be obtained with $F.\alpha./F.\beta$.

`LinearAlgebra.ordschur!` – Function.

```
ordschur!(F::Schur, select::Union{Vector{Bool}, BitVector}) -> F::Schur
```

Same as `ordschur` but overwrites the factorization F .

```
ordschur!(F::GeneralizedSchur, select::Union{Vector{Bool}, BitVector}) -> F::GeneralizedSchur
```

Same as `ordschur` but overwrites the factorization F .

`LinearAlgebra.SVD` – Type.

```
SVD <: Factorization
```

Matrix factorization type of the singular value decomposition (SVD) of a matrix A . This is the return type of `svd(_)`, the corresponding matrix factorization function.

If $F::\text{SVD}$ is the factorization object, U , S , V and Vt can be obtained via $F.U$, $F.S$, $F.V$ and $F.Vt$, such that $A = U * \text{Diagonal}(S) * Vt$. The singular values in S are sorted in descending order.

Iterating the decomposition produces the components U , S , and V .

Examples

```
julia> A = [1. 0. 0. 0. 2.; 0. 0. 3. 0. 0.; 0. 0. 0. 0. 0.; 0. 2. 0. 0. 0.]
4×5 Matrix{Float64}:

julia> u == F.U && s == F.S && v == F.V
true
```

LinearAlgebra.GeneralizedSVD – Type.

GeneralizedSVD <: **Factorization**

Matrix factorization type of the generalized singular value decomposition (SVD) of two matrices A and B, such that $A = F \cdot U \cdot F.D1 \cdot F.R0 \cdot F.Q'$ and $B = F \cdot V \cdot F.D2 \cdot F.R0 \cdot F.Q'$. This is the return type of `svd(_)`, the corresponding matrix factorization function.

For an M-by-N matrix A and P-by-N matrix B,

- U is a M-by-M orthogonal matrix,
- V is a P-by-P orthogonal matrix,
- Q is a N-by-N orthogonal matrix,
- D1 is a M-by-(K+L) diagonal matrix with 1s in the first K entries,
- D2 is a P-by-(K+L) matrix whose top right L-by-L block is diagonal,
- R0 is a (K+L)-by-N matrix whose rightmost (K+L)-by-(K+L) block is nonsingular upper block triangular,

K+L is the effective numerical rank of the matrix $[A; B]$.

Iterating the decomposition produces the components U, V, Q, D1, D2, and R0.

The entries of F.D1 and F.D2 are related, as explained in the LAPACK documentation for the [generalized SVD](#) and the `xGGSVD3` routine which is called underneath (in LAPACK 3.6.0 and newer).

Examples

```
julia> A = [1. 0.; 0. -1.]
2×2 Matrix{Float64}:
 1.0  0.0
 0.0 -1.0

julia> B = [0. 1.; 1. 0.]
2×2 Matrix{Float64}:
 0.0  1.0
 1.0  0.0

julia> F = svd(A, B)
GeneralizedSVD{Float64, Matrix{Float64}, Float64, Vector{Float64}}
U factor:
2×2 Matrix{Float64}:
 1.0  0.0
 0.0  1.0

2×2 Matrix{Float64}:
-0.0 -1.0
 1.0  0.0
Q factor:
2×2 Matrix{Float64}:
 1.0  0.0
 0.0  1.0
D1 factor:
2×2 Matrix{Float64}:
 0.707107  0.0
 0.0      0.707107
D2 factor:
```

```

2×2 Matrix{Float64}:
 0.707107  0.0
 0.0      0.707107
R0 factor:
2×2 Matrix{Float64}:
 1.41421  0.0
 0.0     -1.41421

julia> F.U*F.D1*F.R0*F.Q'
2×2 Matrix{Float64}:
 1.0  0.0
 0.0 -1.0

julia> F.V*F.D2*F.R0*F.Q'
2×2 Matrix{Float64}:
-0.0  1.0
 1.0  0.0

```

LinearAlgebra.svd – Function.

```
svd(A; full::Bool = false, alg::Algorithm = default_svd_alg(A)) -> SVD
```

Compute the singular value decomposition (SVD) of A and return an SVD object.

U , S , V and Vt can be obtained from the factorization F with $F.U$, $F.S$, $F.V$ and $F.Vt$, such that $A = U * \text{Diagonal}(S) * Vt$. The algorithm produces Vt and hence Vt is more efficient to extract than V . The singular values in S are sorted in descending order.

Iterating the decomposition produces the components U , S , and V .

If `full = false` (default), a "thin" SVD is returned. For an $M \times N$ matrix A , in the full factorization U is $M \times M$ and V is $N \times N$, while in the thin factorization U is $M \times K$ and V is $N \times K$, where $K = \min(M, N)$ is the number of singular values.

If `alg = DivideAndConquer()` a divide-and-conquer algorithm is used to calculate the SVD. Another (typically slower but more accurate) option is `alg = QRIteration()`.

Julia 1.3

The `alg` keyword argument requires Julia 1.3 or later.

Examples

```

julia> A = rand(4,3);

julia> F = svd(A); # Store the Factorization Object

julia> A ≈ F.U * Diagonal(F.S) * F.Vt
true

julia> U, S, V = F; # destructuring via iteration

julia> A ≈ U * Diagonal(S) * V'
true

```

```
julia> Uonly, = svd(A); # Store U only
```

```
julia> Uonly == U
true
```

```
svd(A, B) -> GeneralizedSVD
```

Compute the generalized SVD of A and B, returning a GeneralizedSVD factorization object F such that $[A; B] = [F.U * F.D1; F.V * F.D2] * F.R0 * F.Q'$

- U is a M-by-M orthogonal matrix,
- V is a P-by-P orthogonal matrix,
- Q is a N-by-N orthogonal matrix,
- D1 is a M-by-(K+L) diagonal matrix with 1s in the first K entries,
- D2 is a P-by-(K+L) matrix whose top right L-by-L block is diagonal,
- R0 is a (K+L)-by-N matrix whose rightmost (K+L)-by-(K+L) block is nonsingular upper block triangular,

K+L is the effective numerical rank of the matrix $[A; B]$.

Iterating the decomposition produces the components U, V, Q, D1, D2, and R0.

The generalized SVD is used in applications such as when one wants to compare how much belongs to A vs. how much belongs to B, as in human vs yeast genome, or signal vs noise, or between clusters vs within clusters. (See Edelman and Wang for discussion: <https://arxiv.org/abs/1901.00485>)

It decomposes $[A; B]$ into $[UC; VS]H$, where $[UC; VS]$ is a natural orthogonal basis for the column space of $[A; B]$, and $H = RQ'$ is a natural non-orthogonal basis for the rowspace of $[A; B]$, where the top rows are most closely attributed to the A matrix, and the bottom to the B matrix. The multi-cosine/sine matrices C and S provide a multi-measure of how much A vs how much B, and U and V provide directions in which these are measured.

Examples

```
julia> A = randn(3,2); B=randn(4,2);
```

```
julia> F = svd(A, B);
```

```
julia> U,V,Q,C,S,R = F;
```

```
julia> H = R*Q';
```

```
julia> [A; B] ≈ [U*C; V*S]*H
true
```

```
julia> [A; B] ≈ [F.U*F.D1; F.V*F.D2]*F.R0*F.Q'
true
```

```
julia> Uonly, = svd(A,B);
```

```
julia> U == Uonly
true
```

LinearAlgebra.svd! - Function.

```
| svd!(A; full::Bool = false, alg::Algorithm = default_svd_alg(A)) -> SVD
```

svd! is the same as [svd](#), but saves space by overwriting the input A, instead of creating a copy. See documentation of [svd](#) for details.

```
| svd!(A, B) -> GeneralizedSVD
```

svd! is the same as [svd](#), but modifies the arguments A and B in-place, instead of making copies. See documentation of [svd](#) for details.

LinearAlgebra.svdvals - Function.

```
| svdvals(A)
```

Return the singular values of A in descending order.

Examples

```
| julia> A = [1. 0. 0. 0. 2.; 0. 0. 3. 0. 0.; 0. 0. 0. 0. 0.; 0. 2. 0. 0. 0.]
4×5 Matrix{Float64}:
 1.0  0.0  0.0  0.0  2.0
 0.0  0.0  3.0  0.0  0.0
 0.0  0.0  0.0  0.0  0.0
 0.0  2.0  0.0  0.0  0.0

julia> svdvals(A)
4-element Vector{Float64}:
 3.0
 2.23606797749979
 2.0
 0.0
```

```
| svdvals(A, B)
```

Return the generalized singular values from the generalized singular value decomposition of A and B. See also [svd](#).

Examples

```
| julia> A = [1. 0.; 0. -1.]
2×2 Matrix{Float64}:
 1.0  0.0
 0.0 -1.0

julia> B = [0. 1.; 1. 0.]
2×2 Matrix{Float64}:
 0.0  1.0
 1.0  0.0

julia> svdvals(A, B)
2-element Vector{Float64}:
 1.0
 1.0
```

`LinearAlgebra.svdvals!` – Function.

```
| svdvals!(A)
```

Return the singular values of A, saving space by overwriting the input. See also [svdvals](#) and [svd](#).

```
| svdvals!(A, B)
```

Return the generalized singular values from the generalized singular value decomposition of A and B, saving space by overwriting A and B. See also [svd](#) and [svdvals](#).

`LinearAlgebra.Givens` – Type.

```
| LinearAlgebra.Givens(i1,i2,c,s) -> G
```

A Givens rotation linear operator. The fields `c` and `s` represent the cosine and sine of the rotation angle, respectively. The `Givens` type supports left multiplication $G \cdot A$ and conjugated transpose right multiplication $A \cdot G'$. The type doesn't have a size and can therefore be multiplied with matrices of arbitrary size as long as $i2 \leq \text{size}(A, 2)$ for $G \cdot A$ or $i2 \leq \text{size}(A, 1)$ for $A \cdot G'$.

See also [givens](#).

`LinearAlgebra.givens` – Function.

```
| givens(f::T, g::T, i1::Integer, i2::Integer) where {T} -> (G::Givens, r::T)
```

Computes the Givens rotation G and scalar r such that for any vector x where

```
| x[i1] = f
| x[i2] = g
```

the result of the multiplication

```
| y = G*x
```

has the property that

```
| y[i1] = r
| y[i2] = 0
```

See also [LinearAlgebra.Givens](#).

```
| givens(A::AbstractArray, i1::Integer, i2::Integer, j::Integer) -> (G::Givens, r)
```

Computes the Givens rotation G and scalar r such that the result of the multiplication

```
| B = G*A
```

has the property that

```
| B[i1,j] = r
| B[i2,j] = 0
```

See also [LinearAlgebra.Givens](#).

```
| givens(x::AbstractVector, i1::Integer, i2::Integer) -> (G::Givens, r)
```

Computes the Givens rotation G and scalar r such that the result of the multiplication

$$B = G * x$$

has the property that

$$\begin{aligned} B[i1] &= r \\ B[i2] &= 0 \end{aligned}$$

See also [LinearAlgebra.Givens](#).

`LinearAlgebra.triu` – Function.

`triu(M)`

Upper triangle of a matrix.

Examples

```
julia> a = fill(1.0, (4,4))
4×4 Matrix{Float64}:
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
```

```
julia> triu(a)
4×4 Matrix{Float64}:
 1.0  1.0  1.0  1.0
 0.0  1.0  1.0  1.0
 0.0  0.0  1.0  1.0
 0.0  0.0  0.0  1.0
```

`triu(M, k::Integer)`

Return the upper triangle of M starting from the k th superdiagonal.

Examples

```
julia> a = fill(1.0, (4,4))
4×4 Matrix{Float64}:
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
```

```
julia> triu(a,3)
4×4 Matrix{Float64}:
 0.0  0.0  0.0  1.0
 0.0  0.0  0.0  0.0
 0.0  0.0  0.0  0.0
 0.0  0.0  0.0  0.0
```

```
julia> triu(a,-3)
4×4 Matrix{Float64}:
```

```

1.0  1.0  1.0  1.0
1.0  1.0  1.0  1.0
1.0  1.0  1.0  1.0
1.0  1.0  1.0  1.0

```

`LinearAlgebra.triu!` – Function.

```
| triu!(M)
```

Upper triangle of a matrix, overwriting M in the process. See also [triu](#).

```
| triu!(M, k::Integer)
```

Return the upper triangle of M starting from the kth superdiagonal, overwriting M in the process.

Examples

```

julia> M = [1 2 3 4 5; 1 2 3 4 5; 1 2 3 4 5; 1 2 3 4 5; 1 2 3 4 5]
5×5 Matrix{Int64}:
 1  2  3  4  5
 1  2  3  4  5
 1  2  3  4  5
 1  2  3  4  5
 1  2  3  4  5

julia> triu!(M, 1)
5×5 Matrix{Int64}:
 0  2  3  4  5
 0  0  3  4  5
 0  0  0  4  5
 0  0  0  0  5
 0  0  0  0  0

```

`LinearAlgebra.tril` – Function.

```
| tril(M)
```

Lower triangle of a matrix.

Examples

```

julia> a = fill(1.0, (4,4))
4×4 Matrix{Float64}:
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0

julia> tril(a)
4×4 Matrix{Float64}:
 1.0  0.0  0.0  0.0
 1.0  1.0  0.0  0.0
 1.0  1.0  1.0  0.0
 1.0  1.0  1.0  1.0

```

```
| tril(M, k::Integer)
```

Return the lower triangle of M starting from the kth superdiagonal.

Examples

```
julia> a = fill(1.0, (4,4))
4×4 Matrix{Float64}:
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0

julia> tril(a,3)
4×4 Matrix{Float64}:
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0
 1.0  1.0  1.0  1.0

julia> tril(a,-3)
4×4 Matrix{Float64}:
 0.0  0.0  0.0  0.0
 0.0  0.0  0.0  0.0
 0.0  0.0  0.0  0.0
 1.0  0.0  0.0  0.0
```

LinearAlgebra.tril! – Function.

```
| tril!(M)
```

Lower triangle of a matrix, overwriting M in the process. See also [tril](#).

```
| tril!(M, k::Integer)
```

Return the lower triangle of M starting from the kth superdiagonal, overwriting M in the process.

Examples

```
julia> M = [1 2 3 4 5; 1 2 3 4 5; 1 2 3 4 5; 1 2 3 4 5; 1 2 3 4 5]
5×5 Matrix{Int64}:
 1  2  3  4  5
 1  2  3  4  5
 1  2  3  4  5
 1  2  3  4  5
 1  2  3  4  5

julia> tril!(M, 2)
5×5 Matrix{Int64}:
 1  2  3  0  0
 1  2  3  4  0
 1  2  3  4  5
 1  2  3  4  5
 1  2  3  4  5
```

`LinearAlgebra.diagind` – Function.

```
| diagind(M, k::Integer=0)
```

An `AbstractRange` giving the indices of the *k*th diagonal of the matrix *M*.

See also: [diag](#), [diagm](#), [Diagonal](#).

Examples

```
| julia> A = [1 2 3; 4 5 6; 7 8 9]
3×3 Matrix{Int64}:
 1  2  3
 4  5  6
 7  8  9

julia> diagind(A, -1)
2:4:6
```

`LinearAlgebra.diag` – Function.

```
| diag(M, k::Integer=0)
```

The *k*th diagonal of a matrix, as a vector.

See also [diagm](#), [diagind](#), [Diagonal](#), [isdiag](#).

Examples

```
| julia> A = [1 2 3; 4 5 6; 7 8 9]
3×3 Matrix{Int64}:
 1  2  3
 4  5  6
 7  8  9

julia> diag(A, 1)
2-element Vector{Int64}:
 2
 6
```

`LinearAlgebra.diagm` – Function.

```
| diagm(kv::Pair{<:Integer,<:AbstractVector}...)
diagm(m::Integer, n::Integer, kv::Pair{<:Integer,<:AbstractVector}...)
```

Construct a matrix from Pairs of diagonals and vectors. Vector `kv.second` will be placed on the `kv.first` diagonal. By default the matrix is square and its size is inferred from `kv`, but a non-square size `m×n` (padded with zeros as needed) can be specified by passing `m,n` as the first arguments. For repeated diagonal indices `kv.first` the values in the corresponding vectors `kv.second` will be added.

`diagm` constructs a full matrix; if you want storage-efficient versions with fast arithmetic, see [Diagonal](#), [Bidiagonal](#), [Tridiagonal](#) and [SymTridiagonal](#).

Examples

```
julia> diagm(1 => [1,2,3])
4×4 Matrix{Int64}:
 0  1  0  0
 0  0  2  0
 0  0  0  3
 0  0  0  0

julia> diagm(1 => [1,2,3], -1 => [4,5])
4×4 Matrix{Int64}:
 0  1  0  0
 4  0  2  0
 0  5  0  3
 0  0  0  0

julia> diagm(1 => [1,2,3], 1 => [1,2,3])
4×4 Matrix{Int64}:
 0  2  0  0
 0  0  4  0
 0  0  0  6
 0  0  0  0
```

```
diagm(v::AbstractVector)
diagm(m::Integer, n::Integer, v::AbstractVector)
```

Construct a matrix with elements of the vector as diagonal elements. By default, the matrix is square and its size is given by `length(v)`, but a non-square size $m \times n$ can be specified by passing `m, n` as the first arguments.

Examples

```
julia> diagm([1,2,3])
3×3 Matrix{Int64}:
 1  0  0
 0  2  0
 0  0  3
```

`LinearAlgebra.rank` – Function.

```
rank(::QRSparse{Tv,Ti}) -> Ti
```

Return the rank of the QR factorization

[source](#)

```
rank(S::SparseMatrixCSC{Tv,Ti}; [tol::Real]) -> Ti
```

Calculate rank of `S` by calculating its QR factorization. Values smaller than `tol` are considered as zero. See SPQR's manual.

[source](#)

```
rank(A::AbstractMatrix; atol::Real=0, rtol::Real=atol>0 ? 0 : ne*)
rank(A::AbstractMatrix, rtol::Real)
```

Compute the numerical rank of a matrix by counting how many outputs of `svdvals(A)` are greater than `max(atol, rtol*σ1)` where `σ1` is A's largest calculated singular value. `atol` and `rtol` are the absolute and relative tolerances, respectively. The default relative tolerance is `n*ε`, where `n` is the size of the smallest dimension of `A`, and `ε` is the [eps](#) of the element type of `A`.

Note

Numerical rank can be a sensitive and imprecise characterization of ill-conditioned matrices with singular values that are close to the threshold tolerance `max(atol, rtol*σ1)`. In such cases, slight perturbations to the singular-value computation or to the matrix can change the result of `rank` by pushing one or more singular values across the threshold. These variations can even occur due to changes in floating-point errors between different Julia versions, architectures, compilers, or operating systems.

Julia 1.1

The `atol` and `rtol` keyword arguments requires at least Julia 1.1. In Julia 1.0 `rtol` is available as a positional argument, but this will be deprecated in Julia 2.0.

Examples

```
julia> rank(Matrix{I, 3, 3})
3

julia> rank(diagm(0 => [1, 0, 2]))
2

julia> rank(diagm(0 => [1, 0.001, 2]), rtol=0.1)
2

julia> rank(diagm(0 => [1, 0.001, 2]), rtol=0.00001)
3

julia> rank(diagm(0 => [1, 0.001, 2]), atol=1.5)
1
```

`LinearAlgebra.norm` – Function.

```
| norm(A, p::Real=2)
```

For any iterable container `A` (including arrays of any dimension) of numbers (or any element type for which `norm` is defined), compute the `p`-norm (defaulting to `p=2`) as if `A` were a vector of the corresponding length.

The `p`-norm is defined as

$$\|A\|_p = \left(\sum_{i=1}^n |a_i|^p \right)^{1/p}$$

with `ai` the entries of `A`, `|ai|` the [norm](#) of `ai`, and `n` the length of `A`. Since the `p`-norm is computed using the [norms](#) of the entries of `A`, the `p`-norm of a vector of vectors is not compatible with the interpretation of it as a block vector in general if `p != 2`.

p can assume any numeric value (even though not all values produce a mathematically valid vector norm). In particular, `norm(A, Inf)` returns the largest value in `abs.(A)`, whereas `norm(A, -Inf)` returns the smallest. If A is a matrix and $p=2$, then this is equivalent to the Frobenius norm.

The second argument p is not necessarily a part of the interface for `norm`, i.e. a custom type may only implement `norm(A)` without second argument.

Use `opnorm` to compute the operator norm of a matrix.

Examples

```
julia> v = [3, -2, 6]
3-element Vector{Int64}:
 3
-2
 6

julia> norm(v)
7.0

julia> norm(v, 1)
11.0

julia> norm(v, Inf)
6.0

julia> norm([1 2 3; 4 5 6; 7 8 9])
16.881943016134134

julia> norm([1 2 3 4 5 6 7 8 9])
16.881943016134134

julia> norm(1:9)
16.881943016134134

julia> norm(hcat(v,v), 1) == norm(vcat(v,v), 1) != norm([v,v], 1)
true

julia> norm(hcat(v,v), 2) == norm(vcat(v,v), 2) == norm([v,v], 2)
true

julia> norm(hcat(v,v), Inf) == norm(vcat(v,v), Inf) != norm([v,v], Inf)
true
```

```
norm(x::Number, p::Real=2)
```

For numbers, return $(|x|^p)^{1/p}$.

Examples

```
julia> norm(2, 1)
2.0

julia> norm(-2, 1)
```

```

2.0

julia> norm(2, 2)
2.0

julia> norm(-2, 2)
2.0

julia> norm(2, Inf)
2.0

julia> norm(-2, Inf)
2.0

```

LinearAlgebra.opnorm – Function.

```
opnorm(A::AbstractMatrix, p::Real=2)
```

Compute the operator norm (or matrix norm) induced by the vector p-norm, where valid values of p are 1, 2, or Inf. (Note that for sparse matrices, p=2 is currently not implemented.) Use `norm` to compute the Frobenius norm.

When p=1, the operator norm is the maximum absolute column sum of A:

$$\|A\|_1 = \max_{1 \leq n \leq m} \sum_{i=1}^m |a_{ij}|$$

with a_{ij} the entries of A , and m and n its dimensions.

When p=2, the operator norm is the spectral norm, equal to the largest singular value of A.

When p=Inf, the operator norm is the maximum absolute row sum of A:

$$\|A\|_\infty = \max_{1 \leq m \leq n} \sum_{j=1}^n |a_{mj}|$$

Examples

```

julia> A = [1 -2 -3; 2 3 -1]
2×3 Matrix{Int64}:
 1  -2  -3
 2   3  -1

julia> opnorm(A, Inf)
6.0

julia> opnorm(A, 1)
5.0

```

```
opnorm(x::Number, p::Real=2)
```

For numbers, return $(|x|^p)^{1/p}$. This is equivalent to [norm](#).

```
opnorm(A::Adjoint{<:Any,<:AbstractVector}, q::Real=2)
opnorm(A::Transpose{<:Any,<:AbstractVector}, q::Real=2)
```

For Adjoint/Transpose-wrapped vectors, return the operator q -norm of A , which is equivalent to the p -norm with value $p = q/(q-1)$. They coincide at $p = q = 2$. Use [norm](#) to compute the p norm of A as a vector.

The difference in norm between a vector space and its dual arises to preserve the relationship between duality and the dot product, and the result is consistent with the operator p -norm of a $1 \times n$ matrix.

Examples

```
julia> v = [1; im];

julia> vc = v';

julia> opnorm(vc, 1)
1.0

julia> norm(vc, 1)
2.0

julia> norm(v, 1)
2.0

julia> opnorm(vc, 2)
1.4142135623730951

julia> norm(vc, 2)
1.4142135623730951

julia> norm(v, 2)
1.4142135623730951

julia> opnorm(vc, Inf)
2.0

julia> norm(vc, Inf)
1.0

julia> norm(v, Inf)
1.0
```

`LinearAlgebra.normalize!` – Function.

```
normalize!(a::AbstractArray, p::Real=2)
```

Normalize the array a in-place so that its p -norm equals unity, i.e. $\text{norm}(a, p) == 1$. See also [normalize](#) and [norm](#).

`LinearAlgebra.normalize` – Function.

```
normalize(a, p::Real=2)
```

Normalize a so that its p -norm equals unity, i.e. $\text{norm}(a, p) == 1$. For scalars, this is similar to $\text{sign}(a)$, except $\text{normalize}(0) = \text{NaN}$. See also [normalize!](#), [norm](#), and [sign](#).

Examples

```
julia> a = [1,2,4];

julia> b = normalize(a)
3-element Vector{Float64}:
 0.2182178902359924
 0.4364357804719848
 0.8728715609439696

julia> norm(b)
1.0

julia> c = normalize(a, 1)
3-element Vector{Float64}:
 0.14285714285714285
 0.2857142857142857
 0.5714285714285714

julia> norm(c, 1)
1.0

julia> a = [1 2 4 ; 1 2 4]
2×3 Matrix{Int64}:
 1  2  4
 1  2  4

julia> norm(a)
6.48074069840786

julia> normalize(a)
2×3 Matrix{Float64}:
 0.154303  0.308607  0.617213
 0.154303  0.308607  0.617213

julia> normalize(3, 1)
1.0

julia> normalize(-8, 1)
-1.0

julia> normalize(0, 1)
NaN
```

`LinearAlgebra.cond` – Function.

```
| cond(M, p::Real=2)
```

Condition number of the matrix M , computed using the operator p -norm. Valid values for p are 1, 2 (default), or Inf .

`LinearAlgebra.condskeel` – Function.

```
| condskeel(M, [x, p::Real=Inf])
```

$$\kappa_S(M, p) = \| |M| |M^{-1}| \|_p$$

$$\kappa_S(M, x, p) = \frac{\| |M| |M^{-1}| |x| \|_p}{\|x\|_p}$$

Skeel condition number κ_S of the matrix `M`, optionally with respect to the vector `x`, as computed using the operator `p`-norm. $|M|$ denotes the matrix of (entry wise) absolute values of `M`; $|M|_{ij} = |M_{ij}|$. Valid values for `p` are 1, 2 and `Inf` (default).

This quantity is also known in the literature as the Bauer condition number, relative condition number, or componentwise relative condition number.

`LinearAlgebra.tr` – Function.

```
| tr(M)
```

Matrix trace. Sums the diagonal elements of `M`.

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> tr(A)
5
```

`LinearAlgebra.det` – Function.

```
| det(M)
```

Matrix determinant.

See also: [logdet](#) and [logabsdet](#).

Examples

```
julia> M = [1 0; 2 2]
2×2 Matrix{Int64}:
 1  0
 2  2

julia> det(M)
2.0
```

`LinearAlgebra.logdet` – Function.

```
| logdet(M)
```

Log of matrix determinant. Equivalent to $\log(\det(M))$, but may provide increased accuracy and/or speed.

Examples

```
julia> M = [1 0; 2 2]
2×2 Matrix{Int64}:
 1  0
 2  2

julia> logdet(M)
0.6931471805599453

julia> logdet(Matrix{I, 3, 3})
0.0
```

LinearAlgebra.logabsdet – Function.

```
| logabsdet(M)
```

Log of absolute value of matrix determinant. Equivalent to $(\log(\text{abs}(\det(M))), \text{sign}(\det(M)))$, but may provide increased accuracy and/or speed.

Examples

```
julia> A = [-1. 0.; 0. 1.]
2×2 Matrix{Float64}:
-1.0  0.0
 0.0  1.0

julia> det(A)
-1.0

julia> logabsdet(A)
(0.0, -1.0)

julia> B = [2. 0.; 0. 1.]
2×2 Matrix{Float64}:
 2.0  0.0
 0.0  1.0

julia> det(B)
2.0

julia> logabsdet(B)
(0.6931471805599453, 1.0)
```

Base.inv – Method.

```
| inv(M)
```

Matrix inverse. Computes matrix N such that $M * N = I$, where I is the identity matrix. Computed by solving the left-division $N = M \setminus I$.

Examples

```
julia> M = [2 5; 1 3]
2×2 Matrix{Int64}:
 2  5
 1  3

julia> N = inv(M)
2×2 Matrix{Float64}:
 3.0 -5.0
-1.0  2.0

julia> M*N == N*M == Matrix{I, 2, 2}
true
```

LinearAlgebra.pinv - Function.

```
pinv(M; atol::Real=0, rtol::Real=atol>0 ? 0 : n*ε)
pinv(M, rtol::Real) = pinv(M; rtol=rtol) # to be deprecated in Julia 2.0
```

Computes the Moore-Penrose pseudoinverse.

For matrices M with floating point elements, it is convenient to compute the pseudoinverse by inverting only singular values greater than $\max(\text{atol}, \text{rtol} \cdot \sigma_1)$ where σ_1 is the largest singular value of M .

The optimal choice of absolute (`atol`) and relative tolerance (`rtol`) varies both with the value of M and the intended application of the pseudoinverse. The default relative tolerance is $n \cdot \epsilon$, where n is the size of the smallest dimension of M , and ϵ is the [eps](#) of the element type of M .

For inverting dense ill-conditioned matrices in a least-squares sense, `rtol = sqrt(eps(real(float(oneunit(eltype(M))))))` is recommended.

For more information, see ⁸, ⁹, ¹⁰, ¹¹.

Examples

```
julia> M = [1.5 1.3; 1.2 1.9]
2×2 Matrix{Float64}:
 1.5  1.3
 1.2  1.9

julia> N = pinv(M)
2×2 Matrix{Float64}:
 1.47287 -1.00775
-0.930233  1.16279

julia> M * N
2×2 Matrix{Float64}:
 1.0 -2.22045e-16
 4.44089e-16  1.0
```

LinearAlgebra.nullspace – Function.

```

nullspace(M; atol::Real=0, rtol::Real=atol>0 ? 0 : n*ε)
nullspace(M, rtol::Real) = nullspace(M; rtol=rtol) # to be deprecated in Julia 2.0

```

Computes a basis for the nullspace of M by including the singular vectors of M whose singular values have magnitudes smaller than $\max(\text{atol}, \text{rtol} \cdot \sigma_1)$, where σ_1 is M 's largest singular value.

By default, the relative tolerance rtol is $n \cdot \epsilon$, where n is the size of the smallest dimension of M , and ϵ is the `eps` of the element type of M .

Examples

```

julia> M = [1 0 0; 0 1 0; 0 0 0]
3×3 Matrix{Int64}:
 1  0  0
 0  1  0
 0  0  0

julia> nullspace(M)
3×1 Matrix{Float64}:
 0.0
 0.0
 1.0

julia> nullspace(M, rtol=3)
3×3 Matrix{Float64}:
 0.0  1.0  0.0
 1.0  0.0  0.0
 0.0  0.0  1.0

julia> nullspace(M, atol=0.95)
3×1 Matrix{Float64}:
 0.0
 0.0
 1.0

```

Base.kron – Function.

```

kron(A, B)

```

Computes the Kronecker product of two vectors, matrices or numbers.

For real vectors v and w , the Kronecker product is related to the outer product by $\text{kron}(v, w) == \text{vec}(w * \text{transpose}(v))$ or $w * \text{transpose}(v) == \text{reshape}(\text{kron}(v, w), (\text{length}(w), \text{length}(v)))$. Note

⁸Issue 8859, "Fix least squares", <https://github.com/JuliaLang/julia/pull/8859>

⁹Åke Björck, "Numerical Methods for Least Squares Problems", SIAM Press, Philadelphia, 1996, "Other Titles in Applied Mathematics", Vol. 51. doi:10.1137/1.9781611971484

¹⁰G. W. Stewart, "Rank Degeneracy", SIAM Journal on Scientific and Statistical Computing, 5(2), 1984, 403-413. doi:10.1137/0905030

¹¹Konstantinos Konstantinides and Kung Yao, "Statistical analysis of effective singular values in matrix rank determination", IEEE Transactions on Acoustics, Speech and Signal Processing, 36(5), 1988, 757-763. doi:10.1109/29.1585

how the ordering of v and w differs on the left and right of these expressions (due to column-major storage). For complex vectors, the outer product $w * v'$ also differs by conjugation of v .

Examples

```
julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> B = [im 1; 1 -im]
2×2 Matrix{Complex{Int64}}:
 0+1im  1+0im
 1+0im  0-1im

julia> kron(A, B)
4×4 Matrix{Complex{Int64}}:
 0+1im  1+0im  0+2im  2+0im
 1+0im  0-1im  2+0im  0-2im
 0+3im  3+0im  0+4im  4+0im
 3+0im  0-3im  4+0im  0-4im

julia> v = [1, 2]; w = [3, 4, 5];

julia> w*transpose(v)
3×2 Matrix{Int64}:
 3  6
 4  8
 5 10

julia> reshape(kron(v,w), (length(w), length(v)))
3×2 Matrix{Int64}:
 3  6
 4  8
 5 10
```

Base.kron! – Function.

```
| kron!(C, A, B)
```

Computes the Kronecker product of A and B and stores the result in C , overwriting the existing content of C . This is the in-place version of [kron](#).

Julia 1.6

This function requires Julia 1.6 or later.

Base.exp – Method.

```
| exp(A::AbstractMatrix)
```

Compute the matrix exponential of A , defined by

$$e^A = \sum_{n=0}^{\infty} \frac{A^n}{n!}.$$

For symmetric or Hermitian A , an eigendecomposition ([eigen](#)) is used, otherwise the scaling and squaring algorithm (see ¹²) is chosen.

Examples

```
julia> A = Matrix{Float64}(I, 2, 2)
2×2 Matrix{Float64}:
 1.0  0.0
 0.0  1.0

julia> exp(A)
2×2 Matrix{Float64}:
 2.71828  0.0
 0.0      2.71828
```

`Base.cis` – Method.

```
| cis(A::AbstractMatrix)
```

More efficient method for `exp(im*A)` of square matrix A (especially if A is Hermitian or real-Symmetric).

See also [cispi](#), [sincos](#), [exp](#).

Julia 1.7

Support for using `cis` with matrices was added in Julia 1.7.

Examples

```
julia> cis([π 0; 0 π]) ≈ -I
true
```

`Base.^` – Method.

```
| ^(A::AbstractMatrix, p::Number)
```

Matrix power, equivalent to $\exp(p \log(A))$

Examples

```
julia> [1 2; 0 3]^3
2×2 Matrix{Int64}:
 1  26
 0  27
```

`Base.^` – Method.

¹²Nicholas J. Higham, "The squaring and scaling method for the matrix exponential revisited", SIAM Journal on Matrix Analysis and Applications, 26(4), 2005, 1179-1193. doi:[10.1137/090768539](https://doi.org/10.1137/090768539)

```
| ^(b::Number, A::AbstractMatrix)
```

Matrix exponential, equivalent to $\exp(\log(b)A)$.

Julia 1.1

Support for raising Irrational numbers (like π) to a matrix was added in Julia 1.1.

Examples

```
julia> 2^[1 2; 0 3]
2×2 Matrix{Float64}:
 2.0  6.0
 0.0  8.0

julia> ^[1 2; 0 3]
2×2 Matrix{Float64}:
 2.71828  17.3673
 0.0      20.0855
```

Base.log – Method.

```
| log(A::AbstractMatrix)
```

If A has no negative real eigenvalue, compute the principal matrix logarithm of A , i.e. the unique matrix X such that $e^X = A$ and $-\pi < \text{Im}(\lambda) < \pi$ for all the eigenvalues λ of X . If A has nonpositive eigenvalues, a nonprincipal matrix function is returned whenever possible.

If A is symmetric or Hermitian, its eigendecomposition ([eigen](#)) is used, if A is triangular an improved version of the inverse scaling and squaring method is employed (see ¹³ and ¹⁴). If A is real with no negative eigenvalues, then the real Schur form is computed. Otherwise, the complex Schur form is computed. Then the upper (quasi-)triangular algorithm in ¹⁴ is used on the upper (quasi-)triangular factor.

Examples

```
julia> A = Matrix{Complex{Float64}}(2.7182818*I, 2, 2)
2×2 Matrix{Complex{Float64}}:
 2.71828  0.0
 0.0      2.71828

julia> log(A)
2×2 Matrix{Complex{Float64}}:
 1.0  0.0
 0.0  1.0
```

Base.sqrt – Method.

¹³Awad H. Al-Mohy and Nicholas J. Higham, "Improved inverse scaling and squaring algorithms for the matrix logarithm", SIAM Journal on Scientific Computing, 34(4), 2012, C153-C169. doi:10.1137/110852553

| `sqrt(x)`

Return \sqrt{x} . Throws `DomainError` for negative `Real` arguments. Use complex negative arguments instead. The prefix operator $\sqrt{}$ is equivalent to `sqrt`.

See also: `hypot`.

Examples

```
julia> sqrt(big(81))
9.0

julia> sqrt(big(-81))
ERROR: DomainError with -81.0:
NaN result for non-NaN input.
Stacktrace:

 2.0
```

[source](#)

| `sqrt(A::AbstractMatrix)`

If A has no negative real eigenvalues, compute the principal matrix square root of A , that is the unique matrix X with eigenvalues having positive real part such that $X^2 = A$. Otherwise, a nonprincipal square root is returned.

If A is real-symmetric or Hermitian, its eigendecomposition (`eigen`) is used to compute the square root. For such matrices, eigenvalues λ that appear to be slightly negative due to roundoff errors are treated as if they were zero. More precisely, matrices with all eigenvalues $\geq -\text{rto1} * (\max |\lambda|)$ are treated as semidefinite (yielding a Hermitian square root), with negative eigenvalues taken to be zero. `rto1` is a keyword argument to `sqrt` (in the Hermitian/real-symmetric case only) that defaults to machine precision scaled by `size(A,1)`.

Otherwise, the square root is determined by means of the Björck-Hammarling method ¹⁵, which computes the complex Schur form (`schur`) and then the complex square root of the triangular factor. If a real square root exists, then an extension of this method ¹⁶ that computes the real Schur form and then the real square root of the quasi-triangular factor is instead used.

¹⁵Åke Björck and Sven Hammarling, "A Schur method for the square root of a matrix", Linear Algebra and its Applications, 52-53, 1983, 127-140. doi:10.1016/0024-3795(83)80010-X

¹⁶Nicholas J. Higham, "Computing real square roots of a real matrix", Linear Algebra and its Applications, 88-89, 1987, 405-430. doi:10.1016/0024-3795(87)90118-2

Examples

```
julia> A = [4 0; 0 4]
2×2 Matrix{Int64}:
 4  0
 0  4

julia> sqrt(A)
2×2 Matrix{Float64}:
 2.0  0.0
 0.0  2.0
```

`Base.cos` – Method.

```
| cos(A::AbstractMatrix)
```

Compute the matrix cosine of a square matrix A.

If A is symmetric or Hermitian, its eigendecomposition ([eigen](#)) is used to compute the cosine. Otherwise, the cosine is determined by calling [exp](#).

Examples

```
julia> cos(fill(1.0, (2,2)))
2×2 Matrix{Float64}:
 0.291927 -0.708073
-0.708073  0.291927
```

`Base.sin` – Method.

```
| sin(A::AbstractMatrix)
```

Compute the matrix sine of a square matrix A.

If A is symmetric or Hermitian, its eigendecomposition ([eigen](#)) is used to compute the sine. Otherwise, the sine is determined by calling [exp](#).

Examples

```
julia> sin(fill(1.0, (2,2)))
2×2 Matrix{Float64}:
 0.454649  0.454649
 0.454649  0.454649
```

`Base.Math.sincos` – Method.

```
| sincos(A::AbstractMatrix)
```

Compute the matrix sine and cosine of a square matrix A.

Examples

```
julia> S, C = sincos(fill(1.0, (2,2)));

julia> S
2×2 Matrix{Float64}:
 0.454649  0.454649
 0.454649  0.454649

julia> C
2×2 Matrix{Float64}:
 0.291927  -0.708073
-0.708073   0.291927
```

`Base.tan` – Method.

```
| tan(A::AbstractMatrix)
```

Compute the matrix tangent of a square matrix A.

If A is symmetric or Hermitian, its eigendecomposition ([eigen](#)) is used to compute the tangent. Otherwise, the tangent is determined by calling [exp](#).

Examples

```
julia> tan(fill(1.0, (2,2)))
2×2 Matrix{Float64}:
-1.09252  -1.09252
-1.09252  -1.09252
```

`Base.Math.sec` – Method.

```
| sec(A::AbstractMatrix)
```

Compute the matrix secant of a square matrix A.

`Base.Math.csc` – Method.

```
| csc(A::AbstractMatrix)
```

Compute the matrix cosecant of a square matrix A.

`Base.Math.cot` – Method.

```
| cot(A::AbstractMatrix)
```

Compute the matrix cotangent of a square matrix A.

`Base.cosh` – Method.

```
| cosh(A::AbstractMatrix)
```

Compute the matrix hyperbolic cosine of a square matrix A.

`Base.sinh` – Method.

```
| sinh(A::AbstractMatrix)
```

Compute the matrix hyperbolic sine of a square matrix A.

Base.tanh – Method.

```
| tanh(A::AbstractMatrix)
```

Compute the matrix hyperbolic tangent of a square matrix A.

Base.Math.sech – Method.

```
| sech(A::AbstractMatrix)
```

Compute the matrix hyperbolic secant of square matrix A.

Base.Math.csch – Method.

```
| csch(A::AbstractMatrix)
```

Compute the matrix hyperbolic cosecant of square matrix A.

Base.Math.coth – Method.

```
| coth(A::AbstractMatrix)
```

Compute the matrix hyperbolic cotangent of square matrix A.

Base.acos – Method.

```
| acos(A::AbstractMatrix)
```

Compute the inverse matrix cosine of a square matrix A.

If A is symmetric or Hermitian, its eigendecomposition ([eigen](#)) is used to compute the inverse cosine. Otherwise, the inverse cosine is determined by using [log](#) and [sqrt](#). For the theory and logarithmic formulas used to compute this function, see ¹⁷.

Examples

```
| julia> acos(cos([0.5 0.1; -0.2 0.3]))
2×2 Matrix{ComplexF64}:
 0.5-8.32667e-17im  0.1+0.0im
-0.2+2.63678e-16im  0.3-3.46945e-16im
```

Base.asin – Method.

```
| asin(A::AbstractMatrix)
```

Compute the inverse matrix sine of a square matrix A.

If A is symmetric or Hermitian, its eigendecomposition ([eigen](#)) is used to compute the inverse sine. Otherwise, the inverse sine is determined by using [log](#) and [sqrt](#). For the theory and logarithmic formulas used to compute this function, see ¹⁸.

Examples

¹⁷Mary Aprahamian and Nicholas J. Higham, "Matrix Inverse Trigonometric and Inverse Hyperbolic Functions: Theory and Algorithms", MIMS EPrint: 2016.4. <https://doi.org/10.1137/16M1057577>

¹⁸Mary Aprahamian and Nicholas J. Higham, "Matrix Inverse Trigonometric and Inverse Hyperbolic Functions: Theory and Algorithms", MIMS EPrint: 2016.4. <https://doi.org/10.1137/16M1057577>

```
julia> asin(sin([0.5 0.1; -0.2 0.3]))
2×2 Matrix{ComplexF64}:
 0.5-4.16334e-17im  0.1-5.55112e-17im
-0.2+9.71445e-17im  0.3-1.249e-16im
```

Base.atan – Method.

```
atan(A::AbstractMatrix)
```

Compute the inverse matrix tangent of a square matrix A.

If A is symmetric or Hermitian, its eigendecomposition ([eigen](#)) is used to compute the inverse tangent. Otherwise, the inverse tangent is determined by using [log](#). For the theory and logarithmic formulas used to compute this function, see ¹⁹.

Examples

```
julia> atan(tan([0.5 0.1; -0.2 0.3]))
2×2 Matrix{ComplexF64}:
 0.5+1.38778e-17im  0.1-2.77556e-17im
-0.2+6.93889e-17im  0.3-4.16334e-17im
```

Base.Math.asec – Method.

```
asec(A::AbstractMatrix)
```

Compute the inverse matrix secant of A.

Base.Math.acsc – Method.

```
acsc(A::AbstractMatrix)
```

Compute the inverse matrix cosecant of A.

Base.Math.acot – Method.

```
acot(A::AbstractMatrix)
```

Compute the inverse matrix cotangent of A.

Base.acosh – Method.

```
acosh(A::AbstractMatrix)
```

Compute the inverse hyperbolic matrix cosine of a square matrix A. For the theory and logarithmic formulas used to compute this function, see ²⁰.

Base.asinh – Method.

¹⁹Mary Aprahamian and Nicholas J. Higham, "Matrix Inverse Trigonometric and Inverse Hyperbolic Functions: Theory and Algorithms", MIMS EPrint: 2016.4. <https://doi.org/10.1137/16M1057577>

²⁰Mary Aprahamian and Nicholas J. Higham, "Matrix Inverse Trigonometric and Inverse Hyperbolic Functions: Theory and Algorithms", MIMS EPrint: 2016.4. <https://doi.org/10.1137/16M1057577>

```
| asinh(A: AbstractMatrix)
```

Compute the inverse hyperbolic matrix sine of a square matrix A. For the theory and logarithmic formulas used to compute this function, see ²¹.

Base.atanh – Method.

```
| atanh(A: AbstractMatrix)
```

Compute the inverse hyperbolic matrix tangent of a square matrix A. For the theory and logarithmic formulas used to compute this function, see ²².

Base.Math.asech – Method.

```
| asech(A: AbstractMatrix)
```

Compute the inverse matrix hyperbolic secant of A.

Base.Math.acsch – Method.

```
| acsch(A: AbstractMatrix)
```

Compute the inverse matrix hyperbolic cosecant of A.

Base.Math.acoth – Method.

```
| acoth(A: AbstractMatrix)
```

Compute the inverse matrix hyperbolic cotangent of A.

LinearAlgebra.lyap – Function.

```
| lyap(A, C)
```

Computes the solution X to the continuous Lyapunov equation $AX + XA' + C = 0$, where no eigenvalue of A has a zero real part and no two eigenvalues are negative complex conjugates of each other.

Examples

```
julia> A = [3. 4.; 5. 6]
2×2 Matrix{Float64}:
 3.0  4.0
 5.0  6.0

julia> B = [1. 1.; 1. 2.]
2×2 Matrix{Float64}:
 1.0  1.0
 1.0  2.0
```

²¹Mary Aprahamian and Nicholas J. Higham, "Matrix Inverse Trigonometric and Inverse Hyperbolic Functions: Theory and Algorithms", MIMS EPrint: 2016.4. <https://doi.org/10.1137/16M1057577>

²²Mary Aprahamian and Nicholas J. Higham, "Matrix Inverse Trigonometric and Inverse Hyperbolic Functions: Theory and Algorithms", MIMS EPrint: 2016.4. <https://doi.org/10.1137/16M1057577>

```
julia> X = lyap(A, B)
2×2 Matrix{Float64}:
 0.5  -0.5
-0.5   0.25

julia> A*X + X*A' ≈ -B
true
```

LinearAlgebra.sylvester – Function.

```
| sylvester(A, B, C)
```

Computes the solution X to the Sylvester equation $AX + XB + C = 0$, where A , B and C have compatible dimensions and A and $-B$ have no eigenvalues with equal real part.

Examples

```
julia> A = [3. 4.; 5. 6]
2×2 Matrix{Float64}:
 3.0  4.0
 5.0  6.0

julia> B = [1. 1.; 1. 2.]
2×2 Matrix{Float64}:
 1.0  1.0
 1.0  2.0

julia> C = [1. 2.; -2. 1]
2×2 Matrix{Float64}:
 1.0  2.0
-2.0  1.0

julia> X = sylvester(A, B, C)
2×2 Matrix{Float64}:
-4.46667  1.93333
 3.73333 -1.8

julia> A*X + X*B ≈ -C
true
```

LinearAlgebra.issuccess – Function.

```
| issuccess(F::Factorization)
```

Test that a factorization of a matrix succeeded.

Julia 1.6

`issuccess(::CholeskyPivoted)` requires Julia 1.6 or later.

```
julia> F = cholesky([1 0; 0 1]);

julia> issuccess(F)
```

```

true

julia> F = lu([1 0; 0 0]; check = false);

julia> issuccess(F)
false

```

LinearAlgebra.issymmetric - Function.

```

issymmetric(A) -> Bool

```

Test whether a matrix is symmetric.

Examples

```

julia> a = [1 2; 2 -1]
2×2 Matrix{Int64}:
 1  2
 2 -1

julia> issymmetric(a)
true

julia> b = [1 im; -im 1]
2×2 Matrix{Complex{Int64}}:
 1+0im  0+1im
 0-1im  1+0im

julia> issymmetric(b)
false

```

LinearAlgebra.isposdef - Function.

```

isposdef(A) -> Bool

```

Test whether a matrix is positive definite (and Hermitian) by trying to perform a Cholesky factorization of A.

See also [isposdef!](#), [cholesky](#).

Examples

```

julia> A = [1 2; 2 50]
2×2 Matrix{Int64}:
 1  2
 2 50

julia> isposdef(A)
true

```

LinearAlgebra.isposdef! - Function.

```

isposdef!(A) -> Bool

```

Test whether a matrix is positive definite (and Hermitian) by trying to perform a Cholesky factorization of A , overwriting A in the process. See also [isposdef](#).

Examples

```
julia> A = [1. 2.; 2. 50.];

julia> isposdef!(A)
true

julia> A
2×2 Matrix{Float64}:
 1.0  2.0
 2.0 6.78233
```

LinearAlgebra.istril – Function.

```
istril(A::AbstractMatrix, k::Integer = 0) -> Bool
```

Test whether A is lower triangular starting from the k th superdiagonal.

Examples

```
julia> a = [1 2; 2 -1]
2×2 Matrix{Int64}:
 1  2
 2 -1

julia> istril(a)
false

julia> istril(a, 1)
true

julia> b = [1 0; -im -1]
2×2 Matrix{Complex{Int64}}:
 1+0im  0+0im
 0-1im -1+0im

julia> istril(b)
true

julia> istril(b, -1)
false
```

LinearAlgebra.istriu – Function.

```
istriu(A::AbstractMatrix, k::Integer = 0) -> Bool
```

Test whether A is upper triangular starting from the k th superdiagonal.

Examples

```

julia> a = [1 2; 2 -1]
2×2 Matrix{Int64}:
 1  2
 2 -1

julia> istriu(a)
false

julia> istriu(a, -1)
true

julia> b = [1 im; 0 -1]
2×2 Matrix{Complex{Int64}}:
 1+0im  0+1im
 0+0im  -1+0im

julia> istriu(b)
true

julia> istriu(b, 1)
false

```

LinearAlgebra.isdiag – Function.

```
isdiag(A) -> Bool
```

Test whether a matrix is diagonal in the sense that `iszero(A[i,j])` is true unless `i == j`. Note that it is not necessary for `A` to be square; if you would also like to check that, you need to check that `size(A, 1) == size(A, 2)`.

Examples

```

julia> a = [1 2; 2 -1]
2×2 Matrix{Int64}:
 1  2
 2 -1

julia> isdiag(a)
false

julia> b = [im 0; 0 -im]
2×2 Matrix{Complex{Int64}}:
 0+1im  0+0im
 0+0im  0-1im

julia> isdiag(b)
true

julia> c = [1 0 0; 0 2 0]
2×3 Matrix{Int64}:
 1  0  0
 0  2  0

julia> isdiag(c)

```

```

true

julia> d = [1 0 0; 0 2 3]
2×3 Matrix{Int64}:
 1  0  0
 0  2  3

julia> isdiag(d)
false

```

LinearAlgebra.ishermitian - Function.

```

ishermitian(A) -> Bool

```

Test whether a matrix is Hermitian.

Examples

```

julia> a = [1 2; 2 -1]
2×2 Matrix{Int64}:
 1  2
 2 -1

julia> ishermitian(a)
true

julia> b = [1 im; -im 1]
2×2 Matrix{Complex{Int64}}:
 1+0im  0+1im
 0-1im  1+0im

julia> ishermitian(b)
true

```

Base.transpose - Function.

```

transpose(A)

```

Lazy transpose. Mutating the returned object should appropriately mutate A. Often, but not always, yields `Transpose(A)`, where `Transpose` is a lazy transpose wrapper. Note that this operation is recursive.

This operation is intended for linear algebra usage - for general data manipulation see [permutedims](#), which is non-recursive.

Examples

```

julia> A = [3 2; 0 0]
2×2 Matrix{Int64}:
 3  2
 0  0

julia> B = transpose(A)
2×2 transpose{::Matrix{Int64}} with eltype Int64:

```

```

3  0
2  0

julia> B isa Transpose
true

julia> transpose(B) === A # the transpose of a transpose unwraps the parent
true

julia> Transpose(B) # however, the constructor always wraps its argument
2×2 transpose(transpose(::Matrix{Int64})) with eltype Int64:
 3  2
 0  0

julia> B[1,2] = 4; # modifying B will modify A automatically

julia> A
2×2 Matrix{Int64}:
 3  2
 4  0

```

For complex matrices, the adjoint operation is equivalent to a conjugate-transpose.

```

julia> A = reshape([Complex(x, x) for x in 1:4], 2, 2)
2×2 Matrix{Complex{Int64}}:
 1+1im  3+3im
 2+2im  4+4im

julia> adjoint(A) == conj(transpose(A))
true

```

The transpose of an `AbstractVector` is a row-vector:

```

julia> v = [1,2,3]
3-element Vector{Int64}:
 1
 2
 3

julia> transpose(v) # returns a row-vector
1×3 transpose(::Vector{Int64}) with eltype Int64:
 1  2  3

julia> transpose(v) * v # compute the dot product
14

```

For a matrix of matrices, the individual blocks are recursively operated on:

```

julia> C = [1 3; 2 4]
2×2 Matrix{Int64}:
 1  3
 2  4

```

```
julia> D = reshape([C, 2C, 3C, 4C], 2, 2) # construct a block matrix
2×2 Matrix{Matrix{Int64}}:
 [1 3; 2 4]  [3 9; 6 12]
 [2 6; 4 8]  [4 12; 8 16]

julia> transpose(D) # blocks are recursively transposed
2×2 transpose{::Matrix{Matrix{Int64}}} with eltype Transpose{Int64, Matrix{Int64}}:
 [1 2; 3 4]  [2 4; 6 8]
 [3 6; 9 12] [4 8; 12 16]

transpose(F::Factorization)
```

Lazy transpose of the factorization `F`. By default, returns a [TransposeFactorization](#), except for Factorizations with real eltype, in which case returns an [AdjointFactorization](#).

`LinearAlgebra.transpose!` – Function.

```
transpose!(X::AbstractSparseMatrixCSC{Tv,Ti}, A::AbstractSparseMatrixCSC{Tv,Ti}) where
    Tv, Ti
```

Transpose the matrix `A` and stores it in the matrix `X`. `size(X)` must be equal to `size(transpose(A))`. No additional memory is allocated other than resizing the `rowval` and `nzval` of `X`, if needed.

See `halfperm!`

[source](#)

```
transpose!(dest,src)
```

Transpose array `src` and store the result in the preallocated array `dest`, which should have a size corresponding to `(size(src,2),size(src,1))`. No in-place transposition is supported and unexpected results will happen if `src` and `dest` have overlapping memory regions.

Examples

```
julia> A = [3+2im 9+2im; 8+7im 4+6im]
2×2 Matrix{Complex{Int64}}:
 3+2im  9+2im
 8+7im  4+6im

julia> B = zeros{Complex{Int64}, 2, 2}
2×2 Matrix{Complex{Int64}}:
 0+0im  0+0im
 0+0im  0+0im

julia> transpose!(B, A);

julia> B
2×2 Matrix{Complex{Int64}}:
 3+2im  8+7im
 9+2im  4+6im

julia> A
2×2 Matrix{Complex{Int64}}:
 3+2im  9+2im
 8+7im  4+6im
```

LinearAlgebra.Transpose – Type.

| Transpose

Lazy wrapper type for a transpose view of the underlying linear algebra object, usually an `AbstractVector`/`AbstractMatrix`. Usually, the `Transpose` constructor should not be called directly, use `transpose` instead. To materialize the view use `copy`.

This type is intended for linear algebra usage - for general data manipulation see [permutedims](#).

Examples

```
julia> A = [2 3; 0 0]
2×2 Matrix{Int64}:
 2  3
 0  0

julia> Transpose(A)
2×2 transpose(::Matrix{Int64}) with eltype Int64:
 2  0
 3  0
```

LinearAlgebra.TransposeFactorization – Type.

| TransposeFactorization

Lazy wrapper type for the transpose of the underlying `Factorization` object. Usually, the `TransposeFactorization` constructor should not be called directly, use `transpose(:: Factorization)` instead.

Base.adjoint – Function.

| A'
adjoint(A)

Lazy adjoint (conjugate transposition). Note that `adjoint` is applied recursively to elements.

For number types, `adjoint` returns the complex conjugate, and therefore it is equivalent to the identity function for real numbers.

This operation is intended for linear algebra usage - for general data manipulation see [permutedims](#).

Examples

```
julia> A = [3+2im 9+2im; 0 0]
2×2 Matrix{Complex{Int64}}:
 3+2im  9+2im
 0+0im  0+0im

julia> B = A' # equivalently adjoint(A)
2×2 adjoint(::Matrix{Complex{Int64}}) with eltype Complex{Int64}:
 3-2im  0+0im
 9-2im  0+0im

julia> B isa Adjoint
true
```

```

julia> adjoint(B) === A # the adjoint of an adjoint unwraps the parent
true

julia> Adjoint(B) # however, the constructor always wraps its argument
2×2 adjoint(adjoint(::Matrix{Complex{Int64}})) with eltype Complex{Int64}:
 3+2im  9+2im
 0+0im  0+0im

julia> B[1,2] = 4 + 5im; # modifying B will modify A automatically

julia> A
2×2 Matrix{Complex{Int64}}:
 3+2im  9+2im
 4-5im  0+0im

```

For real matrices, the adjoint operation is equivalent to a transpose.

```

julia> A = reshape([x for x in 1:4], 2, 2)
2×2 Matrix{Int64}:
 1  3
 2  4

julia> A'
2×2 adjoint(::Matrix{Int64}) with eltype Int64:
 1  2
 3  4

julia> adjoint(A) == transpose(A)
true

```

The adjoint of an AbstractVector is a row-vector:

```

julia> x = [3, 4im]
2-element Vector{Complex{Int64}}:
 3 + 0im
 0 + 4im

julia> x'
1×2 adjoint(::Vector{Complex{Int64}}) with eltype Complex{Int64}:
 3+0im  0-4im

julia> x'x # compute the dot product, equivalently x' * x
25 + 0im

```

For a matrix of matrices, the individual blocks are recursively operated on:

```

julia> A = reshape([x + im*x for x in 1:4], 2, 2)
2×2 Matrix{Complex{Int64}}:
 1+1im  3+3im
 2+2im  4+4im

julia> C = reshape([A, 2A, 3A, 4A], 2, 2)

```

```

2×2 Matrix{Matrix{Complex{Int64}}}:
 [1+1im 3+3im; 2+2im 4+4im]  [3+3im 9+9im; 6+6im 12+12im]
 [2+2im 6+6im; 4+4im 8+8im]  [4+4im 12+12im; 8+8im 16+16im]

julia> C'
2×2 adjoint(::Matrix{Matrix{Complex{Int64}}}) with eltype Adjoint{Complex{Int64}},
↪ Matrix{Complex{Int64}}:
 [1-1im 2-2im; 3-3im 4-4im]  [2-2im 4-4im; 6-6im 8-8im]
 [3-3im 6-6im; 9-9im 12-12im] [4-4im 8-8im; 12-12im 16-16im]

adjoint(F::Factorization)

```

Lazy adjoint of the factorization F. By default, returns an [AdjointFactorization](#) wrapper.

`LinearAlgebra.adjoint!` – Function.

```
adjoint!(X::AbstractSparseMatrixCSC{Tv,Ti}, A::AbstractSparseMatrixCSC{Tv,Ti}) where {Tv,Ti}
```

Transpose the matrix A and stores the adjoint of the elements in the matrix X. `size(X)` must be equal to `size(transpose(A))`. No additional memory is allocated other than resizing the `rowval` and `nzval` of X, if needed.

See `halfperm!`

[source](#)

```
adjoint!(dest,src)
```

Conjugate transpose array `src` and store the result in the preallocated array `dest`, which should have a size corresponding to `(size(src,2),size(src,1))`. No in-place transposition is supported and unexpected results will happen if `src` and `dest` have overlapping memory regions.

Examples

```

julia> A = [3+2im 9+2im; 8+7im 4+6im]
2×2 Matrix{Complex{Int64}}:
 3+2im  9+2im
 8+7im  4+6im

julia> B = zeros{Complex{Int64}, 2, 2}
2×2 Matrix{Complex{Int64}}:
 0+0im  0+0im
 0+0im  0+0im

julia> adjoint!(B, A);

julia> B
2×2 Matrix{Complex{Int64}}:
 3-2im  8-7im
 9-2im  4-6im

julia> A
2×2 Matrix{Complex{Int64}}:
 3+2im  9+2im
 8+7im  4+6im

```

LinearAlgebra.Adjoint – Type.

| Adjoint

Lazy wrapper type for an adjoint view of the underlying linear algebra object, usually an AbstractVector/AbstractMatrix. Usually, the Adjoint constructor should not be called directly, use [adjoint](#) instead. To materialize the view use [copy](#).

This type is intended for linear algebra usage - for general data manipulation see [permutedims](#).

Examples

```
julia> A = [3+2im 9+2im; 0 0]
2×2 Matrix{Complex{Int64}}:
 3+2im  9+2im
 0+0im  0+0im

julia> Adjoint(A)
2×2 adjoint(::Matrix{Complex{Int64}}) with eltype Complex{Int64}:
 3-2im  0+0im
 9-2im  0+0im
```

LinearAlgebra.AdjointFactorization – Type.

| AdjointFactorization

Lazy wrapper type for the adjoint of the underlying Factorization object. Usually, the AdjointFactorization constructor should not be called directly, use [adjoint\(:: Factorization\)](#) instead.

Base.copy – Method.

```
copy(A::Transpose)
copy(A::Adjoint)
```

Eagerly evaluate the lazy matrix transpose/adjoint. Note that the transposition is applied recursively to elements.

This operation is intended for linear algebra usage - for general data manipulation see [permutedims](#), which is non-recursive.

Examples

```
julia> A = [1 2im; -3im 4]
2×2 Matrix{Complex{Int64}}:
 1+0im  0+2im
 0-3im  4+0im

julia> T = transpose(A)
2×2 transpose(::Matrix{Complex{Int64}}) with eltype Complex{Int64}:
 1+0im  0-3im
 0+2im  4+0im

julia> copy(T)
2×2 Matrix{Complex{Int64}}:
 1+0im  0-3im
 0+2im  4+0im
```

`LinearAlgebra.stride1` – Function.

```
| stride1(A) -> Int
```

Return the distance between successive array elements in dimension 1 in units of element size.

Examples

```
julia> A = [1,2,3,4]
4-element Vector{Int64}:
 1
 2
 3
 4

julia> LinearAlgebra.stride1(A)
1

julia> B = view(A, 2:2:4)
2-element view(::Vector{Int64}, 2:2:4) with eltype Int64:
 2
 4

julia> LinearAlgebra.stride1(B)
2
```

`LinearAlgebra.checksquare` – Function.

```
| LinearAlgebra.checksquare(A)
```

Check that a matrix is square, then return its common dimension. For multiple arguments, return a vector.

Examples

```
julia> A = fill(1, (4,4)); B = fill(1, (5,5));

julia> LinearAlgebra.checksquare(A, B)
2-element Vector{Int64}:
 4
 5
```

`LinearAlgebra.peakflops` – Function.

```
| LinearAlgebra.peakflops(n::Integer=4096; eltype::DataType=Float64, ntrials::Integer=3,
↪ parallel::Bool=false)
```

`peakflops` computes the peak flop rate of the computer by using double precision `gemm!`. By default, if no arguments are specified, it multiplies two `Float64` matrices of size $n \times n$, where $n = 4096$. If the underlying BLAS is using multiple threads, higher flop rates are realized. The number of BLAS threads can be set with `BLAS.set_num_threads(n)`.

If the keyword argument `eltype` is provided, `peakflops` will construct matrices with elements of type `eltype` for calculating the peak flop rate.

By default, `peakflops` will use the best timing from 3 trials. If the `ntrials` keyword argument is provided, `peakflops` will use those many trials for picking the best timing.

If the keyword argument `parallel` is set to `true`, `peakflops` is run in parallel on all the worker processors. The flop rate of the entire parallel computer is returned. When running in parallel, only 1 BLAS thread is used. The argument `n` still refers to the size of the problem that is solved on each processor.

Julia 1.1

This function requires at least Julia 1.1. In Julia 1.0 it is available from the standard library `InteractiveUtils`.

`LinearAlgebra.hermitionpart` – Function.

```
| hermitianpart(A, uplo=:U) -> Hermitian
```

Return the Hermitian part of the square matrix A , defined as $(A + A') / 2$, as a `Hermitian` matrix. For real matrices A , this is also known as the symmetric part of A ; it is also sometimes called the "operator real part". The optional argument `uplo` controls the corresponding argument of the `Hermitian` view. For real matrices, the latter is equivalent to a `Symmetric` view.

See also `hermitianpart!` for the corresponding in-place operation.

Julia 1.10

This function requires Julia 1.10 or later.

`LinearAlgebra.hermitionpart!` – Function.

```
| hermitianpart!(A, uplo=:U) -> Hermitian
```

Overwrite the square matrix A in-place with its Hermitian part $(A + A') / 2$, and return `Hermitian(A, uplo)`. For real matrices A , this is also known as the symmetric part of A .

See also `hermitianpart` for the corresponding out-of-place operation.

Julia 1.10

This function requires Julia 1.10 or later.

78.5 Low-level matrix operations

In many cases there are in-place versions of matrix operations that allow you to supply a pre-allocated output vector or matrix. This is useful when optimizing critical code in order to avoid the overhead of repeated allocations. These in-place operations are suffixed with `!` below (e.g. `mul!`) according to the usual Julia convention.

`LinearAlgebra.mul!` – Function.

```
| mul!(Y, A, B) -> Y
```

Calculates the matrix-matrix or matrix-vector product AB and stores the result in Y , overwriting the existing value of Y . Note that Y must not be aliased with either A or B .

Examples

```
julia> A=[1.0 2.0; 3.0 4.0]; B=[1.0 1.0; 1.0 1.0]; Y = similar(B); mul!(Y, A, B);

julia> Y
2×2 Matrix{Float64}:
 3.0  3.0
 7.0  7.0
```

Implementation

For custom matrix and vector types, it is recommended to implement 5-argument `mul!` rather than implementing 3-argument `mul!` directly if possible.

```
mul!(C, A, B, α, β) -> C
```

Combined inplace matrix-matrix or matrix-vector multiply-add $AB + C$. The result is stored in `C` by overwriting it. Note that `C` must not be aliased with either `A` or `B`.

Julia 1.3

Five-argument `mul!` requires at least Julia 1.3.

Examples

```
julia> A=[1.0 2.0; 3.0 4.0]; B=[1.0 1.0; 1.0 1.0]; C=[1.0 2.0; 3.0 4.0];

julia> mul!(C, A, B, 100.0, 10.0) == C
true

julia> C
2×2 Matrix{Float64}:
 310.0  320.0
 730.0  740.0
```

`LinearAlgebra.lmul!` – Function.

```
lmul!(a::Number, B::AbstractArray)
```

Scale an array `B` by a scalar `a` overwriting `B` in-place. Use `rmul!` to multiply scalar from right. The scaling operation respects the semantics of the multiplication `*` between `a` and an element of `B`. In particular, this also applies to multiplication involving non-finite numbers such as NaN and $\pm\text{Inf}$.

Julia 1.1

Prior to Julia 1.1, NaN and $\pm\text{Inf}$ entries in `B` were treated inconsistently.

Examples

```
julia> B = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> lmul!(2, B)
2×2 Matrix{Int64}:
 2  4
 6  8
```

```

2  4
6  8

julia> lmul!(0.0, [Inf])
1-element Vector{Float64}:
 NaN

lmul!(A, B)
```

Calculate the matrix-matrix product AB , overwriting B , and return the result. Here, A must be of special matrix type, like, e.g., [Diagonal](#), [UpperTriangular](#) or [LowerTriangular](#), or of some orthogonal type, see [QR](#).

Examples

```

julia> B = [0 1; 1 0];

julia> A = UpperTriangular([1 2; 0 3]);

julia> lmul!(A, B);

julia> B
2×2 Matrix{Int64}:
 2  1
 3  0

julia> B = [1.0 2.0; 3.0 4.0];

julia> F = qr([0 1; -1 0]);

julia> lmul!(F.Q, B)
2×2 Matrix{Float64}:
 3.0  4.0
 1.0  2.0
```

`LinearAlgebra.rmul!` – Function.

```
rmul!(A::AbstractArray, b::Number)
```

Scale an array A by a scalar b overwriting A in-place. Use `lmul!` to multiply scalar from left. The scaling operation respects the semantics of the multiplication `*` between an element of A and b . In particular, this also applies to multiplication involving non-finite numbers such as `NaN` and `±Inf`.

Julia 1.1

Prior to Julia 1.1, `NaN` and `±Inf` entries in A were treated inconsistently.

Examples

```

julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4
```

```
julia> rmul!(A, 2)
2×2 Matrix{Int64}:
 2  4
 6  8

julia> rmul!([NaN], 0.0)
1-element Vector{Float64}:
 NaN
```

```
rmul!(A, B)
```

Calculate the matrix-matrix product AB , overwriting A , and return the result. Here, B must be of special matrix type, like, e.g., [Diagonal](#), [UpperTriangular](#) or [LowerTriangular](#), or of some orthogonal type, see [QR](#).

Examples

```
julia> A = [0 1; 1 0];

julia> B = UpperTriangular([1 2; 0 3]);

julia> rmul!(A, B);

julia> A
2×2 Matrix{Int64}:
 0  3
 1  2

julia> A = [1.0 2.0; 3.0 4.0];

julia> F = qr([0 1; -1 0]);

julia> rmul!(A, F.Q)
2×2 Matrix{Float64}:
 2.0  1.0
 4.0  3.0
```

`LinearAlgebra.ldiv!` – Function.

```
ldiv!(Y, A, B) -> Y
```

Compute $A \setminus B$ in-place and store the result in Y , returning the result.

The argument A should not be a matrix. Rather, instead of matrices it should be a factorization object (e.g. produced by [factorize](#) or [cholesky](#)). The reason for this is that factorization itself is both expensive and typically allocates memory (although it can also be done in-place via, e.g., [lu!](#)), and performance-critical situations requiring `ldiv!` usually also require fine-grained control over the factorization of A .

Note

Certain structured matrix types, such as [Diagonal](#) and [UpperTriangular](#), are permitted, as these are already in a factorized form

Examples

```

julia> A = [1 2.2 4; 3.1 0.2 3; 4 1 2];

julia> X = [1; 2.5; 3];

julia> Y = zero(X);

julia> ldiv!(Y, qr(A), X);

julia> Y
3-element Vector{Float64}:
 0.7128099173553719
-0.051652892561983674
 0.10020661157024757

julia> A \ X
3-element Vector{Float64}:
 0.7128099173553719
-0.05165289256198333
 0.10020661157024785

ldiv!(A, B)

```

Compute $A \setminus B$ in-place and overwriting B to store the result.

The argument A should not be a matrix. Rather, instead of matrices it should be a factorization object (e.g. produced by [factorize](#) or [cholesky](#)). The reason for this is that factorization itself is both expensive and typically allocates memory (although it can also be done in-place via, e.g., [lu!](#)), and performance-critical situations requiring `ldiv!` usually also require fine-grained control over the factorization of A .

Note

Certain structured matrix types, such as `Diagonal` and `UpperTriangular`, are permitted, as these are already in a factorized form

Examples

```

julia> A = [1 2.2 4; 3.1 0.2 3; 4 1 2];

julia> X = [1; 2.5; 3];

julia> Y = copy(X);

julia> ldiv!(qr(A), X);

julia> X
3-element Vector{Float64}:
 0.7128099173553719
-0.051652892561983674
 0.10020661157024757

julia> A \ Y

```

```
3-element Vector{Float64}:
 0.7128099173553719
 -0.05165289256198333
 0.10020661157024785
```

```
ldiv!(a::Number, B::AbstractArray)
```

Divide each entry in an array B by a scalar a overwriting B in-place. Use `rdiv!` to divide scalar from right.

Examples

```
julia> B = [1.0 2.0; 3.0 4.0]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> ldiv!(2.0, B)
2×2 Matrix{Float64}:
 0.5  1.0
 1.5  2.0
```

`LinearAlgebra.rdiv!` – Function.

```
rdiv!(A, B)
```

Compute A / B in-place and overwriting A to store the result.

The argument B should not be a matrix. Rather, instead of matrices it should be a factorization object (e.g. produced by `factorize` or `cholesky`). The reason for this is that factorization itself is both expensive and typically allocates memory (although it can also be done in-place via, e.g., `lu!`), and performance-critical situations requiring `rdiv!` usually also require fine-grained control over the factorization of B.

Note

Certain structured matrix types, such as `Diagonal` and `UpperTriangular`, are permitted, as these are already in a factorized form

```
rdiv!(A::AbstractArray, b::Number)
```

Divide each entry in an array A by a scalar b overwriting A in-place. Use `ldiv!` to divide scalar from left.

Examples

```
julia> A = [1.0 2.0; 3.0 4.0]
2×2 Matrix{Float64}:
 1.0  2.0
 3.0  4.0

julia> rdiv!(A, 2.0)
2×2 Matrix{Float64}:
 0.5  1.0
 1.5  2.0
```

78.6 BLAS functions

In Julia (as in much of scientific computation), dense linear-algebra operations are based on the [LAPACK library](#), which in turn is built on top of basic linear-algebra building-blocks known as the [BLAS](#). There are highly optimized implementations of BLAS available for every computer architecture, and sometimes in high-performance linear algebra routines it is useful to call the BLAS functions directly.

`LinearAlgebra.BLAS` provides wrappers for some of the BLAS functions. Those BLAS functions that overwrite one of the input arrays have names ending in '!'. Usually, a BLAS function has four methods defined, for [Float32](#), [Float64](#), [ComplexF32](#), and [ComplexF64](#) arrays.

BLAS character arguments

Many BLAS functions accept arguments that determine whether to transpose an argument (`trans`), which triangle of a matrix to reference (`uplo` or `u!l`), whether the diagonal of a triangular matrix can be assumed to be all ones (`dA`) or which side of a matrix multiplication the input argument belongs on (`side`). The possibilities are:

Multiplication order

| side | Meaning |
|------|---|
| 'L' | The argument goes on the left side of a matrix-matrix operation. |
| 'R' | The argument goes on the right side of a matrix-matrix operation. |

Triangle referencing

| uplo/u!l | Meaning |
|----------|---|
| 'U' | Only the upper triangle of the matrix will be used. |
| 'L' | Only the lower triangle of the matrix will be used. |

Transposition operation

| trans/tX | Meaning |
|----------|---|
| 'N' | The input matrix X is not transposed or conjugated. |
| 'T' | The input matrix X will be transposed. |
| 'C' | The input matrix X will be conjugated and transposed. |

Unit diagonal

| diag/dX | Meaning |
|---------|---|
| 'N' | The diagonal values of the matrix X will be read. |
| 'U' | The diagonal of the matrix X is assumed to be all ones. |

`LinearAlgebra.BLAS` – Module.

Interface to BLAS subroutines.

`LinearAlgebra.BLAS.set_num_threads` – Function.

```
| set_num_threads(n::Integer)
| set_num_threads(::Nothing)
```

Set the number of threads the BLAS library should use equal to `n::Integer`.

Also accepts `nothing`, in which case julia tries to guess the default number of threads. Passing `nothing` is discouraged and mainly exists for historical reasons.

`LinearAlgebra.BLAS.get_num_threads` – Function.

```
| get_num_threads()
```

Get the number of threads the BLAS library is using.

Julia 1.6

`get_num_threads` requires at least Julia 1.6.

BLAS functions can be divided into three groups, also called three levels, depending on when they were first proposed, the type of input parameters, and the complexity of the operation.

Level 1 BLAS functions

The level 1 BLAS functions were first proposed in [(Lawson, 1979)][Lawson-1979] and define operations between scalars and vectors.

[Lawson-1979]: <https://dl.acm.org/doi/10.1145/355841.355847>

`LinearAlgebra.BLAS.rot!` – Function.

```
| rot!(n, X, incx, Y, incy, c, s)
```

Overwrite `X` with $c \cdot X + s \cdot Y$ and `Y` with $-\text{conj}(s) \cdot X + c \cdot Y$ for the first `n` elements of array `X` with stride `incx` and first `n` elements of array `Y` with stride `incy`. Returns `X` and `Y`.

Julia 1.5

`rot!` requires at least Julia 1.5.

`LinearAlgebra.BLAS.scal!` – Function.

```
| scal!(n, a, X, incx)
| scal!(a, X)
```

Overwrite `X` with $a \cdot X$ for the first `n` elements of array `X` with stride `incx`. Returns `X`.

If `n` and `incx` are not provided, `length(X)` and `stride(X,1)` are used.

`LinearAlgebra.BLAS.scal` – Function.

```
| scal(n, a, X, incx)
| scal(a, X)
```

Return `X` scaled by `a` for the first `n` elements of array `X` with stride `incx`.

If `n` and `incx` are not provided, `length(X)` and `stride(X,1)` are used.

LinearAlgebra.BLAS.blascopy! – Function.

```
| blascopy!(n, X, incx, Y, incy)
```

Copy n elements of array X with stride incx to array Y with stride incy. Returns Y.

LinearAlgebra.BLAS.dot – Function.

```
| dot(n, X, incx, Y, incy)
```

Dot product of two vectors consisting of n elements of array X with stride incx and n elements of array Y with stride incy.

Examples

```
| julia> BLAS.dot(10, fill(1.0, 10), 1, fill(1.0, 20), 2)
10.0
```

LinearAlgebra.BLAS.dotu – Function.

```
| dotu(n, X, incx, Y, incy)
```

Dot function for two complex vectors consisting of n elements of array X with stride incx and n elements of array Y with stride incy.

Examples

```
| julia> BLAS.dotu(10, fill(1.0im, 10), 1, fill(1.0+im, 20), 2)
-10.0 + 10.0im
```

LinearAlgebra.BLAS.dotc – Function.

```
| dotc(n, X, incx, U, incy)
```

Dot function for two complex vectors, consisting of n elements of array X with stride incx and n elements of array U with stride incy, conjugating the first vector.

Examples

```
| julia> BLAS.dotc(10, fill(1.0im, 10), 1, fill(1.0+im, 20), 2)
10.0 - 10.0im
```

LinearAlgebra.BLAS.nrm2 – Function.

```
| nrm2(n, X, incx)
```

2-norm of a vector consisting of n elements of array X with stride incx.

Examples

```
| julia> BLAS.nrm2(4, fill(1.0, 8), 2)
2.0

| julia> BLAS.nrm2(1, fill(1.0, 8), 2)
1.0
```

LinearAlgebra.BLAS.asum – Function.

```
| asum(n, X, incx)
```

Sum of the magnitudes of the first n elements of array X with stride $incx$.

For a real array, the magnitude is the absolute value. For a complex array, the magnitude is the sum of the absolute value of the real part and the absolute value of the imaginary part.

Examples

```
| julia> BLAS.asum(5, fill(1.0im, 10), 2)
5.0
| julia> BLAS.asum(2, fill(1.0im, 10), 5)
2.0
```

LinearAlgebra.BLAS.iamax – Function.

```
| iamax(n, dx, incx)
| iamax(dx)
```

Find the index of the element of dx with the maximum absolute value. n is the length of dx , and $incx$ is the stride. If n and $incx$ are not provided, they assume default values of $n=\text{length}(dx)$ and $incx=\text{stride1}(dx)$.

Level 2 BLAS functions

The level 2 BLAS functions were published in [(Dongarra, 1988)][Dongarra-1988], and define matrix-vector operations.

[Dongarra-1988]: <https://dl.acm.org/doi/10.1145/42288.42291>

return a vector

LinearAlgebra.BLAS.gemv! – Function.

```
| gemv!(tA, alpha, A, x, beta, y)
```

Update the vector y as $\alpha A x + \beta y$ or $\alpha A' x + \beta y$ according to tA . α and β are scalars. Return the updated y .

LinearAlgebra.BLAS.gemv – Method.

```
| gemv(tA, alpha, A, x)
```

Return $\alpha A x$ or $\alpha A' x$ according to tA . α is a scalar.

LinearAlgebra.BLAS.gemv – Method.

```
| gemv(tA, A, x)
```

Return $A x$ or $A' x$ according to tA .

LinearAlgebra.BLAS.gbmv! – Function.

```
| gbmv!(trans, m, kl, ku, alpha, A, x, beta, y)
```

Update vector y as $\alpha A x + \beta y$ or $\alpha A' x + \beta y$ according to [trans](#). The matrix A is a general band matrix of dimension m by $\text{size}(A, 2)$ with kl sub-diagonals and ku super-diagonals. α and β are scalars. Return the updated y .

LinearAlgebra.BLAS.gbmv – Function.

```
| gbmv(trans, m, kl, ku, alpha, A, x)
```

Return $\alpha A x$ or $\alpha A' x$ according to [trans](#). The matrix A is a general band matrix of dimension m by $\text{size}(A, 2)$ with kl sub-diagonals and ku super-diagonals, and α is a scalar.

LinearAlgebra.BLAS.hemv! – Function.

```
| hemv!(ul, alpha, A, x, beta, y)
```

Update the vector y as $\alpha A x + \beta y$. A is assumed to be Hermitian. Only the [ul](#) triangle of A is used. α and β are scalars. Return the updated y .

LinearAlgebra.BLAS.hemv – Method.

```
| hemv(ul, alpha, A, x)
```

Return $\alpha A x$. A is assumed to be Hermitian. Only the [ul](#) triangle of A is used. α is a scalar.

LinearAlgebra.BLAS.hemv – Method.

```
| hemv(ul, A, x)
```

Return $A x$. A is assumed to be Hermitian. Only the [ul](#) triangle of A is used.

LinearAlgebra.BLAS.hpmv! – Function.

```
| hpmv!(uplo, α, AP, x, β, y)
```

Update vector y as $\alpha A x + \beta y$, where A is a Hermitian matrix provided in packed format AP .

With `uplo = 'U'`, the array AP must contain the upper triangular part of the Hermitian matrix packed sequentially, column by column, so that $AP[1]$ contains $A[1, 1]$, $AP[2]$ and $AP[3]$ contain $A[1, 2]$ and $A[2, 2]$ respectively, and so on.

With `uplo = 'L'`, the array AP must contain the lower triangular part of the Hermitian matrix packed sequentially, column by column, so that $AP[1]$ contains $A[1, 1]$, $AP[2]$ and $AP[3]$ contain $A[2, 1]$ and $A[3, 1]$ respectively, and so on.

The scalar inputs α and β must be complex or real numbers.

The array inputs x , y and AP must all be of `ComplexF32` or `ComplexF64` type.

Return the updated y .

Julia 1.5

`hpmv!` requires at least Julia 1.5.

LinearAlgebra.BLAS.sylv! – Function.

```
| symv!(ul, alpha, A, x, beta, y)
```

Update the vector y as $\alpha A x + \beta y$. A is assumed to be symmetric. Only the `ul` triangle of A is used. α and β are scalars. Return the updated y .

LinearAlgebra.BLAS.symv – Method.

```
| symv(ul, alpha, A, x)
```

Return $\alpha A x$. A is assumed to be symmetric. Only the `ul` triangle of A is used. α is a scalar.

LinearAlgebra.BLAS.symv – Method.

```
| symv(ul, A, x)
```

Return $A x$. A is assumed to be symmetric. Only the `ul` triangle of A is used.

LinearAlgebra.BLAS.sbmv! – Function.

```
| sbmv!(uplo, k, alpha, A, x, beta, y)
```

Update vector y as $\alpha A x + \beta y$ where A is a symmetric band matrix of order $\text{size}(A, 2)$ with k super-diagonals stored in the argument A . The storage layout for A is described the reference BLAS module, level-2 BLAS at <http://www.netlib.org/lapack/explore-html/>. Only the `uplo` triangle of A is used.

Return the updated y .

LinearAlgebra.BLAS.sbmv – Method.

```
| sbmv(uplo, k, alpha, A, x)
```

Return $\alpha A x$ where A is a symmetric band matrix of order $\text{size}(A, 2)$ with k super-diagonals stored in the argument A . Only the `uplo` triangle of A is used.

LinearAlgebra.BLAS.sbmv – Method.

```
| sbmv(uplo, k, A, x)
```

Return $A x$ where A is a symmetric band matrix of order $\text{size}(A, 2)$ with k super-diagonals stored in the argument A . Only the `uplo` triangle of A is used.

LinearAlgebra.BLAS.spmv! – Function.

```
| spmv!(uplo, α, AP, x, β, y)
```

Update vector y as $\alpha A x + \beta y$, where A is a symmetric matrix provided in packed format AP .

With `uplo = 'U'`, the array AP must contain the upper triangular part of the symmetric matrix packed sequentially, column by column, so that $AP[1]$ contains $A[1, 1]$, $AP[2]$ and $AP[3]$ contain $A[1, 2]$ and $A[2, 2]$ respectively, and so on.

With `uplo = 'L'`, the array AP must contain the lower triangular part of the symmetric matrix packed sequentially, column by column, so that $AP[1]$ contains $A[1, 1]$, $AP[2]$ and $AP[3]$ contain $A[2, 1]$ and $A[3, 1]$ respectively, and so on.

The scalar inputs α and β must be real.

The array inputs x , y and AP must all be of `Float32` or `Float64` type.

Return the updated y .

Julia 1.5

`spmv!` requires at least Julia 1.5.

`LinearAlgebra.BLAS.trmv!` – Function.

```
| trmv!(ul, tA, dA, A, b)
```

Return $\text{op}(A)*b$, where op is determined by `tA`. Only the `ul` triangle of A is used. `dA` determines if the diagonal values are read or are assumed to be all ones. The multiplication occurs in-place on b .

`LinearAlgebra.BLAS.trmv` – Function.

```
| trmv(ul, tA, dA, A, b)
```

Return $\text{op}(A)*b$, where op is determined by `tA`. Only the `ul` triangle of A is used. `dA` determines if the diagonal values are read or are assumed to be all ones.

`LinearAlgebra.BLAS.trsv!` – Function.

```
| trsv!(ul, tA, dA, A, b)
```

Overwrite b with the solution to $A*x = b$ or one of the other two variants determined by `tA` and `ul`. `dA` determines if the diagonal values are read or are assumed to be all ones. Return the updated b .

`LinearAlgebra.BLAS.trsv` – Function.

```
| trsv(ul, tA, dA, A, b)
```

Return the solution to $A*x = b$ or one of the other two variants determined by `tA` and `ul`. `dA` determines if the diagonal values are read or are assumed to be all ones.

return a matrix

`LinearAlgebra.BLAS.ger!` – Function.

```
| ger!(alpha, x, y, A)
```

Rank-1 update of the matrix A with vectors x and y as $\alpha x y^T + A$.

`LinearAlgebra.BLAS.her!` – Function.

```
| her!(uplo, alpha, x, A)
```

Methods for complex arrays only. Rank-1 update of the Hermitian matrix A with vector x as $\alpha x x^H + A$. `uplo` controls which triangle of A is updated. Returns A .

`LinearAlgebra.BLAS.syr!` – Function.

```
| syr!(uplo, alpha, x, A)
```

Rank-1 update of the symmetric matrix A with vector x as $\alpha x \text{transpose}(x) + A$. `uplo` controls which triangle of A is updated. Returns A .

`LinearAlgebra.BLAS.spr!` – Function.

```
| spr!(uplo, α, x, AP)
```

Update matrix A as $A + \alpha * x * x'$, where A is a symmetric matrix provided in packed format AP and x is a vector.

With `uplo = 'U'`, the array AP must contain the upper triangular part of the symmetric matrix packed sequentially, column by column, so that $AP[1]$ contains $A[1, 1]$, $AP[2]$ and $AP[3]$ contain $A[1, 2]$ and $A[2, 2]$ respectively, and so on.

With `uplo = 'L'`, the array AP must contain the lower triangular part of the symmetric matrix packed sequentially, column by column, so that $AP[1]$ contains $A[1, 1]$, $AP[2]$ and $AP[3]$ contain $A[2, 1]$ and $A[3, 1]$ respectively, and so on.

The scalar input α must be real.

The array inputs x and AP must all be of `Float32` or `Float64` type. Return the updated AP .

Julia 1.8

`spr!` requires at least Julia 1.8.

Level 3 BLAS functions

The level 3 BLAS functions were published in [(Dongarra, 1990)][Dongarra-1990], and define matrix-matrix operations.

[Dongarra-1990]: <https://dl.acm.org/doi/10.1145/77626.79170>

`LinearAlgebra.BLAS.gemm!` – Function.

```
| gemm!(tA, tB, alpha, A, B, beta, C)
```

Update C as $\alpha * A * B + \beta * C$ or the other three variants according to `tA` and `tB`. Return the updated C .

`LinearAlgebra.BLAS.gemm` – Method.

```
| gemm(tA, tB, alpha, A, B)
```

Return $\alpha * A * B$ or the other three variants according to `tA` and `tB`.

`LinearAlgebra.BLAS.gemm` – Method.

```
| gemm(tA, tB, A, B)
```

Return $A * B$ or the other three variants according to `tA` and `tB`.

`LinearAlgebra.BLAS.symm!` – Function.

```
| symm!(side, ul, alpha, A, B, beta, C)
```

Update C as $\alpha * A * B + \beta * C$ or $\alpha * B * A + \beta * C$ according to `side`. A is assumed to be symmetric. Only the `ul` triangle of A is used. Return the updated C .

`LinearAlgebra.BLAS.symm` – Method.

```
| symm(side, ul, alpha, A, B)
```

Return $\alpha * A * B$ or $\alpha * B * A$ according to [side](#). A is assumed to be symmetric. Only the [ul](#) triangle of A is used.

`LinearAlgebra.BLAS.symm` – Method.

```
| symm(side, ul, A, B)
```

Return $A * B$ or $B * A$ according to [side](#). A is assumed to be symmetric. Only the [ul](#) triangle of A is used.

`LinearAlgebra.BLAS.hemm!` – Function.

```
| hemm!(side, ul, alpha, A, B, beta, C)
```

Update C as $\alpha * A * B + \beta * C$ or $\alpha * B * A + \beta * C$ according to [side](#). A is assumed to be Hermitian. Only the [ul](#) triangle of A is used. Return the updated C.

`LinearAlgebra.BLAS.hemm` – Method.

```
| hemm(side, ul, alpha, A, B)
```

Return $\alpha * A * B$ or $\alpha * B * A$ according to [side](#). A is assumed to be Hermitian. Only the [ul](#) triangle of A is used.

`LinearAlgebra.BLAS.hemm` – Method.

```
| hemm(side, ul, A, B)
```

Return $A * B$ or $B * A$ according to [side](#). A is assumed to be Hermitian. Only the [ul](#) triangle of A is used.

`LinearAlgebra.BLAS.syrk!` – Function.

```
| syrk!(uplo, trans, alpha, A, beta, C)
```

Rank-k update of the symmetric matrix C as $\alpha * A * \text{transpose}(A) + \beta * C$ or $\alpha * \text{transpose}(A) * A + \beta * C$ according to [trans](#). Only the [uplo](#) triangle of C is used. Return C.

`LinearAlgebra.BLAS.syrk` – Function.

```
| syrk(uplo, trans, alpha, A)
```

Return either the upper triangle or the lower triangle of A, according to [uplo](#), of $\alpha * A * \text{transpose}(A)$ or $\alpha * \text{transpose}(A) * A$, according to [trans](#).

`LinearAlgebra.BLAS.herk!` – Function.

```
| herk!(uplo, trans, alpha, A, beta, C)
```

Methods for complex arrays only. Rank-k update of the Hermitian matrix C as $\alpha * A * A' + \beta * C$ or $\alpha * A' * A + \beta * C$ according to [trans](#). Only the [uplo](#) triangle of C is updated. Returns C.

`LinearAlgebra.BLAS.herk` – Function.

```
| herk(uplo, trans, alpha, A)
```

Methods for complex arrays only. Returns the [uplo](#) triangle of $\alpha * A * A'$ or $\alpha * A' * A$, according to [trans](#).

LinearAlgebra.BLAS.syr2k! – Function.

```
| syr2k!(uplo, trans, alpha, A, B, beta, C)
```

Rank-2k update of the symmetric matrix C as $\alpha A A^T + \alpha B B^T + \beta C$ or $\alpha A^T A + \alpha B^T B + \beta C$ according to [trans](#). Only the [uplo](#) triangle of C is used. Returns C.

LinearAlgebra.BLAS.syr2k – Function.

```
| syr2k(uplo, trans, alpha, A, B)
```

Returns the [uplo](#) triangle of $\alpha A A^T + \alpha B B^T$ or $\alpha A^T A + \alpha B^T B$, according to [trans](#).

```
| syr2k(uplo, trans, A, B)
```

Return the [uplo](#) triangle of $A A^T + B B^T$ or $A^T A + B^T B$, according to [trans](#).

LinearAlgebra.BLAS.her2k! – Function.

```
| her2k!(uplo, trans, alpha, A, B, beta, C)
```

Rank-2k update of the Hermitian matrix C as $\alpha A A^H + \alpha B B^H + \beta C$ or $\alpha A^H A + \alpha B^H B + \beta C$ according to [trans](#). The scalar beta has to be real. Only the [uplo](#) triangle of C is used. Return C.

LinearAlgebra.BLAS.her2k – Function.

```
| her2k(uplo, trans, alpha, A, B)
```

Return the [uplo](#) triangle of $\alpha A A^H + \alpha B B^H$ or $\alpha A^H A + \alpha B^H B$, according to [trans](#).

```
| her2k(uplo, trans, A, B)
```

Return the [uplo](#) triangle of $A A^H + B B^H$ or $A^H A + B^H B$, according to [trans](#).

LinearAlgebra.BLAS.trmm! – Function.

```
| trmm!(side, ul, tA, dA, alpha, A, B)
```

Update B as $\alpha A B$ or one of the other three variants determined by [side](#) and [tA](#). Only the [ul](#) triangle of A is used. [dA](#) determines if the diagonal values are read or are assumed to be all ones. Return the updated B.

LinearAlgebra.BLAS.trmm – Function.

```
| trmm(side, ul, tA, dA, alpha, A, B)
```

Return $\alpha A B$ or one of the other three variants determined by [side](#) and [tA](#). Only the [ul](#) triangle of A is used. [dA](#) determines if the diagonal values are read or are assumed to be all ones.

LinearAlgebra.BLAS.trsm! – Function.

```
| trsm!(side, ul, tA, dA, alpha, A, B)
```

Overwrite B with the solution to $A * X = \alpha * B$ or one of the other three variants determined by `side` and `tA`. Only the `ul` triangle of A is used. `dA` determines if the diagonal values are read or are assumed to be all ones. Returns the updated B.

LinearAlgebra.BLAS.trsm - Function.

```
| trsm(side, ul, tA, dA, alpha, A, B)
```

Return the solution to $A * X = \alpha * B$ or one of the other three variants determined by `side` and `tA`. Only the `ul` triangle of A is used. `dA` determines if the diagonal values are read or are assumed to be all ones.

78.7 LAPACK functions

LinearAlgebra.LAPACK provides wrappers for some of the LAPACK functions for linear algebra. Those functions that overwrite one of the input arrays have names ending in '!'.

Usually a function has 4 methods defined, one each for `Float64`, `Float32`, `ComplexF64` and `ComplexF32` arrays.

Note that the LAPACK API provided by Julia can and will change in the future. Since this API is not user-facing, there is no commitment to support/deprecate this specific set of functions in future releases.

LinearAlgebra.LAPACK - Module.

Interfaces to LAPACK subroutines.

LinearAlgebra.LAPACK.gbtrf! - Function.

```
| gbtrf!(kl, ku, m, AB) -> (AB, ipiv)
```

Compute the LU factorization of a banded matrix AB. `kl` is the first subdiagonal containing a nonzero band, `ku` is the last superdiagonal containing one, and `m` is the first dimension of the matrix AB. Returns the LU factorization in-place and `ipiv`, the vector of pivots used.

LinearAlgebra.LAPACK.gbtrs! - Function.

```
| gbtrs!(trans, kl, ku, m, AB, ipiv, B)
```

Solve the equation $AB * X = B$. `trans` determines the orientation of AB. It may be N (no transpose), T (transpose), or C (conjugate transpose). `kl` is the first subdiagonal containing a nonzero band, `ku` is the last superdiagonal containing one, and `m` is the first dimension of the matrix AB. `ipiv` is the vector of pivots returned from `gbtrf!`. Returns the vector or matrix X, overwriting B in-place.

LinearAlgebra.LAPACK.gebal! - Function.

```
| gebal!(job, A) -> (ilo, ihi, scale)
```

Balance the matrix A before computing its eigensystem or Schur factorization. `job` can be one of N (A will not be permuted or scaled), P (A will only be permuted), S (A will only be scaled), or B (A will be both permuted and scaled). Modifies A in-place and returns `ilo`, `ihi`, and `scale`. If permuting was turned on, $A[i, j] = 0$ if $j > i$ and $1 < j < ilo$ or $j > ihi$. `scale` contains information about the scaling/permutations performed.

LinearAlgebra.LAPACK.gebak! – Function.

```
| gebak!(job, side, ilo, ihi, scale, V)
```

Transform the eigenvectors V of a matrix balanced using `gebal!` to the unscaled/unpermuted eigenvectors of the original matrix. Modifies V in-place. `side` can be `L` (left eigenvectors are transformed) or `R` (right eigenvectors are transformed).

LinearAlgebra.LAPACK.gebrd! – Function.

```
| gebrd!(A) -> (A, d, e, tauq, taup)
```

Reduce A in-place to bidiagonal form $A = QBP'$. Returns A , containing the bidiagonal matrix B ; d , containing the diagonal elements of B ; e , containing the off-diagonal elements of B ; $tauq$, containing the elementary reflectors representing Q ; and $taup$, containing the elementary reflectors representing P .

LinearAlgebra.LAPACK.gelqf! – Function.

```
| gelqf!(A, tau)
```

Compute the LQ factorization of A , $A = LQ$. tau contains scalars which parameterize the elementary reflectors of the factorization. tau must have length greater than or equal to the smallest dimension of A .

Returns A and tau modified in-place.

```
| gelqf!(A) -> (A, tau)
```

Compute the LQ factorization of A , $A = LQ$.

Returns A , modified in-place, and tau , which contains scalars which parameterize the elementary reflectors of the factorization.

LinearAlgebra.LAPACK.geqlf! – Function.

```
| geqlf!(A, tau)
```

Compute the QL factorization of A , $A = QL$. tau contains scalars which parameterize the elementary reflectors of the factorization. tau must have length greater than or equal to the smallest dimension of A .

Returns A and tau modified in-place.

```
| geqlf!(A) -> (A, tau)
```

Compute the QL factorization of A , $A = QL$.

Returns A , modified in-place, and tau , which contains scalars which parameterize the elementary reflectors of the factorization.

LinearAlgebra.LAPACK.geqrf! – Function.

```
| geqrf!(A, tau)
```

Compute the QR factorization of A , $A = QR$. τ contains scalars which parameterize the elementary reflectors of the factorization. τ must have length greater than or equal to the smallest dimension of A .

Returns A and τ modified in-place.

```
| geqrf!(A) -> (A, tau)
```

Compute the QR factorization of A , $A = QR$.

Returns A , modified in-place, and τ , which contains scalars which parameterize the elementary reflectors of the factorization.

`LinearAlgebra.LAPACK.geqp3!` – Function.

```
| geqp3!(A, [jpvt, tau]) -> (A, tau, jpvt)
```

Compute the pivoted QR factorization of A , $AP = QR$ using BLAS level 3. P is a pivoting matrix, represented by $jpvt$. τ stores the elementary reflectors. The arguments $jpvt$ and τ are optional and allow for passing preallocated arrays. When passed, $jpvt$ must have length greater than or equal to n if A is an $(m \times n)$ matrix and τ must have length greater than or equal to the smallest dimension of A .

A , $jpvt$, and τ are modified in-place.

`LinearAlgebra.LAPACK.gerqf!` – Function.

```
| gerqf!(A, tau)
```

Compute the RQ factorization of A , $A = RQ$. τ contains scalars which parameterize the elementary reflectors of the factorization. τ must have length greater than or equal to the smallest dimension of A .

Returns A and τ modified in-place.

```
| gerqf!(A) -> (A, tau)
```

Compute the RQ factorization of A , $A = RQ$.

Returns A , modified in-place, and τ , which contains scalars which parameterize the elementary reflectors of the factorization.

`LinearAlgebra.LAPACK.geqrt!` – Function.

```
| geqrt!(A, T)
```

Compute the blocked QR factorization of A , $A = QR$. T contains upper triangular block reflectors which parameterize the elementary reflectors of the factorization. The first dimension of T sets the block size and it must be between 1 and n . The second dimension of T must equal the smallest dimension of A .

Returns A and T modified in-place.

```
| geqrt!(A, nb) -> (A, T)
```

Compute the blocked QR factorization of A , $A = QR$. nb sets the block size and it must be between 1 and n , the second dimension of A .

Returns A , modified in-place, and T , which contains upper triangular block reflectors which parameterize the elementary reflectors of the factorization.

LinearAlgebra.LAPACK.geqrt3! – Function.

```
| geqrt3!(A, T)
```

Recursively computes the blocked QR factorization of A, $A = QR$. T contains upper triangular block reflectors which parameterize the elementary reflectors of the factorization. The first dimension of T sets the block size and it must be between 1 and n. The second dimension of T must equal the smallest dimension of A.

Returns A and T modified in-place.

```
| geqrt3!(A) -> (A, T)
```

Recursively computes the blocked QR factorization of A, $A = QR$.

Returns A, modified in-place, and T, which contains upper triangular block reflectors which parameterize the elementary reflectors of the factorization.

LinearAlgebra.LAPACK.getrf! – Function.

```
| getrf!(A) -> (A, ipiv, info)
```

Compute the pivoted LU factorization of A, $A = LU$.

Returns A, modified in-place, ipiv, the pivoting information, and an info code which indicates success (info = 0), a singular value in U (info = i, in which case $U[i, i]$ is singular), or an error code (info < 0).

LinearAlgebra.LAPACK.tzrzf! – Function.

```
| tzrzf!(A) -> (A, tau)
```

Transforms the upper trapezoidal matrix A to upper triangular form in-place. Returns A and tau, the scalar parameters for the elementary reflectors of the transformation.

LinearAlgebra.LAPACK.ormrz! – Function.

```
| ormrz!(side, trans, A, tau, C)
```

Multiplies the matrix C by Q from the transformation supplied by tzrzf!. Depending on side or trans the multiplication can be left-sided (side = L, $Q * C$) or right-sided (side = R, $C * Q$) and Q can be unmodified (trans = N), transposed (trans = T), or conjugate transposed (trans = C). Returns matrix C which is modified in-place with the result of the multiplication.

LinearAlgebra.LAPACK.gels! – Function.

```
| gels!(trans, A, B) -> (F, B, ssr)
```

Solves the linear equation $A * X = B$, $\text{transpose}(A) * X = B$, or $\text{adjoint}(A) * X = B$ using a QR or LQ factorization. Modifies the matrix/vector B in place with the solution. A is overwritten with its QR or LQ factorization. trans may be one of N (no modification), T (transpose), or C (conjugate transpose). gels! searches for the minimum norm/least squares solution. A may be under or over determined. The solution is returned in B.

LinearAlgebra.LAPACK.gesv! – Function.

```
| gesv!(A, B) -> (B, A, ipiv)
```

Solves the linear equation $A * X = B$ where A is a square matrix using the LU factorization of A . A is overwritten with its LU factorization and B is overwritten with the solution X . $ipiv$ contains the pivoting information for the LU factorization of A .

LinearAlgebra.LAPACK.getrs! – Function.

```
| getrs!(trans, A, ipiv, B)
```

Solves the linear equation $A * X = B$, $\text{transpose}(A) * X = B$, or $\text{adjoint}(A) * X = B$ for square A . Modifies the matrix/vector B in place with the solution. A is the LU factorization from `getrf!`, with $ipiv$ the pivoting information. $trans$ may be one of N (no modification), T (transpose), or C (conjugate transpose).

LinearAlgebra.LAPACK.getri! – Function.

```
| getri!(A, ipiv)
```

Computes the inverse of A , using its LU factorization found by `getrf!`. $ipiv$ is the pivot information output and A contains the LU factorization of `getrf!`. A is overwritten with its inverse.

LinearAlgebra.LAPACK.gesvx! – Function.

```
| gesvx!(fact, trans, A, AF, ipiv, equed, R, C, B) -> (X, equed, R, C, B, rcond, ferr, berr,  
↪ work)
```

Solves the linear equation $A * X = B$ ($trans = N$), $\text{transpose}(A) * X = B$ ($trans = T$), or $\text{adjoint}(A) * X = B$ ($trans = C$) using the LU factorization of A . $fact$ may be E , in which case A will be equilibrated and copied to AF ; F , in which case AF and $ipiv$ from a previous LU factorization are inputs; or N , in which case A will be copied to AF and then factored. If $fact = F$, $equed$ may be N , meaning A has not been equilibrated; R , meaning A was multiplied by $\text{Diagonal}(R)$ from the left; C , meaning A was multiplied by $\text{Diagonal}(C)$ from the right; or B , meaning A was multiplied by $\text{Diagonal}(R)$ from the left and $\text{Diagonal}(C)$ from the right. If $fact = F$ and $equed = R$ or B the elements of R must all be positive. If $fact = F$ and $equed = C$ or B the elements of C must all be positive.

Returns the solution X ; $equed$, which is an output if $fact$ is not N , and describes the equilibration that was performed; R , the row equilibration diagonal; C , the column equilibration diagonal; B , which may be overwritten with its equilibrated form $\text{Diagonal}(R)*B$ (if $trans = N$ and $equed = R,B$) or $\text{Diagonal}(C)*B$ (if $trans = T,C$ and $equed = C,B$); $rcond$, the reciprocal condition number of A after equilibrating; $ferr$, the forward error bound for each solution vector in X ; $berr$, the forward error bound for each solution vector in X ; and $work$, the reciprocal pivot growth factor.

```
| gesvx!(A, B)
```

The no-equilibration, no-transpose simplification of `gesvx!`.

LinearAlgebra.LAPACK.gelsd! – Function.

```
| gelsd!(A, B, rcond) -> (B, rnk)
```

Computes the least norm solution of $A * X = B$ by finding the SVD factorization of A , then dividing-and-conquering the problem. B is overwritten with the solution X . Singular values below $rcond$ will be treated as zero. Returns the solution in B and the effective rank of A in rnk .

LinearAlgebra.LAPACK.gelsy! – Function.

```
| gelsy!(A, B, rcond) -> (B, rnk)
```

Computes the least norm solution of $A * X = B$ by finding the full QR factorization of A, then dividing-and-conquering the problem. B is overwritten with the solution X. Singular values below rcond will be treated as zero. Returns the solution in B and the effective rank of A in rnk.

LinearAlgebra.LAPACK.gglse! – Function.

```
| gglse!(A, c, B, d) -> (X, res)
```

Solves the equation $A * x = c$ where x is subject to the equality constraint $B * x = d$. Uses the formula $\|c - A*x\|^2 = 0$ to solve. Returns X and the residual sum-of-squares.

LinearAlgebra.LAPACK.geev! – Function.

```
| geev!(jobvl, jobvr, A) -> (W, VL, VR)
```

Finds the eigensystem of A. If jobvl = N, the left eigenvectors of A aren't computed. If jobvr = N, the right eigenvectors of A aren't computed. If jobvl = V or jobvr = V, the corresponding eigenvectors are computed. Returns the eigenvalues in W, the right eigenvectors in VR, and the left eigenvectors in VL.

LinearAlgebra.LAPACK.gesdd! – Function.

```
| gesdd!(job, A) -> (U, S, VT)
```

Finds the singular value decomposition of A, $A = U * S * V'$, using a divide and conquer approach. If job = A, all the columns of U and the rows of V' are computed. If job = N, no columns of U or rows of V' are computed. If job = 0, A is overwritten with the columns of (thin) U and the rows of (thin) V'. If job = S, the columns of (thin) U and the rows of (thin) V' are computed and returned separately.

LinearAlgebra.LAPACK.gesvd! – Function.

```
| gesvd!(jobu, jobvt, A) -> (U, S, VT)
```

Finds the singular value decomposition of A, $A = U * S * V'$. If jobu = A, all the columns of U are computed. If jobvt = A all the rows of V' are computed. If jobu = N, no columns of U are computed. If jobvt = N no rows of V' are computed. If jobu = 0, A is overwritten with the columns of (thin) U. If jobvt = 0, A is overwritten with the rows of (thin) V'. If jobu = S, the columns of (thin) U are computed and returned separately. If jobvt = S the rows of (thin) V' are computed and returned separately. jobu and jobvt can't both be 0.

Returns U, S, and Vt, where S are the singular values of A.

LinearAlgebra.LAPACK.ggsvd! – Function.

```
| ggsvd!(jobu, jobv, jobq, A, B) -> (U, V, Q, alpha, beta, k, l, R)
```

Finds the generalized singular value decomposition of A and B, $U'*A*Q = D1*R$ and $V'*B*Q = D2*R$. D1 has alpha on its diagonal and D2 has beta on its diagonal. If jobu = U, the orthogonal/unitary matrix U is computed. If jobv = V the orthogonal/unitary matrix V is computed. If jobq = Q, the orthogonal/unitary matrix Q is computed. If jobu, jobv or jobq is N, that matrix is not computed. This function is only available in LAPACK versions prior to 3.6.0.

LinearAlgebra.LAPACK.ggsvd3! – Function.

```
| ggsvd3!(jobu, jobv, jobq, A, B) -> (U, V, Q, alpha, beta, k, l, R)
```

Finds the generalized singular value decomposition of A and B, $U^*A^*Q = D1^*R$ and $V^*B^*Q = D2^*R$. D1 has alpha on its diagonal and D2 has beta on its diagonal. If jobu = U, the orthogonal/unitary matrix U is computed. If jobv = V the orthogonal/unitary matrix V is computed. If jobq = Q, the orthogonal/unitary matrix Q is computed. If jobu, jobv, or jobq is N, that matrix is not computed. This function requires LAPACK 3.6.0.

LinearAlgebra.LAPACK.geevx! – Function.

```
| geevx!(balanc, jobvl, jobvr, sense, A) -> (A, w, VL, VR, ilo, ihi, scale, abnrm, rconde,  
↪ rcondv)
```

Finds the eigensystem of A with matrix balancing. If jobvl = N, the left eigenvectors of A aren't computed. If jobvr = N, the right eigenvectors of A aren't computed. If jobvl = V or jobvr = V, the corresponding eigenvectors are computed. If balanc = N, no balancing is performed. If balanc = P, A is permuted but not scaled. If balanc = S, A is scaled but not permuted. If balanc = B, A is permuted and scaled. If sense = N, no reciprocal condition numbers are computed. If sense = E, reciprocal condition numbers are computed for the eigenvalues only. If sense = V, reciprocal condition numbers are computed for the right eigenvectors only. If sense = B, reciprocal condition numbers are computed for the right eigenvectors and the eigenvectors. If sense = E,B, the right and left eigenvectors must be computed.

LinearAlgebra.LAPACK.ggev! – Function.

```
| ggev!(jobvl, jobvr, A, B) -> (alpha, beta, vl, vr)
```

Finds the generalized eigendecomposition of A and B. If jobvl = N, the left eigenvectors aren't computed. If jobvr = N, the right eigenvectors aren't computed. If jobvl = V or jobvr = V, the corresponding eigenvectors are computed.

LinearAlgebra.LAPACK.ggev3! – Function.

```
| ggev3!(jobvl, jobvr, A, B) -> (alpha, beta, vl, vr)
```

Finds the generalized eigendecomposition of A and B using a blocked algorithm. If jobvl = N, the left eigenvectors aren't computed. If jobvr = N, the right eigenvectors aren't computed. If jobvl = V or jobvr = V, the corresponding eigenvectors are computed. This function requires LAPACK 3.6.0.

LinearAlgebra.LAPACK.gttsv! – Function.

```
| gttsv!(dl, d, du, B)
```

Solves the equation $A * X = B$ where A is a tridiagonal matrix with dl on the subdiagonal, d on the diagonal, and du on the superdiagonal.

Overwrites B with the solution X and returns it.

LinearAlgebra.LAPACK.gttrf! – Function.

```
| gttrf!(dl, d, du) -> (dl, d, du, du2, ipiv)
```

Finds the LU factorization of a tridiagonal matrix with d_l on the subdiagonal, d on the diagonal, and d_u on the superdiagonal.

Modifies d_l , d , and d_u in-place and returns them and the second superdiagonal d_u2 and the pivoting vector $ipiv$.

`LinearAlgebra.LAPACK.gttrs!` – Function.

```
| gttrs!(trans, dl, d, du, du2, ipiv, B)
```

Solves the equation $A * X = B$ ($trans = N$), $transpose(A) * X = B$ ($trans = T$), or $adjoint(A) * X = B$ ($trans = C$) using the LU factorization computed by `gttrf!`. B is overwritten with the solution X .

`LinearAlgebra.LAPACK.orglq!` – Function.

```
| orglq!(A, tau, k = length(tau))
```

Explicitly finds the matrix Q of a LQ factorization after calling `gelqf!` on A . Uses the output of `gelqf!`. A is overwritten by Q .

`LinearAlgebra.LAPACK.orgqr!` – Function.

```
| orgqr!(A, tau, k = length(tau))
```

Explicitly finds the matrix Q of a QR factorization after calling `geqrf!` on A . Uses the output of `geqrf!`. A is overwritten by Q .

`LinearAlgebra.LAPACK.orgql!` – Function.

```
| orgql!(A, tau, k = length(tau))
```

Explicitly finds the matrix Q of a QL factorization after calling `geqlf!` on A . Uses the output of `geqlf!`. A is overwritten by Q .

`LinearAlgebra.LAPACK.orgrq!` – Function.

```
| orgrq!(A, tau, k = length(tau))
```

Explicitly finds the matrix Q of a RQ factorization after calling `gerqf!` on A . Uses the output of `gerqf!`. A is overwritten by Q .

`LinearAlgebra.LAPACK.ormlq!` – Function.

```
| ormlq!(side, trans, A, tau, C)
```

Computes $Q * C$ ($trans = N$), $transpose(Q) * C$ ($trans = T$), $adjoint(Q) * C$ ($trans = C$) for $side = L$ or the equivalent right-sided multiplication for $side = R$ using Q from a LQ factorization of A computed using `gelqf!`. C is overwritten.

`LinearAlgebra.LAPACK.ormqr!` – Function.

```
| ormqr!(side, trans, A, tau, C)
```

Computes $Q * C(\text{trans} = N)$, $\text{transpose}(Q) * C(\text{trans} = T)$, $\text{adjoint}(Q) * C(\text{trans} = C)$ for $\text{side} = L$ or the equivalent right-sided multiplication for $\text{side} = R$ using Q from a QR factorization of A computed using `geqrf!`. C is overwritten.

`LinearAlgebra.LAPACK.ormql!` – Function.

```
| ormql!(side, trans, A, tau, C)
```

Computes $Q * C(\text{trans} = N)$, $\text{transpose}(Q) * C(\text{trans} = T)$, $\text{adjoint}(Q) * C(\text{trans} = C)$ for $\text{side} = L$ or the equivalent right-sided multiplication for $\text{side} = R$ using Q from a QL factorization of A computed using `geqlf!`. C is overwritten.

`LinearAlgebra.LAPACK.ormrq!` – Function.

```
| ormrq!(side, trans, A, tau, C)
```

Computes $Q * C(\text{trans} = N)$, $\text{transpose}(Q) * C(\text{trans} = T)$, $\text{adjoint}(Q) * C(\text{trans} = C)$ for $\text{side} = L$ or the equivalent right-sided multiplication for $\text{side} = R$ using Q from a RQ factorization of A computed using `gerqf!`. C is overwritten.

`LinearAlgebra.LAPACK.gemqrt!` – Function.

```
| gemqrt!(side, trans, V, T, C)
```

Computes $Q * C(\text{trans} = N)$, $\text{transpose}(Q) * C(\text{trans} = T)$, $\text{adjoint}(Q) * C(\text{trans} = C)$ for $\text{side} = L$ or the equivalent right-sided multiplication for $\text{side} = R$ using Q from a QR factorization of A computed using `geqrt!`. C is overwritten.

`LinearAlgebra.LAPACK.posv!` – Function.

```
| posv!(uplo, A, B) -> (A, B)
```

Finds the solution to $A * X = B$ where A is a symmetric or Hermitian positive definite matrix. If $\text{uplo} = U$ the upper Cholesky decomposition of A is computed. If $\text{uplo} = L$ the lower Cholesky decomposition of A is computed. A is overwritten by its Cholesky decomposition. B is overwritten with the solution X .

`LinearAlgebra.LAPACK.potrf!` – Function.

```
| potrf!(uplo, A)
```

Computes the Cholesky (upper if $\text{uplo} = U$, lower if $\text{uplo} = L$) decomposition of positive-definite matrix A . A is overwritten and returned with an info code.

`LinearAlgebra.LAPACK.potri!` – Function.

```
| potri!(uplo, A)
```

Computes the inverse of positive-definite matrix A after calling `potrf!` to find its (upper if $\text{uplo} = U$, lower if $\text{uplo} = L$) Cholesky decomposition.

A is overwritten by its inverse and returned.

`LinearAlgebra.LAPACK.potrs!` – Function.

```
| potrs!(uplo, A, B)
```

Finds the solution to $A * X = B$ where A is a symmetric or Hermitian positive definite matrix whose Cholesky decomposition was computed by `potrf!`. If `uplo = U` the upper Cholesky decomposition of A was computed. If `uplo = L` the lower Cholesky decomposition of A was computed. B is overwritten with the solution X .

`LinearAlgebra.LAPACK.pstrf!` – Function.

```
| pstrf!(uplo, A, tol) -> (A, piv, rank, info)
```

Computes the (upper if `uplo = U`, lower if `uplo = L`) pivoted Cholesky decomposition of positive-definite matrix A with a user-set tolerance `tol`. A is overwritten by its Cholesky decomposition.

Returns A , the pivots `piv`, the rank of A , and an `info` code. If `info = 0`, the factorization succeeded. If `info = i > 0`, then A is indefinite or rank-deficient.

`LinearAlgebra.LAPACK.ptsv!` – Function.

```
| ptsv!(D, E, B)
```

Solves $A * X = B$ for positive-definite tridiagonal A . D is the diagonal of A and E is the off-diagonal. B is overwritten with the solution X and returned.

`LinearAlgebra.LAPACK.pttrf!` – Function.

```
| pttrf!(D, E)
```

Computes the LDLt factorization of a positive-definite tridiagonal matrix with D as diagonal and E as off-diagonal. D and E are overwritten and returned.

`LinearAlgebra.LAPACK.pttrs!` – Function.

```
| pttrs!(D, E, B)
```

Solves $A * X = B$ for positive-definite tridiagonal A with diagonal D and off-diagonal E after computing A 's LDLt factorization using `pttrf!`. B is overwritten with the solution X .

`LinearAlgebra.LAPACK.trtri!` – Function.

```
| trtri!(uplo, diag, A)
```

Finds the inverse of (upper if `uplo = U`, lower if `uplo = L`) triangular matrix A . If `diag = N`, A has non-unit diagonal elements. If `diag = U`, all diagonal elements of A are one. A is overwritten with its inverse.

`LinearAlgebra.LAPACK.trtrs!` – Function.

```
| trtrs!(uplo, trans, diag, A, B)
```

Solves $A * X = B$ (`trans = N`), $\text{transpose}(A) * X = B$ (`trans = T`), or $\text{adjoint}(A) * X = B$ (`trans = C`) for (upper if `uplo = U`, lower if `uplo = L`) triangular matrix A . If `diag = N`, A has non-unit diagonal elements. If `diag = U`, all diagonal elements of A are one. B is overwritten with the solution X .

`LinearAlgebra.LAPACK.trcon!` – Function.

```
| trcon!(norm, uplo, diag, A)
```

Finds the reciprocal condition number of (upper if `uplo = U`, lower if `uplo = L`) triangular matrix `A`. If `diag = N`, `A` has non-unit diagonal elements. If `diag = U`, all diagonal elements of `A` are one. If `norm = I`, the condition number is found in the infinity norm. If `norm = 0` or `1`, the condition number is found in the one norm.

`LinearAlgebra.LAPACK.trevc!` – Function.

```
| trevc!(side, howmny, select, T, VL = similar(T), VR = similar(T))
```

Finds the eigensystem of an upper triangular matrix `T`. If `side = R`, the right eigenvectors are computed. If `side = L`, the left eigenvectors are computed. If `side = B`, both sets are computed. If `howmny = A`, all eigenvectors are found. If `howmny = B`, all eigenvectors are found and backtransformed using `VL` and `VR`. If `howmny = S`, only the eigenvectors corresponding to the values in `select` are computed.

`LinearAlgebra.LAPACK.trrfs!` – Function.

```
| trrfs!(uplo, trans, diag, A, B, X, Ferr, Berr) -> (Ferr, Berr)
```

Estimates the error in the solution to $A * X = B$ (`trans = N`), $\text{transpose}(A) * X = B$ (`trans = T`), $\text{adjoint}(A) * X = B$ (`trans = C`) for `side = L`, or the equivalent equations a right-handed side $= R X * A$ after computing `X` using `trtrs!`. If `uplo = U`, `A` is upper triangular. If `uplo = L`, `A` is lower triangular. If `diag = N`, `A` has non-unit diagonal elements. If `diag = U`, all diagonal elements of `A` are one. `Ferr` and `Berr` are optional inputs. `Ferr` is the forward error and `Berr` is the backward error, each component-wise.

`LinearAlgebra.LAPACK.stev!` – Function.

```
| stev!(job, dv, ev) -> (dv, Zmat)
```

Computes the eigensystem for a symmetric tridiagonal matrix with `dv` as diagonal and `ev` as off-diagonal. If `job = N` only the eigenvalues are found and returned in `dv`. If `job = V` then the eigenvectors are also found and returned in `Zmat`.

`LinearAlgebra.LAPACK.stebz!` – Function.

```
| stebz!(range, order, vl, vu, il, iu, abstol, dv, ev) -> (dv, iblock, isplit)
```

Computes the eigenvalues for a symmetric tridiagonal matrix with `dv` as diagonal and `ev` as off-diagonal. If `range = A`, all the eigenvalues are found. If `range = V`, the eigenvalues in the half-open interval $(vl, vu]$ are found. If `range = I`, the eigenvalues with indices between `il` and `iu` are found. If `order = B`, eigenvalues are ordered within a block. If `order = E`, they are ordered across all the blocks. `abstol` can be set as a tolerance for convergence.

`LinearAlgebra.LAPACK.stegr!` – Function.

```
| stegr!(jobz, range, dv, ev, vl, vu, il, iu) -> (w, Z)
```

Computes the eigenvalues (`jobz = N`) or eigenvalues and eigenvectors (`jobz = V`) for a symmetric tridiagonal matrix with `dv` as diagonal and `ev` as off-diagonal. If `range = A`, all the eigenvalues are found. If `range = V`, the eigenvalues in the half-open interval $(vl, vu]$ are found. If `range = I`, the eigenvalues with indices between `il` and `iu` are found. The eigenvalues are returned in `w` and the eigenvectors in `Z`.

LinearAlgebra.LAPACK.stein! – Function.

```
| stein!(dv, ev_in, w_in, iblock_in, isplit_in)
```

Computes the eigenvectors for a symmetric tridiagonal matrix with `dv` as diagonal and `ev_in` as off-diagonal. `w_in` specifies the input eigenvalues for which to find corresponding eigenvectors. `iblock_in` specifies the submatrices corresponding to the eigenvalues in `w_in`. `isplit_in` specifies the splitting points between the submatrix blocks.

LinearAlgebra.LAPACK.syconv! – Function.

```
| syconv!(uplo, A, ipiv) -> (A, work)
```

Converts a symmetric matrix `A` (which has been factorized into a triangular matrix) into two matrices `L` and `D`. If `uplo = U`, `A` is upper triangular. If `uplo = L`, it is lower triangular. `ipiv` is the pivot vector from the triangular factorization. `A` is overwritten by `L` and `D`.

LinearAlgebra.LAPACK.sysv! – Function.

```
| sysv!(uplo, A, B) -> (B, A, ipiv)
```

Finds the solution to $A * X = B$ for symmetric matrix `A`. If `uplo = U`, the upper half of `A` is stored. If `uplo = L`, the lower half is stored. `B` is overwritten by the solution `X`. `A` is overwritten by its Bunch-Kaufman factorization. `ipiv` contains pivoting information about the factorization.

LinearAlgebra.LAPACK.sytrf! – Function.

```
| sytrf!(uplo, A) -> (A, ipiv, info)
```

Computes the Bunch-Kaufman factorization of a symmetric matrix `A`. If `uplo = U`, the upper half of `A` is stored. If `uplo = L`, the lower half is stored.

Returns `A`, overwritten by the factorization, a pivot vector `ipiv`, and the error code `info` which is a non-negative integer. If `info` is positive the matrix is singular and the diagonal part of the factorization is exactly zero at position `info`.

LinearAlgebra.LAPACK.sytri! – Function.

```
| sytri!(uplo, A, ipiv)
```

Computes the inverse of a symmetric matrix `A` using the results of `sytrf!`. If `uplo = U`, the upper half of `A` is stored. If `uplo = L`, the lower half is stored. `A` is overwritten by its inverse.

LinearAlgebra.LAPACK.sytrs! – Function.

```
| sytrs!(uplo, A, ipiv, B)
```

Solves the equation $A * X = B$ for a symmetric matrix `A` using the results of `sytrf!`. If `uplo = U`, the upper half of `A` is stored. If `uplo = L`, the lower half is stored. `B` is overwritten by the solution `X`.

LinearAlgebra.LAPACK.hesv! – Function.

```
| hesv!(uplo, A, B) -> (B, A, ipiv)
```

Finds the solution to $A * X = B$ for Hermitian matrix A . If `uplo = U`, the upper half of A is stored. If `uplo = L`, the lower half is stored. B is overwritten by the solution X . A is overwritten by its Bunch-Kaufman factorization. `ipiv` contains pivoting information about the factorization.

`LinearAlgebra.LAPACK.hetrf!` - Function.

```
| hetrf!(uplo, A) -> (A, ipiv, info)
```

Computes the Bunch-Kaufman factorization of a Hermitian matrix A . If `uplo = U`, the upper half of A is stored. If `uplo = L`, the lower half is stored.

Returns A , overwritten by the factorization, a pivot vector `ipiv`, and the error code `info` which is a non-negative integer. If `info` is positive the matrix is singular and the diagonal part of the factorization is exactly zero at position `info`.

`LinearAlgebra.LAPACK.hetri!` - Function.

```
| hetri!(uplo, A, ipiv)
```

Computes the inverse of a Hermitian matrix A using the results of `sytrf!`. If `uplo = U`, the upper half of A is stored. If `uplo = L`, the lower half is stored. A is overwritten by its inverse.

`LinearAlgebra.LAPACK.hetrs!` - Function.

```
| hetrs!(uplo, A, ipiv, B)
```

Solves the equation $A * X = B$ for a Hermitian matrix A using the results of `sytrf!`. If `uplo = U`, the upper half of A is stored. If `uplo = L`, the lower half is stored. B is overwritten by the solution X .

`LinearAlgebra.LAPACK.syev!` - Function.

```
| syev!(jobz, uplo, A)
```

Finds the eigenvalues (`jobz = N`) or eigenvalues and eigenvectors (`jobz = V`) of a symmetric matrix A . If `uplo = U`, the upper triangle of A is used. If `uplo = L`, the lower triangle of A is used.

`LinearAlgebra.LAPACK.syevr!` - Function.

```
| syevr!(jobz, range, uplo, A, vl, vu, il, iu, abstol) -> (W, Z)
```

Finds the eigenvalues (`jobz = N`) or eigenvalues and eigenvectors (`jobz = V`) of a symmetric matrix A . If `uplo = U`, the upper triangle of A is used. If `uplo = L`, the lower triangle of A is used. If `range = A`, all the eigenvalues are found. If `range = V`, the eigenvalues in the half-open interval $(vl, vu]$ are found. If `range = I`, the eigenvalues with indices between `il` and `iu` are found. `abstol` can be set as a tolerance for convergence.

The eigenvalues are returned in W and the eigenvectors in Z .

`LinearAlgebra.LAPACK.syevd!` - Function.

```
| syevd!(jobz, uplo, A)
```

Finds the eigenvalues (`jobz = N`) or eigenvalues and eigenvectors (`jobz = V`) of a symmetric matrix A . If `uplo = U`, the upper triangle of A is used. If `uplo = L`, the lower triangle of A is used.

Use the divide-and-conquer method, instead of the QR iteration used by `syev!` or multiple relatively robust representations used by `syevr!`. See James W. Demmel et al, SIAM J. Sci. Comput. 30, 3, 1508 (2008) for a comparison of the accuracy and performance of different methods.

LinearAlgebra.LAPACK.sygvd! – Function.

```
| sygvd!(itype, jobz, uplo, A, B) -> (w, A, B)
```

Finds the generalized eigenvalues ($\text{jobz} = \text{N}$) or eigenvalues and eigenvectors ($\text{jobz} = \text{V}$) of a symmetric matrix A and symmetric positive-definite matrix B . If $\text{uplo} = \text{U}$, the upper triangles of A and B are used. If $\text{uplo} = \text{L}$, the lower triangles of A and B are used. If $\text{itype} = 1$, the problem to solve is $A * x = \lambda * B * x$. If $\text{itype} = 2$, the problem to solve is $A * B * x = \lambda * x$. If $\text{itype} = 3$, the problem to solve is $B * A * x = \lambda * x$.

LinearAlgebra.LAPACK.bdsqr! – Function.

```
| bdsqr!(uplo, d, e_, Vt, U, C) -> (d, Vt, U, C)
```

Computes the singular value decomposition of a bidiagonal matrix with d on the diagonal and $e_$ on the off-diagonal. If $\text{uplo} = \text{U}$, $e_$ is the superdiagonal. If $\text{uplo} = \text{L}$, $e_$ is the subdiagonal. Can optionally also compute the product $Q' * C$.

Returns the singular values in d , and the matrix C overwritten with $Q' * C$.

LinearAlgebra.LAPACK.bdsdc! – Function.

```
| bdsdc!(uplo, compq, d, e_) -> (d, e, u, vt, q, iq)
```

Computes the singular value decomposition of a bidiagonal matrix with d on the diagonal and $e_$ on the off-diagonal using a divide and conquer method. If $\text{uplo} = \text{U}$, $e_$ is the superdiagonal. If $\text{uplo} = \text{L}$, $e_$ is the subdiagonal. If $\text{compq} = \text{N}$, only the singular values are found. If $\text{compq} = \text{I}$, the singular values and vectors are found. If $\text{compq} = \text{P}$, the singular values and vectors are found in compact form. Only works for real types.

Returns the singular values in d , and if $\text{compq} = \text{P}$, the compact singular vectors in iq .

LinearAlgebra.LAPACK.gecon! – Function.

```
| gecon!(normtype, A, anorm)
```

Finds the reciprocal condition number of matrix A . If $\text{normtype} = \text{I}$, the condition number is found in the infinity norm. If $\text{normtype} = 0$ or 1 , the condition number is found in the one norm. A must be the result of `getrf!` and anorm is the norm of A in the relevant norm.

LinearAlgebra.LAPACK.gehrd! – Function.

```
| gehrd!(ilo, ihi, A) -> (A, tau)
```

Converts a matrix A to Hessenberg form. If A is balanced with `gebal!` then ilo and ihi are the outputs of `gebal!`. Otherwise they should be $\text{ilo} = 1$ and $\text{ihi} = \text{size}(A, 2)$. tau contains the elementary reflectors of the factorization.

LinearAlgebra.LAPACK.orghr! – Function.

```
| orghr!(ilo, ihi, A, tau)
```

Explicitly finds Q , the orthogonal/unitary matrix from `gehrd!`. ilo , ihi , A , and tau must correspond to the input/output to `gehrd!`.

`LinearAlgebra.LAPACK.gees!` – Function.

```
| gees!(jobvs, A) -> (A, vs, w)
```

Computes the eigenvalues (`jobvs = N`) or the eigenvalues and Schur vectors (`jobvs = V`) of matrix `A`. `A` is overwritten by its Schur form.

Returns `A`, `vs` containing the Schur vectors, and `w`, containing the eigenvalues.

`LinearAlgebra.LAPACK.gges!` – Function.

```
| gges!(jobvsl, jobvsr, A, B) -> (A, B, alpha, beta, vsl, vsr)
```

Computes the generalized eigenvalues, generalized Schur form, left Schur vectors (`jobvsl = V`), or right Schur vectors (`jobvsr = V`) of `A` and `B`.

The generalized eigenvalues are returned in `alpha` and `beta`. The left Schur vectors are returned in `vsl` and the right Schur vectors are returned in `vsr`.

`LinearAlgebra.LAPACK.gges3!` – Function.

```
| gges3!(jobvsl, jobvsr, A, B) -> (A, B, alpha, beta, vsl, vsr)
```

Computes the generalized eigenvalues, generalized Schur form, left Schur vectors (`jobvsl = V`), or right Schur vectors (`jobvsr = V`) of `A` and `B` using a blocked algorithm. This function requires LAPACK 3.6.0.

The generalized eigenvalues are returned in `alpha` and `beta`. The left Schur vectors are returned in `vsl` and the right Schur vectors are returned in `vsr`.

`LinearAlgebra.LAPACK.trexc!` – Function.

```
| trexc!(compq, ifst, ilst, T, Q) -> (T, Q)
| trexc!(ifst, ilst, T, Q) -> (T, Q)
```

Reorder the Schur factorization `T` of a matrix, such that the diagonal block of `T` with row index `ifst` is moved to row index `ilst`. If `compq = V`, the Schur vectors `Q` are reordered. If `compq = N` they are not modified. The 4-arg method calls the 5-arg method with `compq = V`.

`LinearAlgebra.LAPACK.trsen!` – Function.

```
| trsen!(job, compq, select, T, Q) -> (T, Q, w, s, sep)
| trsen!(select, T, Q) -> (T, Q, w, s, sep)
```

Reorder the Schur factorization of a matrix and optionally finds reciprocal condition numbers. If `job = N`, no condition numbers are found. If `job = E`, only the condition number for this cluster of eigenvalues is found. If `job = V`, only the condition number for the invariant subspace is found. If `job = B` then the condition numbers for the cluster and subspace are found. If `compq = V` the Schur vectors `Q` are updated. If `compq = N` the Schur vectors are not modified. `select` determines which eigenvalues are in the cluster. The 3-arg method calls the 5-arg method with `job = N` and `compq = V`.

Returns `T`, `Q`, reordered eigenvalues in `w`, the condition number of the cluster of eigenvalues `s`, and the condition number of the invariant subspace `sep`.

`LinearAlgebra.LAPACK.tgsen!` – Function.

```
| tgsen!(select, S, T, Q, Z) -> (S, T, alpha, beta, Q, Z)
```

Reorders the vectors of a generalized Schur decomposition. select specifies the eigenvalues in each cluster.

LinearAlgebra.LAPACK.trsyl! - Function.

```
| tsyl!(transa, transb, A, B, C, isgn=1) -> (C, scale)
```

Solves the Sylvester matrix equation $A * X +/- X * B = scale * C$ where A and B are both quasi-upper triangular. If transa = N, A is not modified. If transa = T, A is transposed. If transa = C, A is conjugate transposed. Similarly for transb and B. If isgn = 1, the equation $A * X + X * B = scale * C$ is solved. If isgn = -1, the equation $A * X - X * B = scale * C$ is solved.

Returns X (overwriting C) and scale.

LinearAlgebra.LAPACK.hseqr! - Function.

```
| hseqr!(job, compz, ilo, ihi, H, Z) -> (H, Z, w)
```

Computes all eigenvalues and (optionally) the Schur factorization of a matrix reduced to Hessenberg form. If H is balanced with gebal! then ilo and ihi are the outputs of gebal!. Otherwise they should be ilo = 1 and ihi = size(H,2). tau contains the elementary reflectors of the factorization.

Chapter 79

Logging

The `Logging` module provides a way to record the history and progress of a computation as a log of events. Events are created by inserting a logging statement into the source code, for example:

```
| @warn "Abandon printf debugging, all ye who enter here!"  
| r Warning: Abandon printf debugging, all ye who enter here!  
| L @ Main REPL[1]:1
```

The system provides several advantages over peppering your source code with calls to `println()`. First, it allows you to control the visibility and presentation of messages without editing the source code. For example, in contrast to the `@warn` above

```
| @debug "The sum of some values $(sum(rand(100)))"
```

will produce no output by default. Furthermore, it's very cheap to leave debug statements like this in the source code because the system avoids evaluating the message if it would later be ignored. In this case `sum(rand(100))` and the associated string processing will never be executed unless debug logging is enabled.

Second, the logging tools allow you to attach arbitrary data to each event as a set of key-value pairs. This allows you to capture local variables and other program state for later analysis. For example, to attach the local array variable `A` and the sum of a vector `v` as the key `s` you can use

```
| A = ones(Int, 4, 4)  
| v = ones(100)  
| @info "Some variables" A s=sum(v)  
  
# output  
| r Info: Some variables  
| | A =  
| | 4×4 Matrix{Int64}:  
| | 1 1 1 1  
| | 1 1 1 1  
| | 1 1 1 1  
| | 1 1 1 1  
| L s = 100.0
```

All of the logging macros `@debug`, `@info`, `@warn` and `@error` share common features that are described in detail in the documentation for the more general macro `@logmsg`.

79.1 Log event structure

Each event generates several pieces of data, some provided by the user and some automatically extracted. Let's examine the user-defined data first:

- The log level is a broad category for the message that is used for early filtering. There are several standard levels of type `LogLevel`; user-defined levels are also possible. Each is distinct in purpose:
 - `Logging.Debug` (log level -1000) is information intended for the developer of the program. These events are disabled by default.
 - `Logging.Info` (log level 0) is for general information to the user. Think of it as an alternative to using `println` directly.
 - `Logging.Warn` (log level 1000) means something is wrong and action is likely required but that for now the program is still working.
 - `Logging.Error` (log level 2000) means something is wrong and it is unlikely to be recovered, at least by this part of the code. Often this log-level is unneeded as throwing an exception can convey all the required information.
- The message is an object describing the event. By convention `AbstractStrings` passed as messages are assumed to be in markdown format. Other types will be displayed using `print(io, obj)` or `string(obj)` for text-based output and possibly `show(io, mime, obj)` for other multimedia displays used in the installed logger.
- Optional key-value pairs allow arbitrary data to be attached to each event. Some keys have conventional meaning that can affect the way an event is interpreted (see `@logmsg`).

The system also generates some standard information for each event:

- The module in which the logging macro was expanded.
- The file and line where the logging macro occurs in the source code.
- A message id that is a unique, fixed identifier for the source code statement where the logging macro appears. This identifier is designed to be fairly stable even if the source code of the file changes, as long as the logging statement itself remains the same.
- A group for the event, which is set to the base name of the file by default, without extension. This can be used to group messages into categories more finely than the log level (for example, all deprecation warnings have group `:depwarn`), or into logical groupings across or within modules.

Notice that some useful information such as the event time is not included by default. This is because such information can be expensive to extract and is also dynamically available to the current logger. It's simple to define a `custom logger` to augment event data with the time, backtrace, values of global variables and other useful information as required.

79.2 Processing log events

As you can see in the examples, logging statements make no mention of where log events go or how they are processed. This is a key design feature that makes the system composable and natural for concurrent use. It does this by separating two different concerns:

- Creating log events is the concern of the module author who needs to decide where events are triggered and which information to include.
- Processing of log events — that is, display, filtering, aggregation and recording — is the concern of the application author who needs to bring multiple modules together into a cooperating application.

Loggers

Processing of events is performed by a logger, which is the first piece of user configurable code to see the event. All loggers must be subtypes of [AbstractLogger](#).

When an event is triggered, the appropriate logger is found by looking for a task-local logger with the global logger as fallback. The idea here is that the application code knows how log events should be processed and exists somewhere at the top of the call stack. So we should look up through the call stack to discover the logger — that is, the logger should be dynamically scoped. (This is a point of contrast with logging frameworks where the logger is lexically scoped; provided explicitly by the module author or as a simple global variable. In such a system it's awkward to control logging while composing functionality from multiple modules.)

The global logger may be set with [global_logger](#), and task-local loggers controlled using [with_logger](#). Newly spawned tasks inherit the logger of the parent task.

There are three logger types provided by the library. [ConsoleLogger](#) is the default logger you see when starting the REPL. It displays events in a readable text format and tries to give simple but user friendly control over formatting and filtering. [NullLogger](#) is a convenient way to drop all messages where necessary; it is the logging equivalent of the `devnull` stream. [SimpleLogger](#) is a very simplistic text formatting logger, mainly useful for debugging the logging system itself.

Custom loggers should come with overloads for the functions described in the [reference section](#).

Early filtering and message handling

When an event occurs, a few steps of early filtering occur to avoid generating messages that will be discarded:

1. The message log level is checked against a global minimum level (set via [disable_logging](#)). This is a crude but extremely cheap global setting.
2. The current logger state is looked up and the message level checked against the logger's cached minimum level, as found by calling [Logging.min_enabled_level](#). This behavior can be overridden via environment variables (more on this later).
3. The [Logging.shouldlog](#) function is called with the current logger, taking some minimal information (level, module, group, id) which can be computed statically. Most usefully, `shouldlog` is passed an event id which can be used to discard events early based on a cached predicate.

If all these checks pass, the message and key-value pairs are evaluated in full and passed to the current logger via the `Logging.handle_message` function. `handle_message()` may perform additional filtering as required and display the event to the screen, save it to a file, etc.

Exceptions that occur while generating the log event are captured and logged by default. This prevents individual broken events from crashing the application, which is helpful when enabling little-used debug events in a production system. This behavior can be customized per logger type by extending `Logging.catch_exceptions`.

79.3 Testing log events

Log events are a side effect of running normal code, but you might find yourself wanting to test particular informational messages and warnings. The Test module provides a `@test_logs` macro that can be used to pattern match against the log event stream.

79.4 Environment variables

Message filtering can be influenced through the `JULIA_DEBUG` environment variable, and serves as an easy way to enable debug logging for a file or module. Loading julia with `JULIA_DEBUG=loading` will activate `@debug` log messages in `loading.jl`. For example, in Linux shells:

```
$ JULIA_DEBUG=loading julia -e 'using OhMyREPL'
Debug: Rejecting cache file /home/user/.julia/compiled/v0.7/OhMyREPL.ji due to it containing an
      invalid cache header
@ Base loading.jl:1328
[ Info: Recompiling stale cache file /home/user/.julia/compiled/v0.7/OhMyREPL.ji for module
      OhMyREPL
Debug: Rejecting cache file /home/user/.julia/compiled/v0.7/Tokenize.ji due to it containing an
      invalid cache header
@ Base loading.jl:1328
...
```

On windows, the same can be achieved in CMD via first running `set JULIA_DEBUG="loading"` and in Powershell via `$env:JULIA_DEBUG="loading"`.

Similarly, the environment variable can be used to enable debug logging of modules, such as `Pkg`, or module roots (see `Base.moduleroot`). To enable all debug logging, use the special value `all`.

To turn debug logging on from the REPL, set `ENV["JULIA_DEBUG"]` to the name of the module of interest. Functions defined in the REPL belong to module `Main`; logging for them can be enabled like this:

```
julia> foo() = @debug "foo"
foo (generic function with 1 method)

julia> foo()

julia> ENV["JULIA_DEBUG"] = Main
Main

julia> foo()
└ Debug: foo
  └ @ Main REPL[1]:1
```

Use a comma separator to enable debug for multiple modules: `JULIA_DEBUG=loading,Main`.

79.5 Examples

Example: Writing log events to a file

Sometimes it can be useful to write log events to a file. Here is an example of how to use a task-local and global logger to write information to a text file:

```
# Load the logging module
julia> using Logging

# Open a textfile for writing
julia> io = open("log.txt", "w+")
IOStream(<file log.txt>)

# Create a simple logger
julia> logger = SimpleLogger(io)
SimpleLogger(IOStream(<file log.txt>), Info, Dict{Any,Int64}())

# Log a task-specific message
julia> with_logger(logger) do
    @info("a context specific log message")
end

# Write all buffered messages to the file
julia> flush(io)

# Set the global logger to logger
julia> global_logger(logger)
SimpleLogger(IOStream(<file log.txt>), Info, Dict{Any,Int64}())

# This message will now also be written to the file
julia> @info("a global log message")

# Close the file
julia> close(io)
```

Example: Enable debug-level messages

Here is an example of creating a `ConsoleLogger` that lets through any messages with log level higher than, or equal, to `Logging.Debug`.

```
julia> using Logging

# Create a ConsoleLogger that prints any log messages with level >= Debug to stderr
julia> debuglogger = ConsoleLogger(stderr, Logging.Debug)

# Enable debuglogger for a task
julia> with_logger(debuglogger) do
    @debug "a context specific log message"
end
```

```
# Set the global logger
julia> global_logger(debuglogger)
```

79.6 Reference

Logging module

Logging.Logging – Module.

Utilities for capturing, filtering and presenting streams of log events. Normally you don't need to import Logging to create log events; for this the standard logging macros such as `@info` are already exported by Base and available by default.

Creating events

Logging.@logmsg – Macro.

```
@debug message [key=value | value ...]
@info  message [key=value | value ...]
@warn  message [key=value | value ...]
@error message [key=value | value ...]

@logmsg level message [key=value | value ...]
```

Create a log record with an informational message. For convenience, four logging macros `@debug`, `@info`, `@warn` and `@error` are defined which log at the standard severity levels Debug, Info, Warn and Error. `@logmsg` allows `level` to be set programmatically to any `LogLevel` or custom log level types.

`message` should be an expression which evaluates to a string which is a human readable description of the log event. By convention, this string will be formatted as markdown when presented.

The optional list of `key=value` pairs supports arbitrary user defined metadata which will be passed through to the logging backend as part of the log record. If only a `value` expression is supplied, a key representing the expression will be generated using [Symbol](#). For example, `x` becomes `x=x`, and `foo(10)` becomes `Symbol("foo(10)")=foo(10)`. For splatting a list of key value pairs, use the normal splatting syntax, `@info "blah" kws...`.

There are some keys which allow automatically generated log data to be overridden:

- `_module=mod` can be used to specify a different originating module from the source location of the message.
- `_group=symbol` can be used to override the message group (this is normally derived from the base name of the source file).
- `_id=symbol` can be used to override the automatically generated unique message identifier. This is useful if you need to very closely associate messages generated on different source lines.
- `_file=string` and `_line=integer` can be used to override the apparent source location of a log message.

There's also some key value pairs which have conventional meaning:

- `maxlog=integer` should be used as a hint to the backend that the message should be displayed no more than `maxlog` times.
- `exception=ex` should be used to transport an exception with a log message, often used with `@error`. An associated backtrace `bt` may be attached using the tuple `exception=(ex, bt)`.

Examples

```
@debug "Verbose debugging information. Invisible by default"
@info "An informational message"
@warn "Something was odd. You should pay attention"
@error "A non fatal error occurred"

x = 10
@info "Some variables attached to the message" x a=42.0

@debug begin
    sA = sum(A)
    "sum(A) = $sA is an expensive operation, evaluated only when `shouldlog` returns true"
end

for i=1:10000
    @info "With the default backend, you will only see (i = $i) ten times" maxlog=10
    @debug "Algorithm1" i progress=i/10000
end
```

source

Logging.LogLevel – Type.

```
| LogLevel(level)
```

Severity/verbosity of a log record.

The log level provides a key against which potential log records may be filtered, before any other work is done to construct the log record data structure itself.

Examples

```
| julia> Logging.LogLevel(0) == Logging.Info
true
```

source

Logging.Debug – Constant.

```
| Debug
```

Alias for `LogLevel(-1000)`.

Logging.Info – Constant.

```
| Info
```

Alias for `LogLevel(0)`.

Logging.Warn – Constant.

```
| Warn
```

Alias for `LogLevel(1000)`.

Logging.Error – Constant.

```
| Error
```

Alias for `LogLevel(2000)`.

Processing events with AbstractLogger

Event processing is controlled by overriding functions associated with AbstractLogger:

| Methods to implement | | Brief description |
|--|--------------------|--|
| <code>Logging.handle_message</code> | | Handle a log event |
| <code>Logging.shouldlog</code> | | Early filtering of events |
| <code>Logging.min_enabled_level</code> | | Lower bound for log level of accepted events |
| Optional methods | Default definition | Brief description |
| <code>Logging.catch_exceptions</code> | true | Catch exceptions during event evaluation |

Logging.AbstractLogger – Type.

A logger controls how log records are filtered and dispatched. When a log record is generated, the logger is the first piece of user configurable code which gets to inspect the record and decide what to do with it.

[source](#)

Logging.handle_message – Function.

```
| handle_message(logger, level, message, _module, group, id, file, line; key1=val1, ...)
```

Log a message to logger at level. The logical location at which the message was generated is given by module `_module` and group; the source location by `file` and `line`. `id` is an arbitrary unique value (typically a [Symbol](#)) to be used as a key to identify the log statement when filtering.

[source](#)

Logging.shouldlog – Function.

```
| shouldlog(logger, level, _module, group, id)
```

Return true when logger accepts a message at level, generated for `_module`, group and with unique log identifier `id`.

[source](#)

Logging.min_enabled_level – Function.

```
| min_enabled_level(logger)
```

Return the minimum enabled level for logger for early filtering. That is, the log level below or equal to which all messages are filtered.

[source](#)

`Logging.catch_exceptions` – Function.

```
| catch_exceptions(logger)
```

Return true if the logger should catch exceptions which happen during log record construction. By default, messages are caught

By default all exceptions are caught to prevent log message generation from crashing the program. This lets users confidently toggle little-used functionality - such as debug logging - in a production system.

If you want to use logging as an audit trail you should disable this for your logger type.

[source](#)

`Logging.disable_logging` – Function.

```
| disable_logging(level)
```

Disable all log messages at log levels equal to or less than `level`. This is a global setting, intended to make debug logging extremely cheap when disabled.

Examples

```
| Logging.disable_logging(Logging.Info) # Disable debug and info
```

[source](#)

Using Loggers

Logger installation and inspection:

`Logging.global_logger` – Function.

```
| global_logger()
```

Return the global logger, used to receive messages when no specific logger exists for the current task.

```
| global_logger(logger)
```

Set the global logger to `logger`, and return the previous global logger.

[source](#)

`Logging.with_logger` – Function.

```
| with_logger(function, logger)
```

Execute `function`, directing all log messages to `logger`.

Example

```
function test(x)
    @info "x = $x"
end

with_logger(logger) do
    test(1)
    test([1,2])
end
```

source

Logging.current_logger - Function.

```
| current_logger()
```

Return the logger for the current task, or the global logger if none is attached to the task.

source

Loggers that are supplied with the system:

Logging.NullLogger - Type.

```
| NullLogger()
```

Logger which disables all messages and produces no output - the logger equivalent of /dev/null.

source

Logging.ConsoleLogger - Type.

```
| ConsoleLogger([stream,] min_level=Info; meta_formatter=default_metafmt,
                 show_limited=true, right_justify=0)
```

Logger with formatting optimized for readability in a text console, for example interactive work with the Julia REPL.

Log levels less than `min_level` are filtered out.

Message formatting can be controlled by setting keyword arguments:

- `meta_formatter` is a function which takes the log event metadata (`level`, `_module`, `group`, `id`, `file`, `line`) and returns a color (as would be passed to `printstyled`), prefix and suffix for the log message. The default is to prefix with the log level and a suffix containing the module, file and line location.
- `show_limited` limits the printing of large data structures to something which can fit on the screen by setting the `:limit` `IOContext` key during formatting.
- `right_justify` is the integer column which log metadata is right justified at. The default is zero (metadata goes on its own line).

Logging.SimpleLogger - Type.

```
| SimpleLogger([stream,] min_level=Info)
```

Simplistic logger for logging all messages with level greater than or equal to `min_level` to `stream`. If `stream` is closed then messages with log level greater or equal to `Warn` will be logged to `stderr` and below to `stdout`.

[source](#)

Chapter 80

Markdown

This section describes Julia's markdown syntax, which is enabled by the Markdown standard library. The following Markdown elements are supported:

80.1 Inline elements

Here "inline" refers to elements that can be found within blocks of text, i.e. paragraphs. These include the following elements.

Bold

Surround words with two asterisks, ******, to display the enclosed text in boldface.

| A paragraph containing a **bold** word.

Italics

Surround words with one asterisk, *****, to display the enclosed text in italics.

| A paragraph containing an *italicized* word.

Literals

Surround text that should be displayed exactly as written with single backticks, **`**.

| A paragraph containing a `literal` word.

Literals should be used when writing text that refers to names of variables, functions, or other parts of a Julia program.

Tip

To include a backtick character within literal text use three backticks rather than one to enclose the text.

| A paragraph containing ``` `backtick` characters ```.

By extension any odd number of backticks may be used to enclose a lesser number of backticks.

L^AT_EX

Surround text that should be displayed as mathematics using L^AT_EX syntax with double backticks, ``.

| A paragraph containing some ``\LaTeX`` markup.

Tip

As with literals in the previous section, if literal backticks need to be written within double backticks use an even number greater than two. Note that if a single literal backtick needs to be included within L^AT_EX markup then two enclosing backticks is sufficient.

Note

The \ character should be escaped appropriately if the text is embedded in a Julia source code, for example, "``\LaTeX`` syntax in a docstring.", since it is interpreted as a string literal. Alternatively, in order to avoid escaping, it is possible to use the raw string macro together with the @doc macro:

```
|@doc raw"``\LaTeX`` syntax in a docstring." functionname
```

Links

Links to either external or internal targets can be written using the following syntax, where the text enclosed in square brackets, [], is the name of the link and the text enclosed in parentheses, (), is the URL.

| A paragraph containing a link to [Julia](http://www.julialang.org).

It's also possible to add cross-references to other documented functions/methods/variables within the Julia documentation itself. For example:

```
"""
    tryparse(type, str; base)

Like [parse](@ref), but returns either a value of the requested type,
or [nothing](@ref) if the string does not contain a valid number.
"""
```

This will create a link in the generated docs to the [parse](#) documentation (which has more information about what this function actually does), and to the [nothing](#) documentation. It's good to include cross references to mutating/non-mutating versions of a function, or to highlight a difference between two similar-seeming functions.

Note

The above cross referencing is not a Markdown feature, and relies on [Documenter.jl](#), which is used to build base Julia's documentation.

Footnote references

Named and numbered footnote references can be written using the following syntax. A footnote name must be a single alphanumeric word containing no punctuation.

| A paragraph containing a numbered footnote [^1] and a named one [^named].

Note

The text associated with a footnote can be written anywhere within the same page as the footnote reference. The syntax used to define the footnote text is discussed in the [Footnotes](#) section below.

80.2 Toplevel elements

The following elements can be written either at the "toplevel" of a document or within another "toplevel" element.

Paragraphs

A paragraph is a block of plain text, possibly containing any number of inline elements defined in the [Inline elements](#) section above, with one or more blank lines above and below it.

| This is a paragraph.

| And this is **another** paragraph containing some emphasized text.
| A new line, but still part of the same paragraph.

Headers

A document can be split up into different sections using headers. Headers use the following syntax:

```
| # Level One  
| ## Level Two  
| ### Level Three  
| #### Level Four  
| ##### Level Five  
| ##### Level Six
```

A header line can contain any inline syntax in the same way as a paragraph can.

Tip

Try to avoid using too many levels of header within a single document. A heavily nested document may be indicative of a need to restructure it or split it into several pages covering separate topics.

Code blocks

Source code can be displayed as a literal block using an indent of four spaces as shown in the following example.

```
This is a paragraph.  
  
    function func(x)  
        # ...  
    end  
  
Another paragraph.
```

Additionally, code blocks can be enclosed using triple backticks with an optional "language" to specify how a block of code should be highlighted.

```
A code block without a "language":  
  
```  
function func(x)
 # ...
end
```  
  
and another one with the "language" specified as `julia`:  
  
```julia  
function func(x)
 # ...
end
```
```

Note

"Fenced" code blocks, as shown in the last example, should be preferred over indented code blocks since there is no way to specify what language an indented code block is written in.

Block quotes

Text from external sources, such as quotations from books or websites, can be quoted using > characters prepended to each line of the quote as follows.

```
Here's a quote:  
  
> Julia is a high-level, high-performance dynamic programming language for  
> technical computing, with syntax that is familiar to users of other  
> technical computing environments.
```

Note that a single space must appear after the > character on each line. Quoted blocks may themselves contain other toplevel or inline elements.

Images

The syntax for images is similar to the link syntax mentioned above. Prepending a ! character to a link will display an image from the specified URL rather than a link to it.

```
| ![alternative text](link/to/image.png)
```

Lists

Unordered lists can be written by prepending each item in a list with either *, +, or -.

```
| A list of items:
```

```
| * item one
| * item two
| * item three
```

Note the two spaces before each * and the single space after each one.

Lists can contain other nested toplevel elements such as lists, code blocks, or quoteblocks. A blank line should be left between each list item when including any toplevel elements within a list.

```
| Another list:
```

```
| * item one
|
| * item two
|
|   ``
|   f(x) = x
|   ``
|
| * And a sublist:
|
|   + sub-item one
|   + sub-item two
```

Note

The contents of each item in the list must line up with the first line of the item. In the above example the fenced code block must be indented by four spaces to align with the i in item two.

Ordered lists are written by replacing the "bullet" character, either *, +, or -, with a positive integer followed by either . or).

```
| Two ordered lists:
```

```
| 1. item one
| 2. item two
| 3. item three
|
| 5) item five
| 6) item six
| 7) item seven
```

An ordered list may start from a number other than one, as in the second list of the above example, where it is numbered from five. As with unordered lists, ordered lists can contain nested toplevel elements.

Display equations

Large \LaTeX equations that do not fit inline within a paragraph may be written as display equations using a fenced code block with the "language" `math` as in the example below.

```
```math
f(a) = \frac{1}{2\pi} \int_0^{2\pi} (\alpha + R \cos(\theta)) d\theta
```
```

Footnotes

This syntax is paired with the inline syntax for [Footnote references](#). Make sure to read that section as well.

Footnote text is defined using the following syntax, which is similar to footnote reference syntax, aside from the `:` character that is appended to the footnote label.

```
[^1]: Numbered footnote text.

[^note]:

    Named footnote text containing several toplevel elements.

    * item one
    * item two
    * item three

```julia
function func(x)
 # ...
end
```
```

Note

No checks are done during parsing to make sure that all footnote references have matching footnotes.

Horizontal rules

The equivalent of an `<hr>` HTML tag can be achieved using three hyphens (`---`). For example:

```
Text above the line.

---

And text below the line.
```

Tables

Basic tables can be written using the syntax described below. Note that markdown tables have limited features and cannot contain nested toplevel elements unlike other elements discussed above – only inline elements are allowed. Tables must always contain a header row with column names. Cells cannot span multiple rows or columns of the table.

```
Column One	Column Two	Column Three
Row `1`	Column `2`	
*Row* 2	**Row** 2	Column ``3``
```

Note

As illustrated in the above example each column of | characters must be aligned vertically.

A : character on either end of a column's header separator (the row containing - characters) specifies whether the row is left-aligned, right-aligned, or (when : appears on both ends) center-aligned. Providing no : characters will default to right-aligning the column.

Admonitions

Specially formatted blocks, known as admonitions, can be used to highlight particular remarks. They can be defined using the following !!! syntax:

```
!!! note

    This is the content of the note.

!!! warning "Beware!"

    And this is another one.

    This warning admonition has a custom title: ` "Beware!" `.
```

The first word after !!! declares the type of the admonition. There are standard admonition types that should produce special styling. Namely (in order of decreasing severity): danger, warning, info/note, and tip.

You can also use your own admonition types, as long as the type name only contains lowercase Latin characters (a-z). For example, you could have a terminology block like this:

```
!!! terminology "julia vs Julia"

    Strictly speaking, "Julia" refers to the language,
    and "julia" to the standard implementation.
```

However, unless the code rendering the Markdown special-cases that particular admonition type, it will get the default styling.

A custom title for the box can be provided as a string (in double quotes) after the admonition type. If no title text is specified after the admonition type, then the type name will be used as the title (e.g. "Note" for the note admonition).

Admonitions, like most other toplevel elements, can contain other toplevel elements (e.g. lists, images).

80.3 Markdown Syntax Extensions

Julia's markdown supports interpolation in a very similar way to basic string literals, with the difference that it will store the object itself in the Markdown tree (as opposed to converting it to a string). When the Markdown content is rendered the usual show methods will be called, and these can be overridden

as usual. This design allows the Markdown to be extended with arbitrarily complex features (such as references) without cluttering the basic syntax.

In principle, the Markdown parser itself can also be arbitrarily extended by packages, or an entirely custom flavour of Markdown can be used, but this should generally be unnecessary.

Chapter 81

Memory-mapped I/O

Low level module for mmap (memory mapping of files).

Mmap.[Anonymous](#) – Type.

```
Mmap.Anonymous(name::AbstractString="", readonly::Bool=false, create::Bool=true)
```

Create an IO-like object for creating zeroed-out mmaped-memory that is not tied to a file for use in [mmap](#). Used by [SharedArray](#) for creating shared memory arrays.

Examples

```
julia> using Mmap

julia> anon = Mmap.Anonymous();

julia> isreadable(anon)
true

julia> iswritable(anon)
true

julia> isopen(anon)
true
```

Mmap.[mmap](#) – Function.

```
mmap(io::Union{IOStream,AbstractString,Mmap.AnonymousMmap}{}, type::Type{Array{T,N}}, dims,
↪ offset); grow::Bool=true, shared::Bool=true)
mmap(type::Type{Array{T,N}}, dims)
```

Create an Array whose values are linked to a file, using memory-mapping. This provides a convenient way of working with data too large to fit in the computer's memory.

The type is an `Array{T,N}` with a bits-type element of `T` and dimension `N` that determines how the bytes of the array are interpreted. Note that the file must be stored in binary format, and no format conversions are possible (this is a limitation of operating systems, not Julia).

`dims` is a tuple or single [Integer](#) specifying the size or length of the array.

The file is passed via the stream argument, either as an open `IOStream` or filename string. When you initialize the stream, use "r" for a "read-only" array, and "w+" to create a new array used to write values to disk.

If no type argument is specified, the default is `Vector{UInt8}`.

Optionally, you can specify an offset (in bytes) if, for example, you want to skip over a header in the file. The default value for the offset is the current stream position for an `IOStream`.

The `grow` keyword argument specifies whether the disk file should be grown to accommodate the requested size of array (if the total file size is < requested array size). Write privileges are required to grow the file.

The `shared` keyword argument specifies whether the resulting Array and changes made to it will be visible to other processes mapping the same file.

For example, the following code

```
# Create a file for mmaping
# (you could alternatively use mmap to do this step, too)
using Mmap
A = rand(1:20, 5, 30)
s = open("/tmp/mmap.bin", "w+")
# We'll write the dimensions of the array as the first two Ints in the file
write(s, size(A,1))
write(s, size(A,2))
# Now write the data
write(s, A)
close(s)

# Test by reading it back in
s = open("/tmp/mmap.bin") # default is read-only
m = read(s, Int)
n = read(s, Int)
A2 = mmap(s, Matrix{Int}, (m,n))
```

creates a m-by-n `Matrix{Int}`, linked to the file associated with stream s.

A more portable file would need to encode the word size – 32 bit or 64 bit – and endianness information in the header. In practice, consider encoding binary data using standard formats like HDF5 (which can be used with memory-mapping).

```
mmap(io, BitArray, [dims, offset])
```

Create a `BitArray` whose values are linked to a file, using memory-mapping; it has the same purpose, works in the same way, and has the same arguments, as `mmap`, but the byte representation is different.

Examples

```
julia> using Mmap

julia> io = open("mmap.bin", "w+");

julia> B = mmap(io, BitArray, (25,30000));
```

```
julia> B[3, 4000] = true;

julia> Mmap.sync!(B);

julia> close(io);

julia> io = open("mmap.bin", "r+");

julia> C = mmap(io, BitArray, (25,30000));

julia> C[3, 4000]
true

julia> C[2, 4000]
false

julia> close(io)

julia> rm("mmap.bin")
```

This creates a 25-by-30000 BitArray, linked to the file associated with stream `io`.

Mmap.sync! – Function.

```
Mmap.sync!(array)
```

Forces synchronization between the in-memory version of a memory-mapped Array or [BitArray](#) and the on-disk version.

Chapter 82

Network Options

`NetworkOptions.ca_roots` - Function.

```
| ca_roots() :: Union{Nothing, String}
```

The `ca_roots()` function tells the caller where, if anywhere, to find a file or directory of PEM-encoded certificate authority roots. By default, on systems like Windows and macOS where the built-in TLS engines know how to verify hosts using the system's built-in certificate verification mechanism, this function will return nothing. On classic UNIX systems (excluding macOS), root certificates are typically stored in a file in `/etc`: the common places for the current UNIX system will be searched and if one of these paths exists, it will be returned; if none of these typical root certificate paths exist, then the path to the set of root certificates that are bundled with Julia is returned.

The default value returned by `ca_roots()` may be overridden by setting the `JULIA_SSL_CA_ROOTS_PATH`, `SSL_CERT_DIR`, or `SSL_CERT_FILE` environment variables, in which case this function will always return the value of the first of these variables that is set (whether the path exists or not). If `JULIA_SSL_CA_ROOTS_PATH` is set to the empty string, then the other variables are ignored (as if unset); if the other variables are set to the empty string, they behave as if they are not set.

`NetworkOptions.ca_roots_path` - Function.

```
| ca_roots_path() :: String
```

The `ca_roots_path()` function is similar to the `ca_roots()` function except that it always returns a path to a file or directory of PEM-encoded certificate authority roots. When called on a system like Windows or macOS, where system root certificates are not stored in the file system, it will currently return the path to the set of root certificates that are bundled with Julia. (In the future, this function may instead extract the root certificates from the system and save them to a file whose path would be returned.)

If it is possible to configure a library that uses TLS to use the system certificates that is generally preferable: i.e. it is better to use `ca_roots()` which returns nothing to indicate that the system certs should be used. The `ca_roots_path()` function should only be used when configuring libraries which require a path to a file or directory for root certificates.

The default value returned by `ca_roots_path()` may be overridden by setting the `JULIA_SSL_CA_ROOTS_PATH`, `SSL_CERT_DIR`, or `SSL_CERT_FILE` environment variables, in which case this function will always return the value of the first of these variables that is set (whether the path exists or not). If `JULIA_SSL_CA_ROOTS_PATH`

is set to the empty string, then the other variables are ignored (as if unset); if the other variables are set to the empty string, they behave as if they are not set.

`NetworkOptions.ssh_dir` - Function.

```
| ssh_dir() :: String
```

The `ssh_dir()` function returns the location of the directory where the `ssh` program keeps/looks for configuration files. By default this is `~/.ssh` but this can be overridden by setting the environment variable `SSH_DIR`.

`NetworkOptions.ssh_key_pass` - Function.

```
| ssh_key_pass() :: String
```

The `ssh_key_pass()` function returns the value of the environment variable `SSH_KEY_PASS` if it is set or nothing if it is not set. In the future, this may be able to find a password by other means, such as secure system storage, so packages that need a password to decrypt an SSH private key should use this API instead of directly checking the environment variable so that they gain such capabilities automatically when they are added.

`NetworkOptions.ssh_key_name` - Function.

```
| ssh_key_name() :: String
```

The `ssh_key_name()` function returns the base name of key files that SSH should use for when establishing a connection. There is usually no reason that this function should be called directly and libraries should generally use the `ssh_key_path` and `ssh_pub_key_path` functions to get full paths. If the environment variable `SSH_KEY_NAME` is set then this function returns that; otherwise it returns `id_rsa` by default.

`NetworkOptions.ssh_key_path` - Function.

```
| ssh_key_path() :: String
```

The `ssh_key_path()` function returns the path of the SSH private key file that should be used for SSH connections. If the `SSH_KEY_PATH` environment variable is set then it will return that value. Otherwise it defaults to returning

```
| joinpath(ssh_dir(), ssh_key_name())
```

This default value in turn depends on the `SSH_DIR` and `SSH_KEY_NAME` environment variables.

`NetworkOptions.ssh_pub_key_path` - Function.

```
| ssh_pub_key_path() :: String
```

The `ssh_pub_key_path()` function returns the path of the SSH public key file that should be used for SSH connections. If the `SSH_PUB_KEY_PATH` environment variable is set then it will return that value. If that isn't set but `SSH_KEY_PATH` is set, it will return that path with the `.pub` suffix appended. If neither is set, it defaults to returning

```
| joinpath(ssh_dir(), ssh_key_name() * ".pub")
```

This default value in turn depends on the `SSH_DIR` and `SSH_KEY_NAME` environment variables.

`NetworkOptions.ssh_known_hosts_files` - Function.

```
| ssh_known_hosts_files() :: Vector{String}
```

The `ssh_known_hosts_files()` function returns a vector of paths of SSH known hosts files that should be used when establishing the identities of remote servers for SSH connections. By default this function returns

```
| [joinpath(ssh_dir(), "known_hosts"), bundled_known_hosts]
```

where `bundled_known_hosts` is the path of a copy of a known hosts file that is bundled with this package (containing known hosts keys for `github.com` and `gitlab.com`). If the environment variable `SSH_KNOWN_HOSTS_FILES` is set, however, then its value is split into paths on the `:` character (or on `;` on Windows) and this vector of paths is returned instead. If any component of this vector is empty, it is expanded to the default known hosts paths.

Packages that use `ssh_known_hosts_files()` should ideally look for matching entries by comparing the host name and key types, considering the first entry in any of the files which matches to be the definitive identity of the host. If the caller cannot compare the key type (e.g. because it has been hashed) then it must approximate the above algorithm by looking for all matching entries for a host in each file: if a file has any entries for a host then one of them must match; the caller should only continue to search further known hosts files if there are no entries for the host in question in an earlier file.

`NetworkOptions.ssh_known_hosts_file` - Function.

```
| ssh_known_hosts_file() :: String
```

The `ssh_known_hosts_file()` function returns a single path of an SSH known hosts file that should be used when establishing the identities of remote servers for SSH connections. It returns the first path returned by `ssh_known_hosts_files` that actually exists. Callers who can look in more than one known hosts file should use `ssh_known_hosts_files` instead and look for host matches in all the files returned as described in that function's docs.

`NetworkOptions.verify_host` - Function.

```
| verify_host(url::AbstractString, [transport::AbstractString]) :: Bool
```

The `verify_host` function tells the caller whether the identity of a host should be verified when communicating over secure transports like TLS or SSH. The `url` argument may be:

1. a proper URL starting with `proto://`
2. an ssh-style bare host name or host name prefixed with `user@`
3. an scp-style host as above, followed by `:` and a path location

In each case the host name part is parsed out and the decision about whether to verify or not is made based solely on the host name, not anything else about the input URL. In particular, the protocol of the URL does not matter (more below).

The `transport` argument indicates the kind of transport that the query is about. The currently known values are `SSL/ssl` (alias `TLS/tls`) and `SSH/ssh`. If the transport is omitted, the query will return `true` only if the host name should not be verified regardless of transport.

The host name is matched against the host patterns in the relevant environment variables depending on whether transport is supplied and what its value is:

- `JULIA_NO_VERIFY_HOSTS` — hosts that should not be verified for any transport
- `JULIA_SSL_NO_VERIFY_HOSTS` — hosts that should not be verified for SSL/TLS
- `JULIA_SSH_NO_VERIFY_HOSTS` — hosts that should not be verified for SSH
- `JULIA_ALWAYS_VERIFY_HOSTS` — hosts that should always be verified

The values of each of these variables is a comma-separated list of host name patterns with the following syntax — each pattern is split on `.` into parts and each part must one of:

1. A literal domain name component consisting of one or more ASCII letter, digit, hyphen or underscore (technically not part of a legal host name, but sometimes used). A literal domain name component matches only itself.
2. A `**`, which matches zero or more domain name components.
3. A `*`, which match any one domain name component.

When matching a host name against a pattern list in one of these variables, the host name is split on `.` into components and that sequence of words is matched against the pattern: a literal pattern matches exactly one host name component with that value; a `*` pattern matches exactly one host name component with any value; a `**` pattern matches any number of host name components. For example:

- `**` matches any host name
- `**.org` matches any host name in the `.org` top-level domain
- `example.com` matches only the exact host name `example.com`
- `*.example.com` matches `api.example.com` but not `example.com` or `v1.api.example.com`
- `**.example.com` matches any domain under `example.com`, including `example.com` itself, `api.example.com` and `v1.api.example.com`

Chapter 83

Pkg

Pkg is Julia's builtin package manager, and handles operations such as installing, updating and removing packages.

Note

What follows is a very brief introduction to Pkg. For more information on `Project.toml` files, `Manifest.toml` files, package version compatibility (`[compat]`), environments, registries, etc., it is highly recommended to read the full manual, which is available here: <https://pkgdocs.julialang.org>.

What follows is a quick overview of the basic features of Pkg. It should help new users become familiar with basic Pkg features such as adding and removing packages and working with environments.

Note

Some Pkg output is omitted in this section in order to keep this basic guide focused. This will help maintain a good pace and not get bogged down in details. If you require more details, refer to subsequent sections of the Pkg manual.

Note

This guide uses the Pkg REPL to execute Pkg commands. For non-interactive use, we recommend the Pkg API. The Pkg API is fully documented in the [API Reference](#) section of the Pkg documentation.

Pkg comes with a REPL. Enter the Pkg REPL by pressing `]` from the Julia REPL. To get back to the Julia REPL, press `Ctrl+C` or `backspace` (when the REPL cursor is at the beginning of the input).

Upon entering the Pkg REPL, you should see the following prompt:

```
| (@v1.8) pkg>
```

To add a package, use `add`:

```
(@v1.8) pkg> add Example
Resolving package versions...
Installed Example — v0.5.3
Updating `~/.julia/environments/v1.8/Project.toml`
[7876af07] + Example v0.5.3
Updating `~/.julia/environments/v1.8/Manifest.toml`
[7876af07] + Example v0.5.3
```

After the package is installed, it can be loaded into the Julia session:

```
julia> import Example

julia> Example.hello("friend")
"Hello, friend"
```

We can also specify multiple packages at once to install:

```
(@v1.8) pkg> add JSON StaticArrays
```

The `status` command (or the shorter `st` command) can be used to see installed packages.

```
(@v1.8) pkg> st
Status `~/.julia/environments/v1.6/Project.toml`
[7876af07] Example v0.5.3
[682c06a0] JSON v0.21.3
[90137ffa] StaticArrays v1.5.9
```

Note

Some Pkg REPL commands have a short and a long version of the command, for example `status` and `st`.

To remove packages, use `rm` (or `remove`):

```
(@v1.8) pkg> rm JSON StaticArrays
```

Use `up` (or `update`) to update the installed packages

```
(@v1.8) pkg> up
```

If you have been following this guide it is likely that the packages installed are at the latest version so `up` will not do anything. Below we show the status output in the case where we deliberately have installed an old version of the `Example` package and then upgrade it:

```
(@v1.8) pkg> st
Status `~/julia/environments/v1.8/Project.toml`
^ [7876af07] Example v0.5.1
Info Packages marked with ^ have new versions available and may be upgradable.

(@v1.8) pkg> up
  Updating `~/julia/environments/v1.8/Project.toml`
  [7876af07] ↑ Example v0.5.1 ⇒ v0.5.3
```

We can see that the status output tells us that there is a newer version available and that up upgrades the package.

For more information about managing packages, see the [Managing Packages](#) section of the documentation.

Up to this point, we have covered basic package management: adding, updating, and removing packages.

You may have noticed the (@v1.8) in the REPL prompt. This lets us know that v1.8 is the **active environment**. Different environments can have different totally different packages and versions installed from another environment. The active environment is the environment that will be modified by Pkg commands such as add, rm and update.

Let's set up a new environment so we may experiment. To set the active environment, use activate:

```
(@v1.8) pkg> activate tutorial
[ Info: activating new environment at `~/tutorial/Project.toml`.
```

Pkg lets us know we are creating a new environment and that this environment will be stored in the ~/tutorial directory. The path to the environment is created relative to the current working directory of the REPL.

Pkg has also updated the REPL prompt in order to reflect the new active environment:

```
(tutorial) pkg>
```

We can ask for information about the active environment by using status:

```
(tutorial) pkg> status
Status `~/tutorial/Project.toml`
(empty environment)
```

~/tutorial/Project.toml is the location of the active environment's **project file**. A project file is a TOML file where Pkg stores the packages that have been explicitly installed. Notice this new environment is empty. Let us add some packages and observe:

```
(tutorial) pkg> add Example JSON
...

(tutorial) pkg> status
Status `~/tutorial/Project.toml`
[7876af07] Example v0.5.3
[682c06a0] JSON v0.21.3
```

We can see that the tutorial environment now contains Example and JSON.

Note

If you have the same package (at the same version) installed in multiple environments, the package will only be downloaded and stored on the hard drive once. This makes environments very lightweight and effectively free to create. Only using the default environment with a huge number of packages in it is a common beginners mistake in Julia. Learning how to use environments effectively will improve your experience with Julia packages.

For more information about environments, see the [Working with Environments](#) section of the documentation.

If you are ever stuck, you can ask Pkg for help:

```
| (@v1.8) pkg> ?
```

You should see a list of available commands along with short descriptions. You can ask for more detailed help by specifying a command:

```
| (@v1.8) pkg> ?develop
```

This guide should help you get started with Pkg. Pkg has much more to offer in terms of powerful package management, read the full manual to learn more!

Chapter 84

Printf

Printf.@printf - Macro.

```
| @printf([io::IO], "%Fmt", args...)
```

Print args using C printf style format specification string. Optionally, an IO may be passed as the first argument to redirect output.

Examples

```
julia> @printf "Hello %s" "world"
Hello world

julia> @printf "Scientific notation %e" 1.234
Scientific notation 1.234000e+00

julia> @printf "Scientific notation three digits %.3e" 1.23456
Scientific notation three digits 1.235e+00

julia> @printf "Decimal two digits %.2f" 1.23456
Decimal two digits 1.23

julia> @printf "Padded to length 5 %5i" 123
Padded to length 5   123

julia> @printf "Padded with zeros to length 6 %06i" 123
Padded with zeros to length 6 000123

julia> @printf "Use shorter of decimal or scientific %g %g" 1.23 12300000.0
Use shorter of decimal or scientific 1.23 1.23e+07

julia> @printf "Use dynamic width and precision %*,*f" 10 2 0.12345
Use dynamic width and precision      0.12
```

For a systematic specification of the format, see [here](#). See also `@sprintf` to get the result as a String instead of it being printed.

Caveats

Inf and NaN are printed consistently as Inf and NaN for flags %a, %A, %e, %E, %f, %F, %g, and %G. Furthermore, if a floating point number is equally close to the numeric values of two possible output strings, the output string further away from zero is chosen.

Examples

```
julia> @printf("%f %F %f %F", Inf, Inf, NaN, NaN)
Inf Inf NaN NaN

julia> @printf "%.0f %.1f %f" 0.5 0.025 -0.0078125
0 0.0 -0.007812
```

Julia 1.8

Starting in Julia 1.8, %s (string) and %c (character) widths are computed using `textwidth`, which e.g. ignores zero-width characters (such as combining characters for diacritical marks) and treats certain "wide" characters (e.g. emoji) as width 2.

Julia 1.10

Dynamic width specifiers like %*s and %0*.*f require Julia 1.10.

Printf.@sprintf – Macro.

```
@sprintf("%Fmt", args...)
```

Return `@printf` formatted output as string.

Examples

```
julia> @sprintf "this is a %s %15.1f" "test" 34.567
"this is a test          34.6"
```

Chapter 85

Profiling

85.1 CPU Profiling

There are two main approaches to CPU profiling julia code:

85.2 Via @profile

Where profiling is enabled for a given call via the @profile macro.

```
julia> using Profile

julia> @profile foo()

julia> Profile.print()
Overhead | [+additional indent] Count File:Line; Function
=====
| 147 @Base/client.jl:506; _start()
| 147 @Base/client.jl:318; exec_options(opts::Base.JLOptions)
...
```

85.3 Triggered During Execution

Tasks that are already running can also be profiled for a fixed time period at any user-triggered time.

To trigger the profiling:

- MacOS & FreeBSD (BSD-based platforms): Use ctrl-t or pass a SIGINFO signal to the julia process i.e. % kill -INFO \$julia_pid
- Linux: Pass a SIGUSR1 signal to the julia process i.e. % kill -USR1 \$julia_pid
- Windows: Not currently supported.

First, a single stack trace at the instant that the signal was thrown is shown, then a 1 second profile is collected, followed by the profile report at the next yield point, which may be at task completion for code without yield points e.g. tight loops.

Optionally set environment variable `JULIA_PROFILE_PEEK_HEAP_SNAPSHOT` to 1 to also automatically collect a [heap snapshot](#).

```
julia> foo()
=== the user sends a trigger while foo is running ===
load: 2.53 cmd: julia 88903 running 6.16u 0.97s

=====
Information request received. A stacktrace will print followed by a 1.0 second profile
=====

signal (29): Information request: 29
__psynch_cvwait at /usr/lib/system/libsystem_kernel.dylib (unknown line)
_pthread_cond_wait at /usr/lib/system/libsystem_pthread.dylib (unknown line)
...

=====
Profile collected. A report will print if the Profile module is loaded
=====

Overhead | [+additional indent] Count File:Line; Function
=====
Thread 1 Task 0x000000011687c010 Total snapshots: 572. Utilization: 100%
  |147 @Base/client.jl:506; _start()
    | 147 @Base/client.jl:318; exec_options(opts::Base.JLOptions)
  ...

Thread 2 Task 0x0000000116960010 Total snapshots: 572. Utilization: 0%
  |572 @Base/task.jl:587; task_done_hook(t::Task)
    | 572 @Base/task.jl:879; wait()
  ...
```

Customization

The duration of the profiling can be adjusted via [Profile.set_peek_duration](#)

The profile report is broken down by thread and task. Pass a no-arg function to `Profile.peek_report[]` to override this. i.e. `Profile.peek_report[] = () -> Profile.print()` to remove any grouping. This could also be overridden by an external profile data consumer.

85.4 Reference

`Profile.@profile` – Macro.

`| @profile`

`@profile <expression>` runs your expression while taking periodic backtraces. These are appended to an internal buffer of backtraces.

[source](#)

The methods in `Profile` are not exported and need to be called e.g. as `Profile.print()`.

`Profile.clear` – Function.

```
| clear()
```

Clear any existing backtraces from the internal buffer.

[source](#)

`Profile.print` - Function.

```
| print([io::IO = stdout,] [data::Vector = fetch()], [lidict::Union{LineInfoDict,  
↪ LineInfoFlatDict} = getdict(data)]; kwargs...)
```

Prints profiling results to `io` (by default, `stdout`). If you do not supply a data vector, the internal buffer of accumulated backtraces will be used.

The keyword arguments can be any combination of:

- `format` - Determines whether backtraces are printed with (default, `:tree`) or without (`:flat`) indentation indicating tree structure.
- `C` - If `true`, backtraces from C and Fortran code are shown (normally they are excluded).
- `combine` - If `true` (default), instruction pointers are merged that correspond to the same line of code.
- `maxdepth` - Limits the depth higher than `maxdepth` in the `:tree` format.
- `sortedby` - Controls the order in `:flat` format. `:filefuncline` (default) sorts by the source line, `:count` sorts in order of number of collected samples, and `:overhead` sorts by the number of samples incurred by each function by itself.
- `groupby` - Controls grouping over tasks and threads, or no grouping. Options are `:none` (default), `:thread`, `:task`, `[:thread, :task]`, or `[:task, :thread]` where the last two provide nested grouping.
- `noisefloor` - Limits frames that exceed the heuristic noise floor of the sample (only applies to format `:tree`). A suggested value to try for this is 2.0 (the default is 0). This parameter hides samples for which $n \leq \text{noisefloor} * \sqrt{N}$, where n is the number of samples on this line, and N is the number of samples for the callee.
- `mincount` - Limits the printout to only those lines with at least `mincount` occurrences.
- `recur` - Controls the recursion handling in `:tree` format. `:off` (default) prints the tree as normal. `:flat` instead compresses any recursion (by ip), showing the approximate effect of converting any self-recursion into an iterator. `:flatc` does the same but also includes collapsing of C frames (may do odd things around `julia_apply`).
- `threads::Union{Int,AbstractVector{Int}}` - Specify which threads to include snapshots from in the report. Note that this does not control which threads samples are collected on (which may also have been collected on another machine).
- `tasks::Union{Int,AbstractVector{Int}}` - Specify which tasks to include snapshots from in the report. Note that this does not control which tasks samples are collected within.

Julia 1.8

The `groupby`, `threads`, and `tasks` keyword arguments were introduced in Julia 1.8.

Note

Profiling on windows is limited to the main thread. Other threads have not been sampled and will not show in the report.

source

```
| print([io::IO = stdout,] data::Vector, lidict::LineInfoDict; kwargs...)
```

Prints profiling results to `io`. This variant is used to examine results exported by a previous call to `retrieve`. Supply the vector data of backtraces and a dictionary `lidict` of line information.

See `Profile.print([io], data)` for an explanation of the valid keyword arguments.

source

`Profile.init` - Function.

```
| init(; n::Integer, delay::Real)
```

Configure the delay between backtraces (measured in seconds), and the number `n` of instruction pointers that may be stored per thread. Each instruction pointer corresponds to a single line of code; backtraces generally consist of a long list of instruction pointers. Note that 6 spaces for instruction pointers per backtrace are used to store metadata and two NULL end markers. Current settings can be obtained by calling this function with no arguments, and each can be set independently using keywords or in the order `(n, delay)`.

source

`Profile.fetch` - Function.

```
| fetch(;include_meta = true) -> data
```

Return a copy of the buffer of profile backtraces. Note that the values in `data` have meaning only on this machine in the current session, because it depends on the exact memory addresses used in JIT-compiling. This function is primarily for internal use; `retrieve` may be a better choice for most users. By default metadata such as `threadid` and `taskid` is included. Set `include_meta` to `false` to strip metadata.

source

`Profile.retrieve` - Function.

```
| retrieve(; kwargs...) -> data, lidict
```

"Exports" profiling results in a portable format, returning the set of all backtraces (`data`) and a dictionary that maps the (session-specific) instruction pointers in `data` to `LineInfo` values that store the file name, function name, and line number. This function allows you to save profiling results for future analysis.

source

`Profile.callers` - Function.

```
| callers(funcname, [data, lidict], [filename=<filename>], [linerange=<start:stop>]) ->
  ↳ Vector{Tuple{count, lineinfo}}
```

Given a previous profiling run, determine who called a particular function. Supplying the `filename` (and optionally, range of line numbers over which the function is defined) allows you to disambiguate an overloaded method. The returned value is a vector containing a count of the number of calls and line information about the caller. One can optionally supply backtrace data obtained from `retrieve`; otherwise, the current internal profile buffer is used.

source

Profile.clear_malloc_data - Function.

```
| clear_malloc_data()
```

Clears any stored memory allocation data when running julia with --track-allocation. Execute the command(s) you want to test (to force JIT-compilation), then call `clear_malloc_data`. Then execute your command(s) again, quit Julia, and examine the resulting *.mem files.

[source](#)

Profile.get_peek_duration - Function.

```
| get_peek_duration()
```

Get the duration in seconds of the profile "peek" that is triggered via SIGINFO or SIGUSR1, depending on platform.

[source](#)

Profile.set_peek_duration - Function.

```
| set_peek_duration(t::Float64)
```

Set the duration in seconds of the profile "peek" that is triggered via SIGINFO or SIGUSR1, depending on platform.

[source](#)

85.5 Memory profiling

Profile.Allocs.@profile - Macro.

```
| Profile.Allocs.@profile [sample_rate=0.1] expr
```

Profile allocations that happen during expr, returning both the result and an AllocResults struct.

A sample rate of 1.0 will record everything; 0.0 will record nothing.

```
julia> Profile.Allocs.@profile sample_rate=0.01 peakflops()
1.03733270279065e11

julia> results = Profile.Allocs.fetch()

julia> last(sort(results.allocs, by=x->x.size))
Profile.Allocs.Alloc(Vector{Any}, Base.StackTraces.StackFrame[_new_array_ at array.c:127,
↪ ...], 5576)
```

The best way to visualize these is currently with the [PProf.jl](#) package, by invoking `PProf.Allocs.pprof`.

Note

The current implementation of the Allocations Profiler does not capture types for all allocations. Allocations for which the profiler could not capture the type are represented as having type `Profile.Allocs.UnknownType`.

You can read more about the missing types and the plan to improve this, here: <https://github.com/JuliaLang/julia/issues/43688>.

Julia 1.8

The allocation profiler was added in Julia 1.8.

source

The methods in `Profile.Allocs` are not exported and need to be called e.g. as `Profile.Allocs.fetch()`.

`Profile.Allocs.clear` – Function.

```
| Profile.Allocs.clear()
```

Clear all previously profiled allocation information from memory.

source

`Profile.Allocs.fetch` – Function.

```
| Profile.Allocs.fetch()
```

Retrieve the recorded allocations, and decode them into Julia objects which can be analyzed.

source

`Profile.Allocs.start` – Function.

```
| Profile.Allocs.start(sample_rate::Real)
```

Begin recording allocations with the given sample rate. A sample rate of 1.0 will record everything; 0.0 will record nothing.

source

`Profile.Allocs.stop` – Function.

```
| Profile.Allocs.stop()
```

Stop recording allocations.

source**85.6 Heap Snapshots**

`Profile.take_heap_snapshot` – Function.

```
| Profile.take_heap_snapshot(io::IOStream, all_one::Bool=false)
| Profile.take_heap_snapshot(filepath::String, all_one::Bool=false)
| Profile.take_heap_snapshot(all_one::Bool=false; dir::String)
```

Write a snapshot of the heap, in the JSON format expected by the Chrome Devtools Heap Snapshot viewer (.heapsnapshot extension) to a file (`$pid_$timestamp.heapsnapshot`) in the current directory by default (or `tempdir` if the current directory is unwritable), or in `dir` if given, or the given full file path, or IO stream.

If `all_one` is true, then report the size of every object as one so they can be easily counted. Otherwise, report the actual size.

source

The methods in `Profile` are not exported and need to be called e.g. as `Profile.take_heap_snapshot()`.

```
julia> using Profile  
julia> Profile.take_heap_snapshot("snapshot.heapsnapshot")
```

Traces and records julia objects on the heap. This only records objects known to the Julia garbage collector. Memory allocated by external libraries not managed by the garbage collector will not show up in the snapshot.

The resulting heap snapshot file can be uploaded to chrome devtools to be viewed. For more information, see the [chrome devtools docs](#).

Chapter 86

The Julia REPL

Julia comes with a full-featured interactive command-line REPL (read-eval-print loop) built into the `julia` executable. In addition to allowing quick and easy evaluation of Julia statements, it has a searchable history, tab-completion, many helpful keybindings, and dedicated help and shell modes. The REPL can be started by simply calling `julia` with no arguments or double-clicking on the executable:

```
$ julia

      _       _       _
     (_)     | |      | |
    _ _ _   | |      | |
_/	\_ '			\_ '				
_/								

Documentation: https://docs.julialang.org
Type "?" for help, "]"? for Pkg help.
Version 1.10.2 (2024-03-01)
Official https://julialang.org/ release

julia>
```

To exit the interactive session, type `^D` – the control key together with the `d` key on a blank line – or type `exit()` followed by the return or enter key. The REPL greets you with a banner and a `julia>` prompt.

86.1 The different prompt modes

The Julian mode

The REPL has five main modes of operation. The first and most common is the Julian prompt. It is the default mode of operation; each new line initially starts with `julia>`. It is here that you can enter Julia expressions. Hitting return or enter after a complete expression has been entered will evaluate the entry and show the result of the last expression.

```
julia> string(1 + 2)
"3"
```

There are a number of useful features unique to interactive work. In addition to showing the result, the REPL also binds the result to the variable `ans`. A trailing semicolon on the line can be used as a flag to suppress showing the result.

```
julia> string(3 * 4);

julia> ans
"12"
```

In Julia mode, the REPL supports something called prompt pasting. This activates when pasting text that starts with `julia>` into the REPL. In that case, only expressions starting with `julia>` (as well as the other REPL mode prompts: `shell>`, `help?>`, `pkg>`) are parsed, but others are removed. This makes it possible to paste a chunk of text that has been copied from a REPL session without having to scrub away prompts and outputs. This feature is enabled by default but can be disabled or enabled at will with `REPL.enable_promptpaste(::Bool)`. If it is enabled, you can try it out by pasting the code block above this paragraph straight into the REPL. This feature does not work on the standard Windows command prompt due to its limitation at detecting when a paste occurs.

Objects are printed at the REPL using the `show` function with a specific `IOContext`. In particular, the `:limit` attribute is set to `true`. Other attributes can receive in certain show methods a default value if it's not already set, like `:compact`. It's possible, as an experimental feature, to specify the attributes used by the REPL via the `Base.active_repl.options.iocontext` dictionary (associating values to attributes). For example:

```
julia> rand(2, 2)
2×2 Array{Float64,2}:
 0.8833   0.329197
 0.719708 0.59114

julia> show(IOContext(stdout, :compact => false), "text/plain", rand(2, 2))
0.43540323669187075 0.15759787870609387
0.2540832269192739 0.4597637838786053

julia> Base.active_repl.options.iocontext[:compact] = false;

julia> rand(2, 2)
2×2 Array{Float64,2}:
 0.2083967319174056 0.13330606013126012
 0.6244375177790158 0.9777957560761545
```

In order to define automatically the values of this dictionary at startup time, one can use the `atreplinit` function in the `~/.julia/config/startup.jl` file, for example:

```
atreplinit() do repl
    repl.options.iocontext[:compact] = false
end
```

Help mode

When the cursor is at the beginning of the line, the prompt can be changed to a help mode by typing `?`. Julia will attempt to print help or documentation for anything entered in help mode:

```
julia> ? # upon typing ?, the prompt changes (in place) to: help?>

help?> string
```

```
search: string String Cstring Cwstring RevString randstring bytestring SubString

string(xs...)

Create a string from any values using the print function.
```

Macros, types and variables can also be queried:

```
help?> @time
@time

A macro to execute an expression, printing the time it took to execute, the number of
allocations,
and the total number of bytes its execution caused to be allocated, before returning the value
of the
expression.

See also @timev, @timed, @elapsed, and @allocated.

help?> Int32
search: Int32 UInt32

Int32 <: Signed

32-bit signed integer type.
```

A string or regex literal searches all docstrings using [apropos](#):

```
help?> "aprop"
REPL.stripmd
Base.Docs.apropos

help?> r"ap..p"
Base.:
Base.shell_escape_posixly
Distributed.CachingPool
REPL.stripmd
Base.Docs.apropos
```

Another feature of help mode is the ability to access extended docstrings. You can do this by typing something like `??Print` rather than `?Print` which will display the `# Extended help` section from the source codes documentation.

Help mode can be exited by pressing backspace at the beginning of the line.

Shell mode

Just as help mode is useful for quick access to documentation, another common task is to use the system shell to execute system commands. Just as `?` entered help mode when at the beginning of the line, a semicolon (`;`) will enter the shell mode. And it can be exited by pressing backspace at the beginning of the line.

```
julia> ; # upon typing ;, the prompt changes (in place) to: shell>
```

```
| shell> echo hello
hello
```

Note

For Windows users, Julia's shell mode does not expose windows shell commands. Hence, this will fail:

```
| julia> ; # upon typing ;, the prompt changes (in place) to: shell>
shell> dir
ERROR: IOError: could not spawn `dir`: no such file or directory (ENOENT)
Stacktrace!
.....
```

However, you can get access to PowerShell like this:

```
| julia> ; # upon typing ;, the prompt changes (in place) to: shell>
shell> powershell
Windows PowerShell
Copyright (C) Microsoft Corporation. All rights reserved.
PS C:\Users\elm>
```

... and to cmd.exe like that (see the dir command):

```
| julia> ; # upon typing ;, the prompt changes (in place) to: shell>
shell> cmd
Microsoft Windows [version 10.0.17763.973]
(c) 2018 Microsoft Corporation. All rights reserved.
C:\Users\elm>dir
Volume in drive C has no label
Volume Serial Number is 1643-0CD7
Directory of C:\Users\elm

29/01/2020  22:15    <DIR>          .
29/01/2020  22:15    <DIR>          ..
02/02/2020  08:06    <DIR>          .atom
```

Pkg mode

The Package manager mode accepts specialized commands for loading and updating packages. It is entered by pressing the] key at the Julian REPL prompt and exited by pressing CTRL-C or pressing the backspace key at the beginning of the line. The prompt for this mode is pkg>. It supports its own help-mode, which is entered by pressing ? at the beginning of the line of the pkg> prompt. The Package manager mode is documented in the Pkg manual, available at <https://julialang.github.io/Pkg.jl/v1/>.

Search modes

In all of the above modes, the executed lines get saved to a history file, which can be searched. To initiate an incremental search through the previous history, type `^R` – the control key together with the `r` key. The prompt will change to `(reverse-i-search)`':`, and as you type the search query will appear in the quotes. The most recent result that matches the query will dynamically update to the right of the colon as more is typed. To find an older result using the same query, simply type `^R` again.

Just as `^R` is a reverse search, `^S` is a forward search, with the prompt `(i-search)`':`. The two may be used in conjunction with each other to move through the previous or next matching results, respectively.

All executed commands in the Julia REPL are logged into `~/.julia/logs/repl_history.jl` along with a timestamp of when it was executed and the current REPL mode you were in. Search mode queries this log file in order to find the commands which you previously ran. This can be disabled at startup by passing the `--history-file=no` flag to Julia.

86.2 Key bindings

The Julia REPL makes great use of key bindings. Several control-key bindings were already introduced above (`^D` to exit, `^R` and `^S` for searching), but there are many more. In addition to the control-key, there are also meta-key bindings. These vary more by platform, but most terminals default to using alt- or option-held down with a key to send the meta-key (or can be configured to do so), or pressing `Esc` and then the key.

Customizing keybindings

Julia's REPL keybindings may be fully customized to a user's preferences by passing a dictionary to `REPL.setup_interface`. The keys of this dictionary may be characters or strings. The key `'*'` refers to the default action. Control plus character `x` bindings are indicated with `"^x"`. Meta plus `x` can be written `"\M-x"` or `"\ex"`, and Control plus `x` can be written `"\C-x"` or `"^x"`. The values of the custom keymap must be nothing (indicating that the input should be ignored) or functions that accept the signature `(PromptState, AbstractREPL, Char)`. The `REPL.setup_interface` function must be called before the REPL is initialized, by registering the operation with `atreplinit`. For example, to bind the up and down arrow keys to move through history without prefix search, one could put the following code in `~/.julia/config/startup.jl`:

```
import REPL
import REPL.LineEdit

const mykeys = Dict{Any,Any}()
    # Up Arrow
    "\e[A" => (s,o...) -> (LineEdit.edit_move_up(s) || LineEdit.history_prev(s,
    ↪ LineEdit.mode(s).hist)),
    # Down Arrow
    "\e[B" => (s,o...) -> (LineEdit.edit_move_down(s) || LineEdit.history_next(s,
    ↪ LineEdit.mode(s).hist))
)

function customize_keys(repl)
    repl.interface = REPL.setup_interface(repl; extra_repl_keymap = mykeys)
end

atreplinit(customize_keys)
```

Users should refer to `LineEdit.jl` to discover the available actions on key input.

86.3 Tab completion

In both the Julian and help modes of the REPL, one can enter the first few characters of a function or type and then press the tab key to get a list all matches:

```
julia> x[TAB]
julia> xor
```

In some cases it only completes part of the name, up to the next ambiguity:

```
julia> mapf[TAB]
julia> mapfold
```

If you hit tab again, then you get the list of things that might complete this:

```
julia> mapfold[TAB]
mapfoldl mapfoldr
```

Like other components of the REPL, the search is case-sensitive:

```
julia> stri[TAB]
stride      strides      string      strip

julia> Stri[TAB]
StridedArray StridedMatrix StridedVecOrMat StridedVector String
```

The tab key can also be used to substitute LaTeX math symbols with their Unicode equivalents, and get a list of LaTeX matches as well:

```
julia> \pi[TAB]
julia> π
π = 3.1415926535897...

julia> e\_1[TAB] = [1,0]
julia> e₁ = [1,0]
2-element Array{Int64,1}:
 1
 0

julia> e^1[TAB] = [1 0]
julia> e¹ = [1 0]
1×2 Array{Int64,2}:
 1  0

julia> \sqrt[TAB]2      # √ is equivalent to the sqrt function
julia> √2
```

```

1.4142135623730951

julia> \hbar[TAB](h) = h / 2\pi[TAB]
julia> ħ(h) = h / 2π
ħ (generic function with 1 method)

julia> \h[TAB]
\hat          \hermitconjmatrix \hksvarow          \hrectangle
\hatapprox    \hexagon          \hookleftarrow \hrectangleblack
\hbar         \hexagonblack     \hookrightarrow \hslash
\heartsuit    \hksearrow        \house          \hspace

julia> α="\alpha[TAB]" # LaTeX completion also works in strings
julia> α="α"

```

A full list of tab-completions can be found in the [Unicode Input](#) section of the manual.

Completion of paths works for strings and julia's shell mode:

```

julia> path="/[TAB]"
.dockerenv .juliabox/ boot/      etc/      lib/      media/    opt/      root/
↪  sbin/      sys/      usr/
.dockerinit bin/      dev/      home/     lib64/    mnt/      proc/     run/
↪  srv/      tmp/      var/
shell> /[TAB]
.dockerenv .juliabox/ boot/      etc/      lib/      media/    opt/      root/
↪  sbin/      sys/      usr/
.dockerinit bin/      dev/      home/     lib64/    mnt/      proc/     run/
↪  srv/      tmp/      var/

```

Dictionary keys can also be tab completed:

```

julia> foo = Dict{"qwer1"=>1, "qwer2"=>2, "asdf"=>3}
Dict{String,Int64} with 3 entries:
  "qwer2" => 2
  "asdf"  => 3
  "qwer1" => 1

julia> foo["q[TAB]
"qwer1" "qwer2"
julia> foo["qwer

```

Tab completion can also help completing fields:

```

julia> x = 3 + 4im;

julia> x.[TAB][TAB]
im re

julia> import UUIDs

```

```
julia> UUIDs.uuid[TAB][TAB]
uuid1      uuid4      uuid5      uuid_version
```

Fields for output from functions can also be completed:

```
julia> split("", "")[1][TAB]
lastindex  offset  string
```

The completion of fields for output from functions uses type inference, and it can only suggest fields if the function is type stable.

Tab completion can help with investigation of the available methods matching the input arguments:

```
julia> max([TAB] # All methods are displayed, not shown here due to size of the list

julia> max([1, 2], [TAB] # All methods where `Vector{Int}` matches as first argument
max(x, y) in Base at operators.jl:215
max(a, b, c, xs...) in Base at operators.jl:281

julia> max([1, 2], max(1, 2), [TAB] # All methods matching the arguments.
max(x, y) in Base at operators.jl:215
max(a, b, c, xs...) in Base at operators.jl:281
```

Keywords are also displayed in the suggested methods after `;`, see below line where `limit` and `keepempty` are keyword arguments:

```
julia> split("1 1 1", [TAB]
split(str::AbstractString; limit, keepempty) in Base at strings/util.jl:302
split(str::T, splitter; limit, keepempty) where T<:AbstractString in Base at strings/util.jl:277
```

The completion of the methods uses type inference and can therefore see if the arguments match even if the arguments are output from functions. The function needs to be type stable for the completion to be able to remove non-matching methods.

If you wonder which methods can be used with particular argument types, use `?` as the function name. This shows an example of looking for functions in `InteractiveUtils` that accept a single string:

```
julia> InteractiveUtils.?("somefile")[TAB]
edit(path::AbstractString) in InteractiveUtils at InteractiveUtils/src/editless.jl:197
less(file::AbstractString) in InteractiveUtils at InteractiveUtils/src/editless.jl:266
```

This listed methods in the `InteractiveUtils` module that can be called on a string. By default, this excludes methods where all arguments are typed as `Any`, but you can see those too by holding down `SHIFT-TAB` instead of `TAB`:

```
julia> InteractiveUtils.?("somefile")[SHIFT-TAB]
apropos(string) in REPL at REPL/src/docview.jl:796
clipboard(x) in InteractiveUtils at InteractiveUtils/src/clipboard.jl:64
code_llvm(f) in InteractiveUtils at InteractiveUtils/src/codeview.jl:221
code_native(f) in InteractiveUtils at InteractiveUtils/src/codeview.jl:243
edit(path::AbstractString) in InteractiveUtils at InteractiveUtils/src/editless.jl:197
edit(f) in InteractiveUtils at InteractiveUtils/src/editless.jl:225
eval(x) in InteractiveUtils at InteractiveUtils/src/InteractiveUtils.jl:3
include(x) in InteractiveUtils at InteractiveUtils/src/InteractiveUtils.jl:3
less(file::AbstractString) in InteractiveUtils at InteractiveUtils/src/editless.jl:266
less(f) in InteractiveUtils at InteractiveUtils/src/editless.jl:274
report_bug(kind) in InteractiveUtils at InteractiveUtils/src/InteractiveUtils.jl:391
separate_kwargs(args...; kwargs...) in InteractiveUtils at InteractiveUtils/src/macros.jl:7
```

You can also use ?("somefile")[TAB] and look across all modules, but the method lists can be long.

By omitting the closing parenthesis, you can include functions that might require additional arguments:

```
julia> using Mmap

help?> Mmap.?("file",[TAB]
Mmap.Anonymous(name::String, readonly::Bool, create::Bool) in Mmap at Mmap/src/Mmap.jl:16
mmap(file::AbstractString) in Mmap at Mmap/src/Mmap.jl:245
mmap(file::AbstractString, ::Type{T}) where T<:Array in Mmap at Mmap/src/Mmap.jl:245
mmap(file::AbstractString, ::Type{T}, dims::Tuple{Vararg{Integer, N}}) where {T<:Array, N} in
↳ Mmap at Mmap/src/Mmap.jl:245
mmap(file::AbstractString, ::Type{T}, dims::Tuple{Vararg{Integer, N}}, offset::Integer; grow,
↳ shared) where {T<:Array, N} in Mmap at Mmap/src/Mmap.jl:245
mmap(file::AbstractString, ::Type{T}, len::Integer) where T<:Array in Mmap at
↳ Mmap/src/Mmap.jl:251
mmap(file::AbstractString, ::Type{T}, len::Integer, offset::Integer; grow, shared) where T<:Array
↳ in Mmap at Mmap/src/Mmap.jl:251
mmap(file::AbstractString, ::Type{T}, dims::Tuple{Vararg{Integer, N}}) where {T<:BitArray, N} in
↳ Mmap at Mmap/src/Mmap.jl:316
mmap(file::AbstractString, ::Type{T}, dims::Tuple{Vararg{Integer, N}}, offset::Integer; grow,
↳ shared) where {T<:BitArray, N} in Mmap at Mmap/src/Mmap.jl:316
mmap(file::AbstractString, ::Type{T}, len::Integer) where T<:BitArray in Mmap at
↳ Mmap/src/Mmap.jl:322
mmap(file::AbstractString, ::Type{T}, len::Integer, offset::Integer; grow, shared) where
↳ T<:BitArray in Mmap at Mmap/src/Mmap.jl:322
```

86.4 Customizing Colors

The colors used by Julia and the REPL can be customized, as well. To change the color of the Julia prompt you can add something like the following to your ~/.julia/config/startup.jl file, which is to be placed inside your home directory:

```
function customize_colors(repl)
    repl.prompt_color = Base.text_colors[:cyan]
end

atreplinit(customize_colors)
```

The available color keys can be seen by typing `Base.text_colors` in the help mode of the REPL. In addition, the integers 0 to 255 can be used as color keys for terminals with 256 color support.

You can also change the colors for the help and shell prompts and input and answer text by setting the appropriate field of `repl` in the `customize_colors` function above (respectively, `help_color`, `shell_color`, `input_color`, and `answer_color`). For the latter two, be sure that the `envcolors` field is also set to `false`.

It is also possible to apply boldface formatting by using `Base.text_colors[:bold]` as a color. For instance, to print answers in boldface font, one can use the following as a `~/.julia/config/startup.jl`:

```
function customize_colors(repl)
    repl.envcolors = false
    repl.answer_color = Base.text_colors[:bold]
end

atreplinit(customize_colors)
```

You can also customize the color used to render warning and informational messages by setting the appropriate environment variables. For instance, to render error, warning, and informational messages respectively in magenta, yellow, and cyan you can add the following to your `~/.julia/config/startup.jl` file:

```
ENV["JULIA_ERROR_COLOR"] = :magenta
ENV["JULIA_WARN_COLOR"] = :yellow
ENV["JULIA_INFO_COLOR"] = :cyan
```

86.5 Changing the contextual module which is active at the REPL

When entering expressions at the REPL, they are by default evaluated in the Main module;

```
julia> @__MODULE__
Main
```

It is possible to change this contextual module via the function `REPL.activate(m)` where `m` is a `Module` or by typing the module in the REPL and pressing the keybinding `Alt-m` (the cursor must be on the module name). The active module is shown in the prompt:

```
julia> using REPL

julia> REPL.activate(Base)

(Base) julia> @__MODULE__
Base

(Base) julia> using REPL # Need to load REPL into Base module to use it

(Base) julia> REPL.activate(Main)

julia>
```

```
julia> Core<Alt-m> # using the keybinding to change module

(Core) julia>

(Core) julia> Main<Alt-m> # going back to Main via keybinding

julia>
```

Functions that take an optional module argument often defaults to the REPL context module. As an example, calling `varinfo()` will show the variables of the current active module:

```
julia> module CustomMod
    export var, f
    var = 1
    f(x) = x^2
end;

julia> REPL.activate(CustomMod)

(Main.CustomMod) julia> varinfo()
name          size summary
-----
CustomMod      Module
f              0 bytes f (generic function with 1 method)
var           8 bytes Int64
```

86.6 Numbered prompt

It is possible to get an interface which is similar to the IPython REPL and the Mathematica notebook with numbered input prompts and output prefixes. This is done by calling `REPL.numbered_prompt!()`. If you want to have this enabled on startup, add

```
atreplinit() do repl
    @eval import REPL
    if !isdefined(repl, :interface)
        repl.interface = REPL.setup_interface(repl)
    end
    REPL.numbered_prompt!(repl)
end
```

to your `startup.jl` file. In numbered prompt the variable `Out[n]` (where `n` is an integer) can be used to refer to earlier results:

```
In [1]: 5 + 3
Out[1]: 8

In [2]: Out[1] + 5
Out[2]: 13

In [3]: Out
```

```
Out[3]: Dict{Int64, Any} with 2 entries:
 2 => 13
 1 => 8
```

Note

Since all outputs from previous REPL evaluations are saved in the `Out` variable, one should be careful if they are returning many large in-memory objects like arrays, since they will be protected from garbage collection so long as a reference to them remains in `Out`. If you need to remove references to objects in `Out`, you can clear the entire history it stores with `empty!(Out)`, or clear an individual entry with `Out[n] = nothing`.

86.7 TerminalMenus

`TerminalMenus` is a submodule of the Julia REPL and enables small, low-profile interactive menus in the terminal.

Examples

```
import REPL
using REPL.TerminalMenus

options = ["apple", "orange", "grape", "strawberry",
           "blueberry", "peach", "lemon", "lime"]
```

RadioMenu

The `RadioMenu` allows the user to select one option from the list. The `request` function displays the interactive menu and returns the index of the selected choice. If a user presses 'q' or `ctrl-c`, `request` will return a `-1`.

```
# `pagesize` is the number of items to be displayed at a time.
# The UI will scroll if the number of options is greater
# than the `pagesize`
menu = RadioMenu(options, pagesize=4)

# `request` displays the menu and returns the index after the
# user has selected a choice
choice = request("Choose your favorite fruit:", menu)

if choice != -1
    println("Your favorite fruit is ", options[choice], "!")
else
    println("Menu canceled.")
end
```

Output:

```
Choose your favorite fruit:
^  grape
   strawberry
> blueberry
```

```
v peach
Your favorite fruit is blueberry!
```

MultiSelectMenu

The MultiSelectMenu allows users to select many choices from a list.

```
# here we use the default `pagesize` 10
menu = MultiSelectMenu(options)

# `request` returns a `Set` of selected indices
# if the menu is canceled (ctrl-c or q), return an empty set
choices = request("Select the fruits you like:", menu)

if length(choices) > 0
    println("You like the following fruits:")
    for i in choices
        println(" - ", options[i])
    end
else
    println("Menu canceled.")
end
```

Output:

```
Select the fruits you like:
[press: Enter=toggle, a=all, n=none, d=done, q=abort]
[ ] apple
> [X] orange
[X] grape
[ ] strawberry
[ ] blueberry
[X] peach
[ ] lemon
[ ] lime
You like the following fruits:
- orange
- grape
- peach
```

Customization / Configuration

ConfiguredMenu subtypes

Starting with Julia 1.6, the recommended way to configure menus is via the constructor. For instance, the default multiple-selection menu

```
julia> menu = MultiSelectMenu(options, pagesize=5);

julia> request(menu) # ASCII is used by default
[press: Enter=toggle, a=all, n=none, d=done, q=abort]
[ ] apple
[X] orange
```

```
|  [ ] grape
|  > [X] strawberry
|  v [ ] blueberry
```

can instead be rendered with Unicode selection and navigation characters with

```
julia> menu = MultiSelectMenu(options, pagesize=5, charset=:unicode);

julia> request(menu)
[press: Enter=toggle, a=all, n=none, d=done, q=abort]
  □ apple
  ✓ orange
  □ grape
  → ✓ strawberry
  ↓ □ blueberry
```

More fine-grained configuration is also possible:

```
julia> menu = MultiSelectMenu(options, pagesize=5, charset=:unicode, checked="YEP!",
↳ unchecked="NOPE", cursor='');

julia> request(menu)
julia> request(menu)
[press: Enter=toggle, a=all, n=none, d=done, q=abort]
  NOPE apple
  YEP! orange
  NOPE grape
  YEP! strawberry
  ↓ NOPE blueberry
```

Aside from the overall charset option, for RadioMenu the configurable options are:

- `cursor::Char='>' | '→'`: character to use for cursor
- `up_arrow::Char='^' | '↑'`: character to use for up arrow
- `down_arrow::Char='v' | '↓'`: character to use for down arrow
- `updown_arrow::Char='I' | '⤴'`: character to use for up/down arrow in one-line page
- `scroll_wrap::Bool=false`: optionally wrap-around at the beginning/end of a menu
- `ctrl_c_interrupt::Bool=true`: If false, return empty on ^C, if true throw `InterruptException()` on ^C

`MultiSelectMenu` adds:

- `checked::String="[X]" | "✓"`: string to use for checked
- `unchecked::String="[]" | "□"`: string to use for unchecked

You can create new menu types of your own. Types that are derived from `TerminalMenus.ConfiguredMenu` configure the menu options at construction time.

Legacy interface

Prior to Julia 1.6, and still supported throughout Julia 1.x, one can also configure menus by calling `TerminalMenus.config()`.

86.8 References**REPL**

`Base.atreplinit` – Function.

```
| atreplinit(f)
```

Register a one-argument function to be called before the REPL interface is initialized in interactive sessions; this is useful to customize the interface. The argument of `f` is the REPL object. This function should be called from within the `.julia/config/startup.jl` initialization file.

[source](#)

TerminalMenus**Menus**

`REPL.TerminalMenus.RadioMenu` – Type.

```
| RadioMenu
```

A menu that allows a user to select a single option from a list.

Sample Output

```
julia> request(RadioMenu(options, pagesize=4))
Choose your favorite fruit:
^  grape
   strawberry
>  blueberry
v  peach
Your favorite fruit is blueberry!
```

`REPL.TerminalMenus.MultiSelectMenu` – Type.

```
| MultiSelectMenu
```

A menu that allows a user to select a multiple options from a list.

Sample Output

```
julia> request(MultiSelectMenu(options))
Select the fruits you like:
[press: Enter=toggle, a=all, n=none, d=done, q=abort]
[ ] apple
> [X] orange
[X] grape
[ ] strawberry
[ ] blueberry
```

```

    [X] peach
    [ ] lemon
    [ ] lime
You like the following fruits:
- orange
- grape
- peach

```

Configuration

REPL.TerminalMenus.Config – Type.

```

Config(; scroll_wrap=false, ctrl_c_interrupt=true, charset=:ascii, cursor::Char,
↪ up_arrow::Char, down_arrow::Char)

```

Configure behavior for selection menus via keyword arguments:

- `scroll_wrap`, if true, causes the menu to wrap around when scrolling above the first or below the last entry
- `ctrl_c_interrupt`, if true, throws an `InterruptException` if the user hits Ctrl-C during menu selection. If false, `TerminalMenus.request` will return the default result from `TerminalMenus.selected`.
- `charset` affects the default values for `cursor`, `up_arrow`, and `down_arrow`, and can be `:ascii` or `:unicode`
- `cursor` is the character printed to indicate the option that will be chosen by hitting "Enter." Defaults are `'>'` or `'→'`, depending on `charset`.
- `up_arrow` is the character printed when the display does not include the first entry. Defaults are `'^'` or `'↑'`, depending on `charset`.
- `down_arrow` is the character printed when the display does not include the last entry. Defaults are `'v'` or `'↓'`, depending on `charset`.

Subtypes of `ConfiguredMenu` will print `cursor`, `up_arrow`, and `down_arrow` automatically as needed, your `writeline` method should not print them.

Julia 1.6

`Config` is available as of Julia 1.6. On older releases use the global `CONFIG`.

REPL.TerminalMenus.MultiSelectConfig – Type.

```

MultiSelectConfig(; charset=:ascii, checked::String, unchecked::String, kwargs...)

```

Configure behavior for a multiple-selection menu via keyword arguments:

- `checked` is the string to print when an option has been selected. Defaults are `"[X]"` or `"✓"`, depending on `charset`.
- `unchecked` is the string to print when an option has not been selected. Defaults are `"[]"` or `"☐"`, depending on `charset`.

All other keyword arguments are as described for `TerminalMenus.Config`. `checked` and `unchecked` are not printed automatically, and should be printed by your `writeline` method.

Julia 1.6

MultiSelectConfig is available as of Julia 1.6. On older releases use the global CONFIG.

REPL.TerminalMenus.config – Function.

```
| config( <see arguments> )
```

Keyword-only function to configure global menu parameters

Arguments

- `charset::Symbol=:na`: ui characters to use (:ascii or :unicode); overridden by other arguments
- `cursor::Char='>' | '→'`: character to use for cursor
- `up_arrow::Char='^' | '↑'`: character to use for up arrow
- `down_arrow::Char='v' | '↓'`: character to use for down arrow
- `checked::String="[X]" | "✓"`: string to use for checked
- `unchecked::String="[]" | "□"`: string to use for unchecked
- `scroll::Symbol=:nowrap`: If :wrap wrap cursor around top and bottom, if :nowrap do not wrap cursor
- `supress_output::Bool=false`: Ignored legacy argument, pass `suppress_output` as a keyword argument to request instead.
- `ctrl_c_interrupt::Bool=true`: If false, return empty on ^C, if true throw `InterruptedException()` on ^C

Julia 1.6

As of Julia 1.6, config is deprecated. Use Config or MultiSelectConfig instead.

User interaction

REPL.TerminalMenus.request – Function.

```
| request(m::AbstractMenu; cursor=1)
```

Display the menu and enter interactive mode. `cursor` indicates the item number used for the initial cursor position. `cursor` can be either an `Int` or a `RefValue{Int}`. The latter is useful for observation and control of the cursor position from the outside.

Returns `selected(m)`.

Julia 1.6

The `cursor` argument requires Julia 1.6 or later.

```
| request([term,] msg::AbstractString, m::AbstractMenu)
```

Shorthand for `println(msg); request(m)`.

AbstractMenu extension interface

Any subtype of `AbstractMenu` must be mutable, and must contain the fields `pagesize::Int` and `pageoffset::Int`. Any subtype must also implement the following functions:

`REPL.TerminalMenus.pick` – Function.

```
| pick(m::AbstractMenu, cursor::Int)
```

Defines what happens when a user presses the Enter key while the menu is open. If `true` is returned, `request()` will exit. `cursor` indexes the position of the selection.

`REPL.TerminalMenus.cancel` – Function.

```
| cancel(m::AbstractMenu)
```

Define what happens when a user cancels ('q' or ctrl-c) a menu. `request()` will always exit after calling this function.

`REPL.TerminalMenus.writeline` – Function.

```
| writeline(buf::IO, m::AbstractMenu, idx::Int, iscursor::Bool)
```

Write the option at index `idx` to `buf`. `iscursor`, if `true`, indicates that this item is at the current cursor position (the one that will be selected by hitting "Enter").

If `m` is a `ConfiguredMenu`, `TerminalMenus` will print the cursor indicator. Otherwise the callee is expected to handle such printing.

Julia 1.6

`writeline` requires Julia 1.6 or higher.

On older versions of Julia, this was `writeLine(buf::IO, m::AbstractMenu, idx, iscursor::Bool)` and `m` is assumed to be unconfigured. The selection and cursor indicators can be obtained from `TerminalMenus.CONFIG`.

This older function is supported on all Julia 1.x versions but will be dropped in Julia 2.0.

It must also implement either `options` or `numoptions`:

`REPL.TerminalMenus.options` – Function.

```
| options(m::AbstractMenu)
```

Return a list of strings to be displayed as options in the current page.

Alternatively, implement `numoptions`, in which case `options` is not needed.

`REPL.TerminalMenus.numoptions` – Function.

```
| numoptions(m::AbstractMenu) -> Int
```

Return the number of options in menu `m`. Defaults to `length(options(m))`.

Julia 1.6

This function requires Julia 1.6 or later.

If the subtype does not have a field named `selected`, it must also implement

`REPL.TerminalMenus.selected` – Function.

```
| selected(m::AbstractMenu)
```

Return information about the user-selected option. By default it returns `m.selected`.

The following are optional but can allow additional customization:

`REPL.TerminalMenus.header` – Function.

```
| header(m::AbstractMenu) -> String
```

Return a header string to be printed above the menu. Defaults to "".

`REPL.TerminalMenus.keypress` – Function.

```
| keypress(m::AbstractMenu, i::UInt32) -> Bool
```

Handle any non-standard keypress event. If `true` is returned, `TerminalMenus.request` will exit. Defaults to `false`.

| Keybinding | Description |
|------------------------|--|
| Program control | |
| ^D | Exit (when buffer is empty) |
| ^C | Interrupt or cancel |
| ^L | Clear console screen |
| Return/Enter, ^J | New line, executing if it is complete |
| meta-Return/Enter | Insert new line without executing it |
| ? or ; | Enter help or shell mode (when at start of a line) |
| ^R, ^S | Incremental history search, described above |
| Cursor movement | |
| Right arrow, ^F | Move right one character |
| Left arrow, ^B | Move left one character |
| ctrl-Right, meta-F | Move right one word |
| ctrl-Left, meta-B | Move left one word |
| Home, ^A | Move to beginning of line |
| End, ^E | Move to end of line |
| Up arrow, ^P | Move up one line (or change to the previous history entry that matches the text before the cursor) |
| Down arrow, ^N | Move down one line (or change to the next history entry that matches the text before the cursor) |
| Shift-Arrow Key | Move cursor according to the direction of the Arrow key, while activating the region ("shift selection") |
| Page-up, meta-P | Change to the previous history entry |
| Page-down, meta-N | Change to the next history entry |
| meta-< | Change to the first history entry (of the current session if it is before the current position in history) |
| meta-> | Change to the last history entry |
| ^_Space | Set the "mark" in the editing region (and de-activate the region if it's active) |
| ^_Space
^_Space | Set the "mark" in the editing region and make the region "active", i.e. highlighted |
| ^G | De-activate the region (i.e. make it not highlighted) |
| ^X^X | Exchange the current position with the mark |
| Editing | |
| Backspace, ^H | Delete the previous character, or the whole region when it's active |
| Delete, ^D | Forward delete one character (when buffer has text) |
| meta-Backspace | Delete the previous word |
| meta-d | Forward delete the next word |
| ^W | Delete previous text up to the nearest whitespace |
| meta-w | Copy the current region in the kill ring |
| meta-W | "Kill" the current region, placing the text in the kill ring |
| ^U | "Kill" to beginning of line, placing the text in the kill ring |
| ^K | "Kill" to end of line, placing the text in the kill ring |
| ^Y | "Yank" insert the text from the kill ring |
| meta-y | Replace a previously yanked text with an older entry from the kill ring |
| ^T | Transpose the characters about the cursor |
| meta-Up arrow | Transpose current line with line above |
| meta-Down arrow | Transpose current line with line below |
| meta-u | Change the next word to uppercase |
| meta-c | Change the next word to titlecase |
| meta-l | Change the next word to lowercase |
| ^/, ^_ | Undo previous editing action |
| ^Q | Write a number in REPL and press ^Q to open editor at corresponding stackframe or method |

Chapter 87

Random Numbers

Random number generation in Julia uses the [Xoshiro256++](#) algorithm by default, with per-Task state. Other RNG types can be plugged in by inheriting the `AbstractRNG` type; they can then be used to obtain multiple streams of random numbers.

The PRNGs (pseudorandom number generators) exported by the `Random` package are:

- `TaskLocalRNG`: a token that represents use of the currently active Task-local stream, deterministically seeded from the parent task, or by `RandomDevice` (with system randomness) at program start
- `Xoshiro`: generates a high-quality stream of random numbers with a small state vector and high performance using the `Xoshiro256++` algorithm
- `RandomDevice`: for OS-provided entropy. This may be used for cryptographically secure random numbers (CS(P)RNG).
- `MersenneTwister`: an alternate high-quality PRNG which was the default in older versions of Julia, and is also quite fast, but requires much more space to store the state vector and generate a random sequence.

Most functions related to random generation accept an optional `AbstractRNG` object as first argument. Some also accept dimension specifications `dims...` (which can also be given as a tuple) to generate arrays of random values. In a multi-threaded program, you should generally use different RNG objects from different threads or tasks in order to be thread-safe. However, the default RNG is thread-safe as of Julia 1.3 (using a per-thread RNG up to version 1.6, and per-task thereafter).

The provided RNGs can generate uniform random numbers of the following types: `Float16`, `Float32`, `Float64`, `BigFloat`, `Bool`, `Int8`, `UInt8`, `Int16`, `UInt16`, `Int32`, `UInt32`, `Int64`, `UInt64`, `Int128`, `UInt128`, `BigInt` (or complex numbers of those types). Random floating point numbers are generated uniformly in $[0, 1)$. As `BigInt` represents unbounded integers, the interval must be specified (e.g. `rand(big, (1:6))`).

Additionally, normal and exponential distributions are implemented for some `AbstractFloat` and `Complex` types, see [randn](#) and [randexp](#) for details.

To generate random numbers from other distributions, see the [Distributions.jl](#) package.

Warning

Because the precise way in which random numbers are generated is considered an implementation detail, bug fixes and speed improvements may change the stream of numbers that are generated after a version change. Relying on a specific seed or generated stream of numbers during unit testing is thus discouraged - consider testing properties of the methods in question instead.

87.1 Random numbers module

`Random.Random` - Module.

| `Random`

Support for generating random numbers. Provides [rand](#), [randn](#), [AbstractRNG](#), [MersenneTwister](#), and [RandomDevice](#).

87.2 Random generation functions

`Base.rand` - Function.

| `rand([rng=default_rng()], [S], [dims...])`

Pick a random element or array of random elements from the set of values specified by `S`; `S` can be

- an indexable collection (for example `1:9` or `('x', "y", :z)`),
- an `AbstractDict` or `AbstractSet` object,
- a string (considered as a collection of characters), or
- a type: the set of values to pick from is then equivalent to `typemin(S):typemax(S)` for integers (this is not applicable to [BigInt](#)), to $[0, 1)$ for floating point numbers and to $[0, 1) + i[0, 1)$ for complex floating point numbers;

`S` defaults to [Float64](#). When only one argument is passed besides the optional `rng` and is a `Tuple`, it is interpreted as a collection of values (`S`) and not as `dims`.

See also [randn](#) for normally distributed numbers, and [rand!](#) and [randn!](#) for the in-place equivalents.

Julia 1.1

Support for `S` as a tuple requires at least Julia 1.1.

Examples

```
julia> rand{Int, 2}
2-element Array{Int64,1}:
 1339893410598768192
 1575814717733606317

julia> using Random

julia> rand{MersenneTwister(0), Dict{1=>2, 3=>4}}
1=>2
```

```
julia> rand((2, 3))
3

julia> rand{Float64, (2, 3)}
2×3 Array{Float64,2}:
 0.999717  0.0143835  0.540787
 0.696556  0.783855  0.938235
```

Note

The complexity of `rand(rng, s::Union{AbstractDict, AbstractSet})` is linear in the length of `s`, unless an optimized method with constant complexity is available, which is the case for `Dict`, `Set` and dense `BitSets`. For more than a few calls, use `rand(rng, collect(s))` instead, or either `rand(rng, Dict(s))` or `rand(rng, Set(s))` as appropriate.

`Random.rand!` – Function.

```
| rand!([rng=default_rng()], A, [S=eltype(A)])
```

Populate the array `A` with random values. If `S` is specified (`S` can be a type or a collection, cf. [rand](#) for details), the values are picked randomly from `S`. This is equivalent to `copyto!(A, rand(rng, S, size(A)))` but without allocating a new array.

Examples

```
julia> rng = MersenneTwister(1234);

julia> rand!(rng, zeros(5))
5-element Vector{Float64}:
 0.5908446386657102
 0.7667970365022592
 0.5662374165061859
 0.4600853424625171
 0.7940257103317943
```

`Random.bitrand` – Function.

```
| bitrand([rng=default_rng()], [dims...])
```

Generate a `BitArray` of random boolean values.

Examples

```
julia> rng = MersenneTwister(1234);

julia> bitrand(rng, 10)
10-element BitVector:
 0
 0
 0
 0
 1
 0
 0
```

```
| 0
| 1
| 1
```

Base.randn – Function.

```
| randn([rng=default_rng()], [T=Float64], [dims...])
```

Generate a normally-distributed random number of type T with mean 0 and standard deviation 1. Optionally generate an array of normally-distributed random numbers. The Base module currently provides an implementation for the types `Float16`, `Float32`, and `Float64` (the default), and their `Complex` counterparts. When the type argument is complex, the values are drawn from the circularly symmetric complex normal distribution of variance 1 (corresponding to real and imaginary part having independent normal distribution with mean zero and variance 1/2).

See also `randn!` to act in-place.

Examples

```
julia> using Random

julia> rng = MersenneTwister(1234);

julia> randn(rng, ComplexF64)
0.6133070881429037 - 0.6376291670853887im

julia> randn(rng, ComplexF32, (2, 3))
2×3 Matrix{ComplexF32}:
-0.349649-0.638457im  0.376756-0.192146im  -0.396334-0.0136413im
 0.611224+1.56403im  0.355204-0.365563im  0.0905552+1.31012im
```

Random.randn! – Function.

```
| randn!([rng=default_rng()], A::AbstractArray) -> A
```

Fill the array A with normally-distributed (mean 0, standard deviation 1) random numbers. Also see the `rand` function.

Examples

```
julia> rng = MersenneTwister(1234);

julia> randn!(rng, zeros(5))
5-element Vector{Float64}:
 0.8673472019512456
-0.9017438158568171
-0.4944787535042339
-0.9029142938652416
 0.8644013132535154
```

Random.randexp – Function.

```
| randexp([rng=default_rng()], [T=Float64], [dims...])
```

Generate a random number of type `T` according to the exponential distribution with scale 1. Optionally generate an array of such random numbers. The `Base` module currently provides an implementation for the types `Float16`, `Float32`, and `Float64` (the default).

Examples

```
julia> rng = MersenneTwister(1234);

julia> randexp(rng, Float32)
2.4835055f0

julia> randexp(rng, 3, 3)
3×3 Matrix{Float64}:
 1.5167  1.30652  0.344435
 0.604436 2.78029  0.418516
 0.695867 0.693292 0.643644
```

`Random.randexp!` – Function.

```
randexp!([rng=default_rng()], A::AbstractArray) -> A
```

Fill the array `A` with random numbers following the exponential distribution (with scale 1).

Examples

```
julia> rng = MersenneTwister(1234);

julia> randexp!(rng, zeros(5))
5-element Vector{Float64}:
 2.4835053723904896
 1.516703605376473
 0.6044364871025417
 0.6958665886385867
 1.3065196315496677
```

`Random.randstring` – Function.

```
randstring([rng=default_rng()], [chars], [len=8])
```

Create a random string of length `len`, consisting of characters from `chars`, which defaults to the set of upper- and lower-case letters and the digits 0-9. The optional `rng` argument specifies a random number generator, see [Random Numbers](#).

Examples

```
julia> Random.seed!(3); randstring()
"Lxz5hUwn"

julia> randstring(MersenneTwister(3), 'a':'z', 6)
"ocucay"

julia> randstring("ACGT")
"TGCTCCTC"
```

Note

chars can be any collection of characters, of type Char or UInt8 (more efficient), provided [rand](#) can randomly pick characters from it.

87.3 Subsequences, permutations and shuffling

Random.randsubseq – Function.

```
| randsubseq([rng=default_rng(),] A, p) -> Vector
```

Return a vector consisting of a random subsequence of the given array A, where each element of A is included (in order) with independent probability p. (Complexity is linear in $p \cdot \text{length}(A)$, so this function is efficient even if p is small and A is large.) Technically, this process is known as "Bernoulli sampling" of A.

Examples

```
julia> rng = MersenneTwister(1234);

julia> randsubseq(rng, 1:8, 0.3)
2-element Vector{Int64}:
 7
 8
```

Random.randsubseq! – Function.

```
| randsubseq!([rng=default_rng(),] S, A, p)
```

Like [randsubseq](#), but the results are stored in S (which is resized as needed).

Examples

```
julia> rng = MersenneTwister(1234);

julia> S = Int64[];

julia> randsubseq!(rng, S, 1:8, 0.3)
2-element Vector{Int64}:
 7
 8

julia> S
2-element Vector{Int64}:
 7
 8
```

Random.randperm – Function.

```
| randperm([rng=default_rng(),] n::Integer)
```

Construct a random permutation of length n. The optional rng argument specifies a random number generator (see [Random Numbers](#)). The element type of the result is the same as the type of n.

To randomly permute an arbitrary vector, see [shuffle](#) or [shuffle!](#).

Julia 1.1

In Julia 1.1 `randperm` returns a vector `v` with `eltype(v) == typeof(n)` while in Julia 1.0 `eltype(v) == Int`.

Examples

```
julia> randperm(MersenneTwister(1234), 4)
4-element Vector{Int64}:
 2
 1
 4
 3
```

`Random.randperm!` – Function.

```
randperm!([rng=default_rng(),] A::Array{<:Integer})
```

Construct in `A` a random permutation of length `length(A)`. The optional `rng` argument specifies a random number generator (see [Random Numbers](#)). To randomly permute an arbitrary vector, see [shuffle](#) or [shuffle!](#).

Examples

```
julia> randperm!(MersenneTwister(1234), Vector{Int}(undef, 4))
4-element Vector{Int64}:
 2
 1
 4
 3
```

`Random.randcycle` – Function.

```
randcycle([rng=default_rng(),] n::Integer)
```

Construct a random cyclic permutation of length `n`. The optional `rng` argument specifies a random number generator, see [Random Numbers](#). The element type of the result is the same as the type of `n`.

Julia 1.1

In Julia 1.1 `randcycle` returns a vector `v` with `eltype(v) == typeof(n)` while in Julia 1.0 `eltype(v) == Int`.

Examples

```
julia> randcycle(MersenneTwister(1234), 6)
6-element Vector{Int64}:
 3
 5
 4
 6
 1
 2
```

`Random.randcycle!` – Function.

```
| randcycle!([rng=default_rng(),] A::Array{<:Integer})
```

Construct in `A` a random cyclic permutation of length `length(A)`. The optional `rng` argument specifies a random number generator, see [Random Numbers](#).

Examples

```
| julia> randcycle!(MersenneTwister(1234), Vector{Int}(undef, 6))
6-element Vector{Int64}:
 3
 5
 4
 6
 1
 2
```

`Random.shuffle` – Function.

```
| shuffle([rng=default_rng(),] v::AbstractArray)
```

Return a randomly permuted copy of `v`. The optional `rng` argument specifies a random number generator (see [Random Numbers](#)). To permute `v` in-place, see `shuffle!`. To obtain randomly permuted indices, see `randperm`.

Examples

```
| julia> rng = MersenneTwister(1234);

julia> shuffle(rng, Vector{Int}(1:10))
10-element Vector{Int64}:
 6
 1
10
 2
 3
 9
 5
 7
 4
 8
```

`Random.shuffle!` – Function.

```
| shuffle!([rng=default_rng(),] v::AbstractArray)
```

In-place version of `shuffle`: randomly permute `v` in-place, optionally supplying the random-number generator `rng`.

Examples

```
julia> rng = MersenneTwister(1234);

julia> shuffle!(rng, Vector{Int64}(1:16))
16-element Vector{Int64}:
 2
15
 5
14
 1
 9
10
 6
11
 3
16
 7
 4
12
 8
13
```

87.4 Generators (creation and seeding)

Random.default_rng – Function.

```
default_rng() -> rng
```

Return the default global random number generator (RNG).

Note

What the default RNG is is an implementation detail. Across different versions of Julia, you should not expect the default RNG to be always the same, nor that it will return the same stream of random numbers for a given seed.

Julia 1.3

This function was introduced in Julia 1.3.

Random.seed! – Function.

```
seed!([rng=default_rng()], seed) -> rng
seed!([rng=default_rng()]) -> rng
```

Reseed the random number generator: rng will give a reproducible sequence of numbers if and only if a seed is provided. Some RNGs don't accept a seed, like RandomDevice. After the call to seed!, rng is equivalent to a newly created object initialized with the same seed.

If rng is not specified, it defaults to seeding the state of the shared task-local generator.

Examples

```
julia> Random.seed!(1234);
```

```

julia> x1 = rand(2)
2-element Vector{Float64}:
 0.32597672886359486
 0.5490511363155669

julia> Random.seed!(1234);

julia> x2 = rand(2)
2-element Vector{Float64}:
 0.32597672886359486
 0.5490511363155669

julia> x1 == x2
true

julia> rng = Xoshiro(1234); rand(rng, 2) == x1
true

julia> Xoshiro(1) == Random.seed!(rng, 1)
true

julia> rand(Random.seed!(rng), Bool) # not reproducible
true

julia> rand(Random.seed!(rng), Bool) # not reproducible either
false

julia> rand(Xoshiro(), Bool) # not reproducible either
true

```

Random.AbstractRNG – Type.

| **AbstractRNG**

Supertype for random number generators such as [MersenneTwister](#) and [RandomDevice](#).

Random.TaskLocalRNG – Type.

| TaskLocalRNG

The TaskLocalRNG has state that is local to its task, not its thread. It is seeded upon task creation, from the state of its parent task. Therefore, task creation is an event that changes the parent's RNG state.

As an upside, the TaskLocalRNG is pretty fast, and permits reproducible multithreaded simulations (barring race conditions), independent of scheduler decisions. As long as the number of threads is not used to make decisions on task creation, simulation results are also independent of the number of available threads / CPUs. The random stream should not depend on hardware specifics, up to endianness and possibly word size.

Using or seeding the RNG of any other task than the one returned by `current_task()` is undefined behavior: it will work most of the time, and may sometimes fail silently.

Random.Xoshiro – Type.

```
Xoshiro(seed)
Xoshiro()
```

Xoshiro256++ is a fast pseudorandom number generator described by David Blackman and Sebastiano Vigna in "Scrambled Linear Pseudorandom Number Generators", ACM Trans. Math. Softw., 2021. Reference implementation is available at <http://prng.di.unimi.it>

Apart from the high speed, Xoshiro has a small memory footprint, making it suitable for applications where many different random states need to be held for long time.

Julia's Xoshiro implementation has a bulk-generation mode; this seeds new virtual PRNGs from the parent, and uses SIMD to generate in parallel (i.e. the bulk stream consists of multiple interleaved xoshiro instances). The virtual PRNGs are discarded once the bulk request has been serviced (and should cause no heap allocations).

Examples

```
julia> using Random

julia> rng = Xoshiro(1234);

julia> x1 = rand(rng, 2)
2-element Vector{Float64}:
 0.32597672886359486
 0.5490511363155669

julia> rng = Xoshiro(1234);

julia> x2 = rand(rng, 2)
2-element Vector{Float64}:
 0.32597672886359486
 0.5490511363155669

julia> x1 == x2
true
```

Random.MersenneTwister - Type.

```
MersenneTwister(seed)
MersenneTwister()
```

Create a MersenneTwister RNG object. Different RNG objects can have their own seeds, which may be useful for generating different streams of random numbers. The seed may be a non-negative integer or a vector of UInt32 integers. If no seed is provided, a randomly generated one is created (using entropy from the system). See the [seed!](#) function for reseeding an already existing MersenneTwister object.

Examples

```
julia> rng = MersenneTwister(1234);

julia> x1 = rand(rng, 2)
2-element Vector{Float64}:
 0.5908446386657102
```

```

0.7667970365022592

julia> rng = MersenneTwister(1234);

julia> x2 = rand(rng, 2)
2-element Vector{Float64}:
 0.5908446386657102
 0.7667970365022592

julia> x1 == x2
true

```

Random.RandomDevice – Type.

```
RandomDevice()
```

Create a RandomDevice RNG object. Two such objects will always generate different streams of random numbers. The entropy is obtained from the operating system.

87.5 Hooking into the Random API

There are two mostly orthogonal ways to extend Random functionalities:

1. generating random values of custom types
2. creating new generators

The API for 1) is quite functional, but is relatively recent so it may still have to evolve in subsequent releases of the Random module. For example, it's typically sufficient to implement one `rand` method in order to have all other usual methods work automatically.

The API for 2) is still rudimentary, and may require more work than strictly necessary from the implementor, in order to support usual types of generated values.

Generating random values of custom types

Generating random values for some distributions may involve various trade-offs. Pre-computed values, such as an [alias table](#) for discrete distributions, or [“squeezing” functions](#) for univariate distributions, can speed up sampling considerably. How much information should be pre-computed can depend on the number of values we plan to draw from a distribution. Also, some random number generators can have certain properties that various algorithms may want to exploit.

The Random module defines a customizable framework for obtaining random values that can address these issues. Each invocation of `rand` generates a sampler which can be customized with the above trade-offs in mind, by adding methods to `Sampler`, which in turn can dispatch on the random number generator, the object that characterizes the distribution, and a suggestion for the number of repetitions. Currently, for the latter, `Val{1}` (for a single sample) and `Val{Inf}` (for an arbitrary number) are used, with `Random.Repetition` an alias for both.

The object returned by `Sampler` is then used to generate the random values. When implementing the random generation interface for a value `X` that can be sampled from, the implementor should define the method

```
| rand(rng, sampler)
```

for the particular sampler returned by `Sampler(rng, X, repetition)`.

Samplers can be arbitrary values that implement `rand(rng, sampler)`, but for most applications the following predefined samplers may be sufficient:

1. `SamplerType{T}()` can be used for implementing samplers that draw from type `T` (e.g. `rand(Int)`). This is the default returned by `Sampler` for types.
2. `SamplerTrivial(self)` is a simple wrapper for `self`, which can be accessed with `[]`. This is the recommended sampler when no pre-computed information is needed (e.g. `rand(1:3)`), and is the default returned by `Sampler` for values.
3. `SamplerSimple(self, data)` also contains the additional `data` field, which can be used to store arbitrary pre-computed values, which should be computed in a custom method of `Sampler`.

We provide examples for each of these. We assume here that the choice of algorithm is independent of the RNG, so we use `AbstractRNG` in our signatures.

`Random.Sampler` – Type.

```
| Sampler(rng, x, repetition = Val{Inf})
```

Return a sampler object that can be used to generate random values from `rng` for `x`.

When `sp = Sampler(rng, x, repetition)`, `rand(rng, sp)` will be used to draw random values, and should be defined accordingly.

`repetition` can be `Val{1}` or `Val{Inf}`, and should be used as a suggestion for deciding the amount of precomputation, if applicable.

`Random.SamplerType` and `Random.SamplerTrivial` are default fallbacks for types and values, respectively. `Random.SamplerSimple` can be used to store pre-computed values without defining extra types for only this purpose.

`Random.SamplerType` – Type.

```
| SamplerType{T}()
```

A sampler for types, containing no other information. The default fallback for `Sampler` when called with types.

`Random.SamplerTrivial` – Type.

```
| SamplerTrivial(x)
```

Create a sampler that just wraps the given value `x`. This is the default fall-back for values. The `eltype` of this sampler is equal to `eltype(x)`.

The recommended use case is sampling from values without precomputed data.

`Random.SamplerSimple` – Type.

```
| SamplerSimple(x, data)
```

Create a sampler that wraps the given value `x` and the data. The `eltype` of this sampler is equal to `eltype(x)`.

The recommended use case is sampling from values with precomputed data.

Decoupling pre-computation from actually generating the values is part of the API, and is also available to the user. As an example, assume that `rand(rng, 1:20)` has to be called repeatedly in a loop: the way to take advantage of this decoupling is as follows:

```
rng = MersenneTwister()
sp = Random.Sampler(rng, 1:20) # or Random.Sampler(MersenneTwister, 1:20)
for x in X
    n = rand(rng, sp) # similar to n = rand(rng, 1:20)
    # use n
end
```

This is the mechanism that is also used in the standard library, e.g. by the default implementation of random array generation (like in `rand(1:20, 10)`).

Generating values from a type

Given a type `T`, it's currently assumed that if `rand(T)` is defined, an object of type `T` will be produced. `SamplerType` is the default sampler for types. In order to define random generation of values of type `T`, the `rand(rng::AbstractRNG, ::Random.SamplerType{T})` method should be defined, and should return values what `rand(rng, T)` is expected to return.

Let's take the following example: we implement a `Die` type, with a variable number `n` of sides, numbered from 1 to `n`. We want `rand(Die)` to produce a `Die` with a random number of up to 20 sides (and at least 4):

```
struct Die
    nsides::Int # number of sides
end

Random.rand(rng::AbstractRNG, ::Random.SamplerType{Die}) = Die(rand(rng, 4:20))

# output
```

Scalar and array methods for `Die` now work as expected:

```
julia> rand(Die)
Die(5)

julia> rand(MersenneTwister(0), Die)
Die(11)

julia> rand(Die, 3)
3-element Vector{Die}:
 Die(9)
 Die(15)
 Die(14)
```

```
julia> a = Vector{Die}(undef, 3); rand!(a)
3-element Vector{Die}:
 Die(19)
 Die(7)
 Die(17)
```

A simple sampler without pre-computed data

Here we define a sampler for a collection. If no pre-computed data is required, it can be implemented with a `SamplerTrivial` sampler, which is in fact the default fallback for values.

In order to define random generation out of objects of type `S`, the following method should be defined: `rand(rng::AbstractRNG, sp::Random.SamplerTrivial{S})`. Here, `sp` simply wraps an object of type `S`, which can be accessed via `sp[]`. Continuing the `Die` example, we want now to define `rand(d::Die)` to produce an `Int` corresponding to one of `d`'s sides:

```
julia> Random.rand(rng::AbstractRNG, d::Random.SamplerTrivial{Die}) = rand(rng, 1:d[].nsides);

julia> rand(Die(4))
1

julia> rand(Die(4), 3)
3-element Vector{Any}:
 2
 3
 3
```

Given a collection type `S`, it's currently assumed that if `rand(::S)` is defined, an object of type `eltype(S)` will be produced. In the last example, a `Vector{Any}` is produced; the reason is that `eltype(Die) == Any`. The remedy is to define `Base.eltype(::Type{Die}) = Int`.

Generating values for an AbstractFloat type

`AbstractFloat` types are special-cased, because by default random values are not produced in the whole type domain, but rather in $[0, 1)$. The following method should be implemented for `T <: AbstractFloat`: `Random.rand(::AbstractRNG, ::Random.SamplerTrivial{Random.CloseOpen01{T}})`

An optimized sampler with pre-computed data

Consider a discrete distribution, where numbers $1:n$ are drawn with given probabilities that sum to one. When many values are needed from this distribution, the fastest method is using an [alias table](#). We don't provide the algorithm for building such a table here, but suppose it is available in `make_alias_table(probabilities)` instead, and `draw_number(rng, alias_table)` can be used to draw a random number from it.

Suppose that the distribution is described by

```
struct DiscreteDistribution{V <: AbstractVector}
    probabilities::V
end
```

and that we always want to build an alias table, regardless of the number of values needed (we learn how to customize this below). The methods

```
Random.eltype(::Type{<:DiscreteDistribution}) = Int

function Random.Sampler(::Type{<:AbstractRNG}, distribution::DiscreteDistribution, ::Repetition)
    SamplerSimple(distribution, make_alias_table(distribution.probabilities))
end
```

should be defined to return a sampler with pre-computed data, then

```
function rand(rng::AbstractRNG, sp::SamplerSimple{<:DiscreteDistribution})
    draw_number(rng, sp.data)
end
```

will be used to draw the values.

Custom sampler types

The `SamplerSimple` type is sufficient for most use cases with precomputed data. However, in order to demonstrate how to use custom sampler types, here we implement something similar to `SamplerSimple`.

Going back to our `Die` example: `rand(::Die)` uses random generation from a range, so there is an opportunity for this optimization. We call our custom sampler `SamplerDie`.

```
import Random: Sampler, rand

struct SamplerDie <: Sampler{Int} # generates values of type Int
    die::Die
    sp::Sampler{Int} # this is an abstract type, so this could be improved
end

Sampler(RNG::Type{<:AbstractRNG}, die::Die, r::Random.Repetition) =
    SamplerDie(die, Sampler(RNG, 1:die.nsides, r))
# the `r` parameter will be explained later on

rand(rng::AbstractRNG, sp::SamplerDie) = rand(rng, sp.sp)
```

It's now possible to get a sampler with `sp = Sampler(rng, die)`, and use `sp` instead of `die` in any `rand` call involving `rng`. In the simplistic example above, `die` doesn't need to be stored in `SamplerDie` but this is often the case in practice.

Of course, this pattern is so frequent that the helper type used above, namely `Random.SamplerSimple`, is available, saving us the definition of `SamplerDie`: we could have implemented our decoupling with:

```
Sampler(RNG::Type{<:AbstractRNG}, die::Die, r::Random.Repetition) =
    SamplerSimple(die, Sampler(RNG, 1:die.nsides, r))

rand(rng::AbstractRNG, sp::SamplerSimple{Die}) = rand(rng, sp.data)
```

Here, `sp.data` refers to the second parameter in the call to the `SamplerSimple` constructor (in this case equal to `Sampler(rng, 1:die.nsides, r)`), while the `Die` object can be accessed via `sp[]`.

Like `SamplerDie`, any custom sampler must be a subtype of `Sampler{T}` where `T` is the type of the generated values. Note that `SamplerSimple(x, data)` `isa` `Sampler{eltype(x)}`, so this constrains what the first argument to `SamplerSimple` can be (it's recommended to use `SamplerSimple` like in the `Die` example, where `x` is simply forwarded while defining a `Sampler` method). Similarly, `SamplerTrivial(x)` `isa` `Sampler{eltype(x)}`.

Another helper type is currently available for other cases, `Random.SamplerTag`, but is considered as internal API, and can break at any time without proper deprecations.

Using distinct algorithms for scalar or array generation

In some cases, whether one wants to generate only a handful of values or a large number of values will have an impact on the choice of algorithm. This is handled with the third parameter of the `Sampler` constructor. Let's assume we defined two helper types for `Die`, say `SamplerDie1` which should be used to generate only few random values, and `SamplerDieMany` for many values. We can use those types as follows:

```
Sampler(RNG::Type{<:AbstractRNG}, die::Die, ::Val{1}) = SamplerDie1(...)
Sampler(RNG::Type{<:AbstractRNG}, die::Die, ::Val{Inf}) = SamplerDieMany(...)
```

Of course, `rand` must also be defined on those types (i.e. `rand(::AbstractRNG, ::SamplerDie1)` and `rand(::AbstractRNG, ::SamplerDieMany)`). Note that, as usual, `SamplerTrivial` and `SamplerSimple` can be used if custom types are not necessary.

Note: `Sampler(rng, x)` is simply a shorthand for `Sampler(rng, x, Val{Inf})`, and `Random.Repetition` is an alias for `Union{Val{1}, Val{Inf}}`.

Creating new generators

The API is not clearly defined yet, but as a rule of thumb:

1. any `rand` method producing "basic" types (isbitstype integer and floating types in `Base`) should be defined for this specific RNG, if they are needed;
2. other documented `rand` methods accepting an `AbstractRNG` should work out of the box, (provided the methods from 1) what are relied on are implemented), but can of course be specialized for this RNG if there is room for optimization;
3. copy for pseudo-RNGs should return an independent copy that generates the exact same random sequence as the original from that point when called in the same way. When this is not feasible (e.g. hardware-based RNGs), copy must not be implemented.

Concerning 1), a `rand` method may happen to work automatically, but it's not officially supported and may break without warnings in a subsequent release.

To define a new `rand` method for an hypothetical `MyRNG` generator, and a value specification `s` (e.g. `s == Int`, or `s == 1:10`) of type `S==typeof(s)` or `S==Type{s}` if `s` is a type, the same two methods as we saw before must be defined:

1. `Sampler(::Type{MyRNG}, ::S, ::Repetition)`, which returns an object of type say `SamplerS`
2. `rand(rng::MyRNG, sp::SamplerS)`

It can happen that `Sampler(rng::AbstractRNG, ::S, ::Repetition)` is already defined in the `Random` module. It would then be possible to skip step 1) in practice (if one wants to specialize generation for this particular RNG type), but the corresponding `SamplerS` type is considered as internal detail, and may be changed without warning.

Specializing array generation

In some cases, for a given RNG type, generating an array of random values can be more efficient with a specialized method than by merely using the decoupling technique explained before. This is for example the case for `MersenneTwister`, which natively writes random values in an array.

To implement this specialization for `MyRNG` and for a specification `s`, producing elements of type `S`, the following method can be defined: `rand!(rng::MyRNG, a::AbstractArray{S}, ::SamplerS)`, where `SamplerS` is the type of the sampler returned by `Sampler(MyRNG, s, Val{Inf})`. Instead of `AbstractArray`, it's possible to implement the functionality only for a subtype, e.g. `Array{S}`. The non-mutating array method of `rand` will automatically call this specialization internally.

Chapter 88

Reproducibility

By using an RNG parameter initialized with a given seed, you can reproduce the same pseudorandom number sequence when running your program multiple times. However, a minor release of Julia (e.g. 1.3 to 1.4) may change the sequence of pseudorandom numbers generated from a specific seed, in particular if MersenneTwister is used. (Even if the sequence produced by a low-level function like `rand` does not change, the output of higher-level functions like `randsubseq` may change due to algorithm updates.) Rationale: guaranteeing that pseudorandom streams never change prohibits many algorithmic improvements.

If you need to guarantee exact reproducibility of random data, it is advisable to simply save the data (e.g. as a supplementary attachment in a scientific publication). (You can also, of course, specify a particular Julia version and package manifest, especially if you require bit reproducibility.)

Software tests that rely on specific "random" data should also generally either save the data, embed it into the test code, or use third-party packages like `StableRNGs.jl`. On the other hand, tests that should pass for most random data (e.g. testing $A \setminus (A*x) \approx x$ for a random matrix $A = \text{randn}(n, n)$) can use an RNG with a fixed seed to ensure that simply running the test many times does not encounter a failure due to very improbable data (e.g. an extremely ill-conditioned matrix).

The statistical distribution from which random samples are drawn is guaranteed to be the same across any minor Julia releases.

Chapter 89

SHA

89.1 SHA functions

Usage is very straightforward:

```
julia> using SHA

julia> bytes2hex(sha256("test"))
"9f86d081884c7d659a2feaa0c55ad015a3bf4f1b2b0b822cd15d6c15b0f00a08"
```

Each exported function (at the time of this writing, SHA-1, SHA-2 224, 256, 384 and 512, and SHA-3 224, 256, 384 and 512 functions are implemented) takes in either an `AbstractVector{UInt8}`, an `AbstractString` or an `IO` object. This makes it trivial to checksum a file:

```
shell> cat /tmp/test.txt
test
julia> using SHA

julia> open("/tmp/test.txt") do f
    sha2_256(f)
end
32-element Array{UInt8,1}:
 0x9f
 0x86
 0xd0
 0x81
 0x88
 0x4c
 0x7d
 0x65

 0x5d
 0x6c
 0x15
 0xb0
 0xf0
 0x0a
 0x08
```

All SHA functions

Due to the colloquial usage of sha256 to refer to sha2_256, convenience functions are provided, mapping shaxxx() function calls to sha2_xxx(). For SHA-3, no such colloquialisms exist and the user must use the full sha3_xxx() names.

shaxxx() takes AbstractString and array-like objects (NTuple and Array) with elements of type UInt8.

SHA-1

SHA.sha1 – Function.

```
| sha1(data)
```

Hash data using the sha1 algorithm and return the resulting digest. See also [SHA1_CTX](#).

```
| sha1(io::IO)
```

Hash data from io using sha1 algorithm.

SHA-2

SHA.sha224 – Function.

```
| sha224(data)
```

Hash data using the sha224 algorithm and return the resulting digest. See also [SHA2_224_CTX](#).

```
| sha224(io::IO)
```

Hash data from io using sha224 algorithm.

SHA.sha256 – Function.

```
| sha256(data)
```

Hash data using the sha256 algorithm and return the resulting digest. See also [SHA2_256_CTX](#).

```
| sha256(io::IO)
```

Hash data from io using sha256 algorithm.

SHA.sha384 – Function.

```
| sha384(data)
```

Hash data using the sha384 algorithm and return the resulting digest. See also [SHA2_384_CTX](#).

```
| sha384(io::IO)
```

Hash data from io using sha384 algorithm.

SHA.sha512 – Function.

```
| sha512(data)
```

Hash data using the sha512 algorithm and return the resulting digest. See also [SHA2_512_CTX](#).

```
| sha512(io::IO)
```

Hash data from io using sha512 algorithm.

SHA.sha2_224 – Function.

```
| sha2_224(data)
```

Hash data using the sha2_224 algorithm and return the resulting digest. See also [SHA2_224_CTX](#).

```
| sha2_224(io::IO)
```

Hash data from io using sha2_224 algorithm.

SHA.sha2_256 – Function.

```
| sha2_256(data)
```

Hash data using the sha2_256 algorithm and return the resulting digest. See also [SHA2_256_CTX](#).

```
| sha2_256(io::IO)
```

Hash data from io using sha2_256 algorithm.

SHA.sha2_384 – Function.

```
| sha2_384(data)
```

Hash data using the sha2_384 algorithm and return the resulting digest. See also [SHA2_384_CTX](#).

```
| sha2_384(io::IO)
```

Hash data from io using sha2_384 algorithm.

SHA.sha2_512 – Function.

```
| sha2_512(data)
```

Hash data using the sha2_512 algorithm and return the resulting digest. See also [SHA2_512_CTX](#).

```
| sha2_512(io::IO)
```

Hash data from io using sha2_512 algorithm.

SHA-3

SHA.sha3_224 – Function.

```
| sha3_224(data)
```

Hash data using the sha3_224 algorithm and return the resulting digest. See also [SHA3_224_CTX](#).

```
| sha3_224(io::IO)
```

Hash data from io using sha3_224 algorithm.

SHA.sha3_256 – Function.

```
| sha3_256(data)
```

Hash data using the sha3_256 algorithm and return the resulting digest. See also [SHA3_256_CTX](#).

```
| sha3_256(io::IO)
```

Hash data from io using sha3_256 algorithm.

SHA.sha3_384 – Function.

```
| sha3_384(data)
```

Hash data using the sha3_384 algorithm and return the resulting digest. See also [SHA3_384_CTX](#).

```
| sha3_384(io::IO)
```

Hash data from io using sha3_384 algorithm.

SHA.sha3_512 – Function.

```
| sha3_512(data)
```

Hash data using the sha3_512 algorithm and return the resulting digest. See also [SHA3_512_CTX](#).

```
| sha3_512(io::IO)
```

Hash data from io using sha3_512 algorithm.

89.2 Working with context

To create a hash from multiple items the SHAX_XXX_CTX() types can be used to create a stateful hash object that is updated with update! and finalized with digest!

```
julia> using SHA

julia> ctx = SHA2_256_CTX()
SHA2 256-bit hash state

julia> update!(ctx, b"some data")
0x0000000000000009

julia> update!(ctx, b"some more data")
0x0000000000000017

julia> digest!(ctx)
32-element Vector{UInt8}:
 0xbe
 0xcf
 0x23
 0xda
 0xaf
 0x02
 0xf7
 0xa3
```

```

0x57
0x92

0x89
0x4f
0x59
0xd8
0xb3
0xb4
0x81
0x8b
0xc5

```

Note that, at the time of this writing, the SHA3 code is not optimized, and as such is roughly an order of magnitude slower than SHA2.

SHA.update! – Function.

```
update!(context, data[, datalen])
```

Update the SHA context with the bytes in data. See also [digest!](#) for finalizing the hash.

Examples

```

julia> ctx = SHA1_CTX()
SHA1 hash state

julia> update!(ctx, b"data to to be hashed")

```

SHA.digest! – Function.

```
digest!(context)
```

Finalize the SHA context and return the hash as array of bytes (Array{UInt8, 1}).

Examples

```

julia> ctx = SHA1_CTX()
SHA1 hash state

julia> update!(ctx, b"data to to be hashed")

julia> digest!(ctx)
20-element Array{UInt8,1}:
 0x83
 0xe4

 0x89
 0xf5

```

All SHA context types

SHA-1

SHA.SHA1_CTX – Type.

```
| SHA1_CTX()
```

Construct an empty SHA1 context.

SHA-2

Convenience types are also provided, where SHAXXX_CTX is a type alias for SHA2_XXX_CTX.

SHA.SHA224_CTX – Type.

```
| SHA2_224_CTX()
```

Construct an empty SHA2_224 context.

SHA.SHA256_CTX – Type.

```
| SHA2_256_CTX()
```

Construct an empty SHA2_256 context.

SHA.SHA384_CTX – Type.

```
| SHA2_384()
```

Construct an empty SHA2_384 context.

SHA.SHA512_CTX – Type.

```
| SHA2_512_CTX()
```

Construct an empty SHA2_512 context.

SHA.SHA2_224_CTX – Type.

```
| SHA2_224_CTX()
```

Construct an empty SHA2_224 context.

SHA.SHA2_256_CTX – Type.

```
| SHA2_256_CTX()
```

Construct an empty SHA2_256 context.

SHA.SHA2_384_CTX – Type.

```
| SHA2_384()
```

Construct an empty SHA2_384 context.

SHA.SHA2_512_CTX – Type.

```
| SHA2_512_CTX()
```

Construct an empty SHA2_512 context.

SHA-3

SHA.SHA3_224_CTX – Type.

```
| SHA3_224_CTX()
```

Construct an empty SHA3_224 context.

SHA.SHA3_256_CTX – Type.

```
| SHA3_256_CTX()
```

Construct an empty SHA3_256 context.

SHA.SHA3_384_CTX – Type.

```
| SHA3_384_CTX()
```

Construct an empty SHA3_384 context.

SHA.SHA3_512_CTX – Type.

```
| SHA3_512_CTX()
```

Construct an empty SHA3_512 context.

89.3 HMAC functions

```
julia> using SHA

julia> key = collect(codeunits("key_string"))
10-element Vector{UInt8}:
 0x6b
 0x65
 0x79
 0x5f
 0x73
 0x74
 0x72
 0x69
 0x6e
 0x67

julia> bytes2hex(hmac_sha3_256(key, "test-message"))
"bc49a6f2aa29b27ee5ed1e944edd7f3d153e8a01535d98b5e24dac9a589a6248"
```

To create a hash from multiple items, the HMAC_CTX() types can be used to create a stateful hash object that is updated with `update!` and finalized with `digest!`.

```
julia> using SHA

julia> key = collect(codeunits("key_string"))
10-element Vector{UInt8}:
```

SHA.hmac_sha256 – Function.

```
| hmac_sha256(key, data)
```

Hash data using the sha256 algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha256(key, io::IO)
```

Hash data from io with the passed key using sha256 algorithm.

SHA.hmac_sha384 – Function.

```
| hmac_sha384(key, data)
```

Hash data using the sha384 algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha384(key, io::IO)
```

Hash data from io with the passed key using sha384 algorithm.

SHA.hmac_sha512 – Function.

```
| hmac_sha512(key, data)
```

Hash data using the sha512 algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha512(key, io::IO)
```

Hash data from io with the passed key using sha512 algorithm.

SHA.hmac_sha2_224 – Function.

```
| hmac_sha2_224(key, data)
```

Hash data using the sha2_224 algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha2_224(key, io::IO)
```

Hash data from io with the passed key using sha2_224 algorithm.

SHA.hmac_sha2_256 – Function.

```
| hmac_sha2_256(key, data)
```

Hash data using the sha2_256 algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha2_256(key, io::IO)
```

Hash data from io with the passed key using sha2_256 algorithm.

SHA.hmac_sha2_384 – Function.

```
| hmac_sha2_384(key, data)
```

Hash data using the sha2_384 algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha2_384(key, io::IO)
```

Hash data from `io` with the passed key using `sha2_384` algorithm.

`SHA.hmac_sha2_512` – Function.

```
| hmac_sha2_512(key, data)
```

Hash data using the `sha2_512` algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha2_512(key, io::IO)
```

Hash data from `io` with the passed key using `sha2_512` algorithm.

SHA-3

`SHA.hmac_sha3_224` – Function.

```
| hmac_sha3_224(key, data)
```

Hash data using the `sha3_224` algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha3_224(key, io::IO)
```

Hash data from `io` with the passed key using `sha3_224` algorithm.

`SHA.hmac_sha3_256` – Function.

```
| hmac_sha3_256(key, data)
```

Hash data using the `sha3_256` algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha3_256(key, io::IO)
```

Hash data from `io` with the passed key using `sha3_256` algorithm.

`SHA.hmac_sha3_384` – Function.

```
| hmac_sha3_384(key, data)
```

Hash data using the `sha3_384` algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha3_384(key, io::IO)
```

Hash data from `io` with the passed key using `sha3_384` algorithm.

`SHA.hmac_sha3_512` – Function.

```
| hmac_sha3_512(key, data)
```

Hash data using the `sha3_512` algorithm using the passed key. See also [HMAC_CTX](#).

```
| hmac_sha3_512(key, io::IO)
```

Hash data from `io` with the passed key using `sha3_512` algorithm.

Chapter 90

Serialization

Provides serialization of Julia objects.

`Serialization.serialize` - Function.

```
| serialize(stream::IO, value)
```

Write an arbitrary value to a stream in an opaque format, such that it can be read back by `deserialize`. The read-back value will be as identical as possible to the original, but note that `Ptr` values are serialized as all-zero bit patterns (NULL).

An 8-byte identifying header is written to the stream first. To avoid writing the header, construct a `Serializer` and use it as the first argument to `serialize` instead. See also `Serialization.writeheader`.

The data format can change in minor (1.x) Julia releases, but files written by prior 1.x versions will remain readable. The main exception to this is when the definition of a type in an external package changes. If that occurs, it may be necessary to specify an explicit compatible version of the affected package in your environment. Renaming functions, even private functions, inside packages can also put existing files out of sync. Anonymous functions require special care: because their names are automatically generated, minor code changes can cause them to be renamed. Serializing anonymous functions should be avoided in files intended for long-term storage.

In some cases, the word size (32- or 64-bit) of the reading and writing machines must match. In rarer cases the OS or architecture must also match, for example when using packages that contain platform-dependent code.

```
| serialize(filename::AbstractString, value)
```

Open a file and serialize the given value to it.

Julia 1.1

This method is available as of Julia 1.1.

`Serialization.deserialize` - Function.

```
| deserialize(stream)
```

Read a value written by `serialize`. `deserialize` assumes the binary data read from `stream` is correct and has been serialized by a compatible implementation of `serialize`. `deserialize` is designed for

simplicity and performance, and so does not validate the data read. Malformed data can result in process termination. The caller must ensure the integrity and correctness of data read from `stream`.

```
| deserialize(filename::AbstractString)
```

Open a file and deserialize its contents.

Julia 1.1

This method is available as of Julia 1.1.

`Serialization.writeheader` - Function.

```
| Serialization.writeheader(s::AbstractSerializer)
```

Write an identifying header to the specified serializer. The header consists of 8 bytes as follows:

| Offset | Description |
|--------|--|
| 0 | tag byte (0x37) |
| 1-2 | signature bytes "JL" |
| 3 | protocol version |
| 4 | bits 0-1: endianness: 0 = little, 1 = big |
| 4 | bits 2-3: platform: 0 = 32-bit, 1 = 64-bit |
| 5-7 | reserved |

Chapter 91

Shared Arrays

SharedArray represents an array, which is shared across multiple processes, on a single machine.

SharedArrays.SharedArray – Type.

```
SharedArray{T}(dims::NTuple; init=false, pids=Int[])  
SharedArray{T,N}(...)
```

Construct a SharedArray of a bits type T and size dims across the processes specified by pids - all of which have to be on the same host. If N is specified by calling SharedArray{T,N}(dims), then N must match the length of dims.

If pids is left unspecified, the shared array will be mapped across all processes on the current host, including the master. But, localindices and indexpids will only refer to worker processes. This facilitates work distribution code to use workers for actual computation with the master process acting as a driver.

If an init function of the type initfn(S::SharedArray) is specified, it is called on all the participating workers.

The shared array is valid as long as a reference to the SharedArray object exists on the node which created the mapping.

```
SharedArray{T}(filename::AbstractString, dims::NTuple, [offset=0]; mode=nothing, init=false,  
pids=Int[])  
SharedArray{T,N}(...)
```

Construct a SharedArray backed by the file filename, with element type T (must be a bits type) and size dims, across the processes specified by pids - all of which have to be on the same host. This file is mmapmed into the host memory, with the following consequences:

- The array data must be represented in binary format (e.g., an ASCII format like CSV cannot be supported)
- Any changes you make to the array values (e.g., A[3] = 0) will also change the values on disk

If pids is left unspecified, the shared array will be mapped across all processes on the current host, including the master. But, localindices and indexpids will only refer to worker processes. This facilitates work distribution code to use workers for actual computation with the master process acting as a driver.

mode must be one of "r", "r+", "w+", or "a+", and defaults to "r+" if the file specified by filename already exists, or "w+" if not. If an init function of the type `initfn(S::SharedArray)` is specified, it is called on all the participating workers. You cannot specify an init function if the file is not writable.

offset allows you to skip the specified number of bytes at the beginning of the file.

[source](#)

`SharedArrays.SharedVector` – Type.

| **SharedVector**

A one-dimensional [SharedArray](#).

[source](#)

`SharedArrays.SharedMatrix` – Type.

| **SharedMatrix**

A two-dimensional [SharedArray](#).

[source](#)

`Distributed.procs` – Method.

| `procs(S::SharedArray)`

Get the vector of processes mapping the shared array.

[source](#)

`SharedArrays.sdata` – Function.

| `sdata(S::SharedArray)`

Return the actual Array object backing S.

[source](#)

`SharedArrays.indexpids` – Function.

| `indexpids(S::SharedArray)`

Return the current worker's index in the list of workers mapping the SharedArray (i.e. in the same list returned by `procs(S)`), or 0 if the SharedArray is not mapped locally.

[source](#)

`SharedArrays.localindices` – Function.

| `localindices(S::SharedArray)`

Return a range describing the "default" indices to be handled by the current process. This range should be interpreted in the sense of linear indexing, i.e., as a sub-range of `1:length(S)`. In multi-process contexts, returns an empty range in the parent process (or any process for which [indexpids](#) returns 0).

It's worth emphasizing that `localIndices` exists purely as a convenience, and you can partition work on the array among workers any way you wish. For a `SharedArray`, all indices should be equally fast for each worker process.

[source](#)

Chapter 92

Sockets

Sockets.Sockets – Module.

Support for sockets. Provides [IPAddr](#) and subtypes, [TCPSocket](#), and [UDPSocket](#).

Sockets.connect – Method.

```
| connect([host], port::Integer) -> TCPSocket
```

Connect to the host `host` on port `port`.

Sockets.connect – Method.

```
| connect(path::AbstractString) -> PipeEndpoint
```

Connect to the named pipe / UNIX domain socket at `path`.

Note

Path length on Unix is limited to somewhere between 92 and 108 bytes (cf. `man unix`).

Sockets.listen – Method.

```
| listen([addr, ]port::Integer; backlog::Integer=BACKLOG_DEFAULT) -> TCPServer
```

Listen on port on the address specified by `addr`. By default this listens on `localhost` only. To listen on all interfaces pass `IPv4(0)` or `IPv6(0)` as appropriate. `backlog` determines how many connections can be pending (not having called [accept](#)) before the server will begin to reject them. The default value of `backlog` is 511.

Sockets.listen – Method.

```
| listen(path::AbstractString) -> PipeServer
```

Create and listen on a named pipe / UNIX domain socket.

Note

Path length on Unix is limited to somewhere between 92 and 108 bytes (cf. `man unix`).

Sockets.getaddrinfo – Function.

```
| getaddrinfo(host::AbstractString, IPAddr=IPv4) -> IPAddr
```

Gets the first IP address of the host of the specified IPAddr type. Uses the operating system's underlying getaddrinfo implementation, which may do a DNS lookup.

Sockets.getipaddr – Function.

```
| getipaddr() -> IPAddr
```

Get an IP address of the local machine, preferring IPv4 over IPv6. Throws if no addresses are available.

```
| getipaddr(addr_type::Type{T}) where T<:IPAddr -> T
```

Get an IP address of the local machine of the specified type. Throws if no addresses of the specified type are available.

This function is a backwards-compatibility wrapper around [getipaddrs](#). New applications should use [getipaddrs](#) instead.

Examples

```
julia> getipaddr()
ip"192.168.1.28"

julia> getipaddr(IPv6)
ip"fe80::9731:35af:e1c5:6e49"
```

See also [getipaddrs](#).

Sockets.getipaddrs – Function.

```
| getipaddrs(addr_type::Type{T}=IPAddr; loopback::Bool=false) where T<:IPAddr -> Vector{T}
```

Get the IP addresses of the local machine.

Setting the optional addr_type parameter to IPv4 or IPv6 causes only addresses of that type to be returned.

The loopback keyword argument dictates whether loopback addresses (e.g. ip"127.0.0.1", ip"::1") are included.

Julia 1.2

This function is available as of Julia 1.2.

Examples

```
julia> getipaddrs()
5-element Array{IPAddr,1}:
ip"198.51.100.17"
ip"203.0.113.2"
ip"2001:db8:8:4:445e:5fff:fe5d:5500"
ip"2001:db8:8:4:c164:402e:7e3c:3668"
ip"fe80::445e:5fff:fe5d:5500"
```

```
julia> getipaddrs(IPv6)
3-element Array{IPv6,1}:
 ip"2001:db8:8:4:445e:5fff:fe5d:5500"
 ip"2001:db8:8:4:c164:402e:7e3c:3668"
 ip"fe80::445e:5fff:fe5d:5500"
```

See also [islinklocaladdr](#).

`Sockets.islinklocaladdr` – Function.

```
islinklocaladdr(addr::IPAddr)
```

Tests if an IP address is a link-local address. Link-local addresses are not guaranteed to be unique beyond their network segment, therefore routers do not forward them. Link-local addresses are from the address blocks 169.254.0.0/16 or fe80::/10.

Example

```
filter(!islinklocaladdr, getipaddrs())
```

`Sockets.getalladdrinfo` – Function.

```
getalladdrinfo(host::AbstractString) -> Vector{IPAddr}
```

Gets all of the IP addresses of the host. Uses the operating system's underlying `getaddrinfo` implementation, which may do a DNS lookup.

Example

```
julia> getalladdrinfo("google.com")
2-element Array{IPAddr,1}:
 ip"172.217.6.174"
 ip"2607:f8b0:4000:804::200e"
```

`Sockets.DNSError` – Type.

```
DNSError
```

The type of exception thrown when an error occurs in DNS lookup. The `host` field indicates the host URL string. The `code` field indicates the error code based on `libuv`.

`Sockets.getnameinfo` – Function.

```
getnameinfo(host::IPAddr) -> String
```

Performs a reverse-lookup for IP address to return a hostname and service using the operating system's underlying `getnameinfo` implementation.

Examples

```
julia> getnameinfo(IPv4("8.8.8.8"))
"google-public-dns-a.google.com"
```

`Sockets.getsockname` – Function.

```
| getsockname(sock::Union{TCPServer, TCPSocket}) -> (IPAddr, UInt16)
```

Get the IP address and port that the given socket is bound to.

Sockets.getpeername – Function.

```
| getpeername(sock::TCPSocket) -> (IPAddr, UInt16)
```

Get the IP address and port of the remote endpoint that the given socket is connected to. Valid only for connected TCP sockets.

Sockets.IPAddr – Type.

```
| IPAddr
```

Abstract supertype for IP addresses. `IPv4` and `IPv6` are subtypes of this.

Sockets.IPv4 – Type.

```
| IPv4(host::Integer) -> IPv4
```

Return an IPv4 object from ip address host formatted as an `Integer`.

Examples

```
| julia> IPv4(3223256218)
ip"192.30.252.154"
```

Sockets.IPv6 – Type.

```
| IPv6(host::Integer) -> IPv6
```

Return an IPv6 object from ip address host formatted as an `Integer`.

Examples

```
| julia> IPv6(3223256218)
ip "::c01e:fc9a"
```

Sockets.@ip_str – Macro.

```
| @ip_str str -> IPAddr
```

Parse str as an IP address.

Examples

```
| julia> ip"127.0.0.1"
ip"127.0.0.1"

| julia> @ip_str "2001:db8:0:0:0:0:2:1"
ip"2001:db8::2:1"
```

Sockets.TCPSocket – Type.

```
| TCPSocket(; delay=true)
```

Open a TCP socket using libuv. If `delay` is true, libuv delays creation of the socket's file descriptor till the first `bind` call. `TCPSocket` has various fields to denote the state of the socket as well as its send/receive buffers.

`Sockets.UDPSocket` – Type.

```
| UDPSocket()
```

Open a UDP socket using libuv. `UDPSocket` has various fields to denote the state of the socket.

`Sockets.accept` – Function.

```
| accept(server[, client])
```

Accepts a connection on the given server and returns a connection to the client. An uninitialized client stream may be provided, in which case it will be used instead of creating a new stream.

`Sockets.listenany` – Function.

```
| listenany([host::IPAddr,] port_hint; backlog::Integer=BACKLOG_DEFAULT) -> (UInt16, TCPServer)
```

Create a `TCPServer` on any port, using `hint` as a starting point. Returns a tuple of the actual port that the server was created on and the server itself. The `backlog` argument defines the maximum length to which the queue of pending connections for `sockfd` may grow.

`Base.bind` – Function.

```
| bind(socket::Union{TCPServer, UDPSocket, TCPSocket}, host::IPAddr, port::Integer;  
↪  ipv6only=false, reuseaddr=false, kws...)
```

Bind socket to the given `host:port`. Note that `0.0.0.0` will listen on all devices.

- The `ipv6only` parameter disables dual stack mode. If `ipv6only=true`, only an IPv6 stack is created.
- If `reuseaddr=true`, multiple threads or processes can bind to the same address without error if they all set `reuseaddr=true`, but only the last to bind will receive any traffic.

```
| bind(chnl::Channel, task::Task)
```

Associate the lifetime of `chnl` with a task. `Channel` `chnl` is automatically closed when the task terminates. Any uncaught exception in the task is propagated to all waiters on `chnl`.

The `chnl` object can be explicitly closed independent of task termination. Terminating tasks have no effect on already closed `Channel` objects.

When a channel is bound to multiple tasks, the first task to terminate will close the channel. When multiple channels are bound to the same task, termination of the task will close all of the bound channels.

Examples

```

julia> c = Channel{0};

julia> task = @async foreach(i->put!(c, i), 1:4);

julia> bind(c, task);

julia> for i in c
           @show i
       end;
i = 1
i = 2
i = 3
i = 4

julia> isopen(c)
false

```

```

julia> c = Channel{0};

julia> task = @async (put!(c, 1); error("foo"));

julia> bind(c, task);

julia> take!(c)
1

julia> put!(c, 1);
ERROR: TaskFailedException
Stacktrace:
 [...]
  nested task error: foo
 [...]

```

[source](#)

`Sockets.send` – Function.

```
| send(socket::UDPSocket, host::IPAddr, port::Integer, msg)
```

Send msg over socket to host:port.

`Sockets.recv` – Function.

```
| recv(socket::UDPSocket)
```

Read a UDP packet from the specified socket, and return the bytes received. This call blocks.

`Sockets.recvfrom` – Function.

```
| recvfrom(socket::UDPSocket) -> (host_port, data)
```

Read a UDP packet from the specified socket, returning a tuple of (host_port, data), where host_port will be an `InetAddr{IPv4}` or `InetAddr{IPv6}`, as appropriate.

Julia 1.3

Prior to Julia version 1.3, the first returned value was an address (IPAddr). In version 1.3 it was changed to an InetAddr.

Sockets.setopt – Function.

```
| setopt(sock::UDPSocket; multicast_loop=nothing, multicast_ttl=nothing,  
| ↪ enable_broadcast=nothing, ttl=nothing)
```

Set UDP socket options.

- `multicast_loop`: loopback for multicast packets (default: `true`).
- `multicast_ttl`: TTL for multicast packets (default: `nothing`).
- `enable_broadcast`: flag must be set to `true` if socket will be used for broadcast messages, or else the UDP system will return an access error (default: `false`).
- `ttl`: Time-to-live of packets sent on the socket (default: `nothing`).

Sockets.nagle – Function.

```
| nagle(socket::Union{TCPServer, TCPSocket}, enable::Bool)
```

Enables or disables Nagle's algorithm on a given TCP server or socket.

Julia 1.3

This function requires Julia 1.3 or later.

Sockets.quickack – Function.

```
| quickack(socket::Union{TCPServer, TCPSocket}, enable::Bool)
```

On Linux systems, the `TCP_QUICKACK` is disabled or enabled on socket.

Chapter 93

Sparse Arrays

Julia has support for sparse vectors and [sparse matrices](#) in the `SparseArrays` stdlib module. Sparse arrays are arrays that contain enough zeros that storing them in a special data structure leads to savings in space and execution time, compared to dense arrays.

External packages which implement different sparse storage types, multidimensional sparse arrays, and more can be found in [Noteworthy external packages](#)

93.1 Compressed Sparse Column (CSC) Sparse Matrix Storage

In Julia, sparse matrices are stored in the [Compressed Sparse Column \(CSC\) format](#). Julia sparse matrices have the type `SparseMatrixCSC{Tv,Ti}`, where `Tv` is the type of the stored values, and `Ti` is the integer type for storing column pointers and row indices. The internal representation of `SparseMatrixCSC` is as follows:

```
struct SparseMatrixCSC{Tv,Ti<:Integer} <: AbstractSparseMatrixCSC{Tv,Ti}
    m::Int          # Number of rows
    n::Int          # Number of columns
    colptr::Vector{Ti} # Column j is in colptr[j]:(colptr[j+1]-1)
    rowval::Vector{Ti} # Row indices of stored values
    nzval::Vector{Tv}  # Stored values, typically nonzeros
end
```

The compressed sparse column storage makes it easy and quick to access the elements in the column of a sparse matrix, whereas accessing the sparse matrix by rows is considerably slower. Operations such as insertion of previously unstored entries one at a time in the CSC structure tend to be slow. This is because all elements of the sparse matrix that are beyond the point of insertion have to be moved one place over.

All operations on sparse matrices are carefully implemented to exploit the CSC data structure for performance, and to avoid expensive operations.

If you have data in CSC format from a different application or library, and wish to import it in Julia, make sure that you use 1-based indexing. The row indices in every column need to be sorted, and if they are not, the matrix will display incorrectly. If your `SparseMatrixCSC` object contains unsorted row indices, one quick way to sort them is by doing a double transpose. Since the transpose operation is lazy, make a copy to materialize each transpose.

In some applications, it is convenient to store explicit zero values in a `SparseMatrixCSC`. These are accepted by functions in Base (but there is no guarantee that they will be preserved in mutating operations). Such explicitly stored zeros are treated as structural nonzeros by many routines. The `nnz` function returns the number of elements explicitly stored in the sparse data structure, including non-structural zeros. In order to count the exact number of numerical nonzeros, use `count(!iszero, x)`, which inspects every stored element of a sparse matrix. `dropzeros`, and the in-place `dropzeros!`, can be used to remove stored zeros from the sparse matrix.

```
julia> A = sparse([1, 1, 2, 3], [1, 3, 2, 3], [0, 1, 2, 0])
3×3 SparseMatrixCSC{Int64, Int64} with 4 stored entries:
 0  .  1
 .  2  .
 .  .  0

julia> dropzeros(A)
3×3 SparseMatrixCSC{Int64, Int64} with 2 stored entries:
 .  .  1
 .  2  .
 .  .  .
```

93.2 Sparse Vector Storage

Sparse vectors are stored in a close analog to compressed sparse column format for sparse matrices. In Julia, sparse vectors have the type `SparseVector{Tv,Ti}` where `Tv` is the type of the stored values and `Ti` the integer type for the indices. The internal representation is as follows:

```
struct SparseVector{Tv,Ti<:Integer} <: AbstractSparseVector{Tv,Ti}
    n::Int          # Length of the sparse vector
    nzind::Vector{Ti} # Indices of stored values
    nzval::Vector{Tv} # Stored values, typically nonzeros
end
```

As for `SparseMatrixCSC`, the `SparseVector` type can also contain explicitly stored zeros. (See [Sparse Matrix Storage](#).)

93.3 Sparse Vector and Matrix Constructors

The simplest way to create a sparse array is to use a function equivalent to the `zeros` function that Julia provides for working with dense arrays. To produce a sparse array instead, you can use the same name with an `sp` prefix:

```
julia> spzeros(3)
3-element SparseVector{Float64, Int64} with 0 stored entries
```

The `sparse` function is often a handy way to construct sparse arrays. For example, to construct a sparse matrix we can input a vector `I` of row indices, a vector `J` of column indices, and a vector `V` of stored values (this is also known as the **COO (coordinate) format**). `sparse(I,J,V)` then constructs a sparse matrix such that $S[I[k], J[k]] = V[k]$. The equivalent sparse vector constructor is `sparsevec`, which takes the (row) index vector `I` and the vector `V` with the stored values and constructs a sparse vector `R` such that $R[I[k]] = V[k]$.

```
julia> I = [1, 4, 3, 5]; J = [4, 7, 18, 9]; V = [1, 2, -5, 3];

julia> S = sparse(I,J,V)
5×18 SparseMatrixCSC{Int64, Int64} with 4 stored entries:
[]
[]

julia> R = sparsevec(I,V)
5-element SparseVector{Int64, Int64} with 4 stored entries:
 [1]  = 1
 [3]  = -5
 [4]  = 2
 [5]  = 3
```

The inverse of the `sparse` and `sparsevec` functions is `findnz`, which retrieves the inputs used to create the sparse array. `findall(!iszero, x)` returns the Cartesian indices of non-zero entries in `x` (including stored entries equal to zero).

```
julia> findnz(S)
([1, 4, 5, 3], [4, 7, 9, 18], [1, 2, 3, -5])

julia> findall(!iszero, S)
4-element Vector{CartesianIndex{2}}:
 CartesianIndex{1, 4}
 CartesianIndex{4, 7}
 CartesianIndex{5, 9}
 CartesianIndex{3, 18}

julia> findnz(R)
([1, 3, 4, 5], [1, -5, 2, 3])

julia> findall(!iszero, R)
4-element Vector{Int64}:
 1
 3
 4
 5
```

Another way to create a sparse array is to convert a dense array into a sparse array using the `sparse` function:

```
julia> sparse(Matrix{Float64}(1.0I, 5, 5))
5×5 SparseMatrixCSC{Float64, Int64} with 5 stored entries:
 1.0  .  .  .  .
 .  1.0  .  .  .
 .  .  1.0  .  .
 .  .  .  1.0  .
 .  .  .  .  1.0

julia> sparse([1.0, 0.0, 1.0])
3-element SparseVector{Float64, Int64} with 2 stored entries:
```

```
[1] = 1.0
[3] = 1.0
```

You can go in the other direction using the `Array` constructor. The `issparse` function can be used to query if a matrix is sparse.

```
julia> issparse(spzeros(5))
true
```

93.4 Sparse matrix operations

Arithmetic operations on sparse matrices also work as they do on dense matrices. Indexing of, assignment into, and concatenation of sparse matrices work in the same way as dense matrices. Indexing operations, especially assignment, are expensive, when carried out one element at a time. In many cases it may be better to convert the sparse matrix into (I, J, V) format using `findnz`, manipulate the values or the structure in the dense vectors (I, J, V) , and then reconstruct the sparse matrix.

93.5 Correspondence of dense and sparse methods

The following table gives a correspondence between built-in methods on sparse matrices and their corresponding methods on dense matrix types. In general, methods that generate sparse matrices differ from their dense counterparts in that the resulting matrix follows the same sparsity pattern as a given sparse matrix S , or that the resulting sparse matrix has density d , i.e. each matrix element has a probability d of being non-zero.

Details can be found in the [Sparse Vectors and Matrices](#) section of the standard library reference.

| Sparse | Dense | Description |
|---------------------------------|----------------------------|---|
| <code>spzeros(m,n)</code> | <code>zeros(m,n)</code> | Creates a m-by-n matrix of zeros. (<code>spzeros(m,n)</code> is empty.) |
| <code>sparse(I,n)</code> | <code>Matrix{I,n}</code> | Creates a n-by-n identity matrix. |
| <code>sparse(A)</code> | <code>Array{S}</code> | Interconverts between dense and sparse formats. |
| <code>sprand(m,n,d)</code> | <code>rand(m,n)</code> | Creates a m-by-n random matrix (of density d) with iid non-zero elements distributed uniformly on the half-open interval $[0, 1)$. |
| <code>sprandn(m,n,d)</code> | <code>randn(m,n)</code> | Creates a m-by-n random matrix (of density d) with iid non-zero elements distributed according to the standard normal (Gaussian) distribution. |
| <code>sprandn(rng,m,n,d)</code> | <code>rand(rng,m,n)</code> | Creates a m-by-n random matrix (of density d) with iid non-zero elements generated with the <code>rng</code> random number generator |

Chapter 94

SparseArrays API

SparseArrays.AbstractSparseArray – Type.

| **AbstractSparseArray**{Tv,Ti,N}

Supertype for N-dimensional sparse arrays (or array-like types) with elements of type Tv and index type Ti. [SparseMatrixCSC](#), [SparseVector](#) and [SuiteSparse.CHOLMOD.Sparse](#) are subtypes of this.

[source](#)

SparseArrays.AbstractSparseVector – Type.

| **AbstractSparseVector**{Tv,Ti}

Supertype for one-dimensional sparse arrays (or array-like types) with elements of type Tv and index type Ti. Alias for [AbstractSparseArray](#){Tv,Ti,1}.

[source](#)

SparseArrays.AbstractSparseMatrix – Type.

| **AbstractSparseMatrix**{Tv,Ti}

Supertype for two-dimensional sparse arrays (or array-like types) with elements of type Tv and index type Ti. Alias for [AbstractSparseArray](#){Tv,Ti,2}.

[source](#)

SparseArrays.SparseVector – Type.

| [SparseVector](#){Tv,Ti<:**Integer**} <: **AbstractSparseVector**{Tv,Ti}

Vector type for storing sparse vectors. Can be created by passing the length of the vector, a sorted vector of non-zero indices, and a vector of non-zero values.

For instance, the vector [5, 6, 0, 7] can be represented as

| [SparseVector](#)(4, [1, 2, 4], [5, 6, 7])

This indicates that the element at index 1 is 5, at index 2 is 6, at index 3 is zero(Int), and at index 4 is 7.

It may be more convenient to create sparse vectors directly from dense vectors using `sparse` as

```
| sparse([5, 6, 0, 7])
```

yields the same sparse vector.

[source](#)

`SparseArrays.SparseMatrixCSC` – Type.

```
| SparseMatrixCSC{Tv,Ti<:Integer} <: AbstractSparseMatrixCSC{Tv,Ti}
```

Matrix type for storing sparse matrices in the [Compressed Sparse Column](#) format. The standard way of constructing `SparseMatrixCSC` is through the `sparse` function. See also [spzeros](#), [spdiags](#) and [sprand](#).

[source](#)

`SparseArrays.sparse` – Function.

```
| sparse(A)
```

Convert an `AbstractMatrix` `A` into a sparse matrix.

Examples

```
| julia> A = Matrix{Float64}(1.0I, 3, 3)
3×3 Matrix{Float64}:
 1.0  0.0  0.0
 0.0  1.0  0.0
 0.0  0.0  1.0

| julia> sparse(A)
3×3 SparseMatrixCSC{Float64, Int64} with 3 stored entries:
 1.0  .  .
 .  1.0  .
 .  .  1.0
```

[source](#)

```
| sparse(I, J, V, [m, n, combine])
```

Create a sparse matrix `S` of dimensions `m × n` such that `S[I[k], J[k]] = V[k]`. The `combine` function is used to combine duplicates. If `m` and `n` are not specified, they are set to `maximum(I)` and `maximum(J)` respectively. If the `combine` function is not supplied, `combine` defaults to `+` unless the elements of `V` are Booleans in which case `combine` defaults to `|`. All elements of `I` must satisfy `1 ≤ I[k] ≤ m`, and all elements of `J` must satisfy `1 ≤ J[k] ≤ n`. Numerical zeros in `(I, J, V)` are retained as structural nonzeros; to drop numerical zeros, use [dropzeros!](#).

For additional documentation and an expert driver, see `SparseArrays.sparse!`.

Examples

```

julia> Is = [1; 2; 3];

julia> Js = [1; 2; 3];

julia> Vs = [1; 2; 3];

julia> sparse(Is, Js, Vs)
3×3 SparseMatrixCSC{Int64, Int64} with 3 stored entries:
 1  .  .
 .  2  .
 .  .  3

```

source

SparseArrays.sparse! – Function.

```

sparse!(I::AbstractVector{Ti}, J::AbstractVector{Ti}, V::AbstractVector{Tv},
        m::Integer, n::Integer, combine, klasttouch::Vector{Ti},
        csrrowptr::Vector{Ti}, csrcolval::Vector{Ti}, csrnzval::Vector{Tv},
        [csccolptr::Vector{Ti}], [cscrowval::Vector{Ti}], [cscnzval::Vector{Tv}] ) where
        ⇨ {Tv, Ti<:Integer}

```

Parent of and expert driver for `sparse`; see `sparse` for basic usage. This method allows the user to provide preallocated storage for `sparse`'s intermediate objects and result as described below. This capability enables more efficient successive construction of `SparseMatrixCSC`s from coordinate representations, and also enables extraction of an unsorted-column representation of the result's transpose at no additional cost.

This method consists of three major steps: (1) Counting-sort the provided coordinate representation into an unsorted-row CSR form including repeated entries. (2) Sweep through the CSR form, simultaneously calculating the desired CSC form's column-pointer array, detecting repeated entries, and repacking the CSR form with repeated entries combined; this stage yields an unsorted-row CSR form with no repeated entries. (3) Counting-sort the preceding CSR form into a fully-sorted CSC form with no repeated entries.

Input arrays `csrrowptr`, `csrcolval`, and `csrnzval` constitute storage for the intermediate CSR forms and require `length(csrrowptr) >= m + 1`, `length(csrcolval) >= length(I)`, and `length(csrnzval) >= length(I)`. Input array `klasttouch`, workspace for the second stage, requires `length(klasttouch) >= n`. Optional input arrays `csccolptr`, `cscrowval`, and `cscnzval` constitute storage for the returned CSC form `S`. If necessary, these are resized automatically to satisfy `length(csccolptr) = n + 1`, `length(cscrowval) = nnz(S)` and `length(cscnzval) = nnz(S)`; hence, if `nnz(S)` is unknown at the outset, passing in empty vectors of the appropriate type (`Vector{Ti}()` and `Vector{Tv}()` respectively) suffices, or calling the `sparse!` method neglecting `cscrowval` and `cscnzval`.

On return, `csrrowptr`, `csrcolval`, and `csrnzval` contain an unsorted-column representation of the result's transpose.

You may reuse the input arrays' storage (`I`, `J`, `V`) for the output arrays (`csccolptr`, `cscrowval`, `cscnzval`). For example, you may call `sparse!(I, J, V, csrrowptr, csrcolval, csrnzval, I, J, V)`. Note that they will be resized to satisfy the conditions above.

For the sake of efficiency, this method performs no argument checking beyond `1 <= I[k] <= m` and `1 <= J[k] <= n`. Use with care. Testing with `--check-bounds=yes` is wise.

This method runs in $O(m, n, \text{length}(I))$ time. The HALFPERM algorithm described in F. Gustavson, "Two fast algorithms for sparse matrices: multiplication and permuted transposition," ACM TOMS 4(3), 250-269 (1978) inspired this method's use of a pair of counting sorts.

source

```
| SparseArrays.sparse!(I, J, V, [m, n, combine]) -> SparseMatrixCSC
```

Variant of `sparse!` that re-uses the input vectors (`I`, `J`, `V`) for the final matrix storage. After construction the input vectors will alias the matrix buffers; `S.colptr === I`, `S.rowval === J`, and `S.nzval === V` holds, and they will be `resize!`d as necessary.

Note that some work buffers will still be allocated. Specifically, this method is a convenience wrapper around `sparse!(I, J, V, m, n, combine, klasttouch, csrrowptr, csrcolval, csrnzval, csccolptr, cscrowval, cscnzval)` where this method allocates `klasttouch`, `csrrowptr`, `csrcolval`, and `csrnzval` of appropriate size, but reuses `I`, `J`, and `V` for `csccolptr`, `cscrowval`, and `cscnzval`.

Arguments `m`, `n`, and `combine` defaults to `maximum(I)`, `maximum(J)`, and `+`, respectively.

Julia 1.10

This method requires Julia version 1.10 or later.

source

`SparseArrays.sparsevec` – Function.

```
| sparsevec(I, V, [m, combine])
```

Create a sparse vector `S` of length `m` such that `S[I[k]] = V[k]`. Duplicates are combined using the `combine` function, which defaults to `+` if no `combine` argument is provided, unless the elements of `V` are Booleans in which case `combine` defaults to `|`.

Examples

```
julia> II = [1, 3, 3, 5]; V = [0.1, 0.2, 0.3, 0.2];

julia> sparsevec(II, V)
5-element SparseVector{Float64, Int64} with 3 stored entries:
 [1] = 0.1
 [3] = 0.5
 [5] = 0.2

julia> sparsevec(II, V, 8, -)
8-element SparseVector{Float64, Int64} with 3 stored entries:
 [1] = 0.1
 [3] = -0.1
 [5] = 0.2

julia> sparsevec([1, 3, 1, 2, 2], [true, true, false, false, false])
3-element SparseVector{Bool, Int64} with 3 stored entries:
 [1] = 1
 [2] = 0
 [3] = 1
```

source

```
| sparsevec(d::Dict, [m])
```

Create a sparse vector of length `m` where the nonzero indices are keys from the dictionary, and the nonzero values are the values from the dictionary.

Examples

```
| julia> sparsevec(Dict{1 => 3, 2 => 2})
2-element SparseVector{Int64, Int64} with 2 stored entries:
 [1] = 3
 [2] = 2
```

source

```
| sparsevec(A)
```

Convert a vector `A` into a sparse vector of length `m`.

Examples

```
| julia> sparsevec([1.0, 2.0, 0.0, 0.0, 3.0, 0.0])
6-element SparseVector{Float64, Int64} with 3 stored entries:
 [1] = 1.0
 [2] = 2.0
 [5] = 3.0
```

source

`Base.similar` – Method.

```
| similar(A::AbstractSparseMatrixCSC{Tv,Ti}, [::Type{TvNew}, ::Type{TiNew}, m::Integer,
↪ n::Integer]) where {Tv,Ti}
```

Create an uninitialized mutable array with the given element type, index type, and size, based upon the given source `SparseMatrixCSC`. The new sparse matrix maintains the structure of the original sparse matrix, except in the case where dimensions of the output matrix are different from the output.

The output matrix has zeros in the same locations as the input, but uninitialized values for the nonzero locations.

source

`SparseArrays.issparse` – Function.

```
| issparse(S)
```

Returns true if `S` is sparse, and false otherwise.

Examples

```
| julia> sv = sparsevec([1, 4], [2.3, 2.2], 10)
10-element SparseVector{Float64, Int64} with 2 stored entries:
 [1] = 2.3
 [4] = 2.2
```

```
julia> issparse(sv)
true

julia> issparse(Array{sv})
false
```

[source](#)

`SparseArrays.nnz` – Function.

```
nnz(A)
```

Returns the number of stored (filled) elements in a sparse array.

Examples

```
julia> A = sparse(2I, 3, 3)
3×3 SparseMatrixCSC{Int64, Int64} with 3 stored entries:
 2  .  .
 .  2  .
 .  .  2

julia> nnz(A)
3
```

[source](#)

`SparseArrays.findnz` – Function.

```
findnz(A::SparseMatrixCSC)
```

Return a tuple (I, J, V) where I and J are the row and column indices of the stored ("structurally non-zero") values in sparse matrix A, and V is a vector of the values.

Examples

```
julia> A = sparse([1 2 0; 0 0 3; 0 4 0])
3×3 SparseMatrixCSC{Int64, Int64} with 4 stored entries:
 1  2  .
 .  .  3
 .  4  .

julia> findnz(A)
([1, 1, 3, 2], [1, 2, 2, 3], [1, 2, 4, 3])
```

[source](#)

`SparseArrays.spzeros` – Function.

```
spzeros([type], m[, n])
```

Create a sparse vector of length *m* or sparse matrix of size *m* × *n*. This sparse array will not contain any nonzero values. No storage will be allocated for nonzero values during construction. The type defaults to `Float64` if not specified.

Examples

```
julia> spzeros(3, 3)
3×3 SparseMatrixCSC{Float64, Int64} with 0 stored entries:
  .  .  .
  .  .  .
  .  .  .

julia> spzeros(Float32, 4)
4-element SparseVector{Float32, Int64} with 0 stored entries
```

source

```
spzeros([type], I::AbstractVector, J::AbstractVector, [m, n])
```

Create a sparse matrix S of dimensions $m \times n$ with structural zeros at $S[I[k], J[k]]$.

This method can be used to construct the sparsity pattern of the matrix, and is more efficient than using e.g. `sparse(I, J, zeros(length(I)))`.

For additional documentation and an expert driver, see `SparseArrays.spzeros!`.

Julia 1.10

This methods requires Julia version 1.10 or later.

source

`SparseArrays.spzeros!` – Function.

```
spzeros!{::Type{Tv}, I::AbstractVector{Ti}, J::AbstractVector{Ti}, m::Integer, n::Integer,
          klasttouch::Vector{Ti}, csrrowptr::Vector{Ti}, csrcolval::Vector{Ti},
          [csccolptr::Vector{Ti}], [cscrowval::Vector{Ti}, cscnzval::Vector{Tv}]} where
          Tv, Ti<:Integer
```

Parent of and expert driver for `spzeros(I, J)` allowing user to provide preallocated storage for intermediate objects. This method is to `spzeros` what `SparseArrays.sparse!` is to `sparse`. See documentation for `SparseArrays.sparse!` for details and required buffer lengths.

Julia 1.10

This methods requires Julia version 1.10 or later.

source

```
SparseArrays.spzeros!{::Type{Tv}, I, J, [m, n]} -> SparseMatrixCSC{Tv}
```

Variant of `spzeros!` that re-uses the input vectors I and J for the final matrix storage. After construction the input vectors will alias the matrix buffers; $S.colptr == I$ and $S.rowval == J$ holds, and they will be `resize!`d as necessary.

Note that some work buffers will still be allocated. Specifically, this method is a convenience wrapper around `spzeros!(Tv, I, J, m, n, klasttouch, csrrowptr, csrcolval, csccolptr, cscrowval)` where this method allocates `klasttouch`, `csrrowptr`, and `csrcolval` of appropriate size, but reuses I and J for `csccolptr` and `cscrowval`.

Arguments m and n defaults to `maximum(I)` and `maximum(J)`.

Julia 1.10

This method requires Julia version 1.10 or later.

[source](#)

`SparseArrays.spdiagm` – Function.

```
spdiagm(kv::Pair{<:Integer,<:AbstractVector}...)
spdiagm(m::Integer, n::Integer, kv::Pair{<:Integer,<:AbstractVector}...)
```

Construct a sparse diagonal matrix from Pairs of vectors and diagonals. Each vector `kv.second` will be placed on the `kv.first` diagonal. By default, the matrix is square and its size is inferred from `kv`, but a non-square size `m×n` (padded with zeros as needed) can be specified by passing `m,n` as the first arguments.

Examples

```
julia> spdiagm(-1 => [1,2,3,4], 1 => [4,3,2,1])
5×5 SparseMatrixCSC{Int64, Int64} with 8 stored entries:
 .  4  .  .  .
 1  .  3  .  .
 .  2  .  2  .
 .  .  3  .  1
 .  .  .  4  .
```

[source](#)

```
spdiagm(v::AbstractVector)
spdiagm(m::Integer, n::Integer, v::AbstractVector)
```

Construct a sparse matrix with elements of the vector as diagonal elements. By default (no given `m` and `n`), the matrix is square and its size is given by `length(v)`, but a non-square size `m×n` can be specified by passing `m` and `n` as the first arguments.

Julia 1.6

These functions require at least Julia 1.6.

Examples

```
julia> spdiagm([1,2,3])
3×3 SparseMatrixCSC{Int64, Int64} with 3 stored entries:
 1  .  .
 .  2  .
 .  .  3

julia> spdiagm(sparse([1,0,3]))
3×3 SparseMatrixCSC{Int64, Int64} with 2 stored entries:
 1  .  .
 .  .  .
 .  .  3
```

[source](#)

`SparseArrays.sparse_hcat` – Function.

```
| sparse_hcat(A...)
```

Concatenate along dimension 2. Return a `SparseMatrixCSC` object.

Julia 1.8

This method was added in Julia 1.8. It mimics previous concatenation behavior, where the concatenation with specialized "sparse" matrix types from `LinearAlgebra.jl` automatically yielded sparse output even in the absence of any `SparseArray` argument.

source

`SparseArrays.sparse_vcat` – Function.

```
| sparse_vcat(A...)
```

Concatenate along dimension 1. Return a `SparseMatrixCSC` object.

Julia 1.8

This method was added in Julia 1.8. It mimics previous concatenation behavior, where the concatenation with specialized "sparse" matrix types from `LinearAlgebra.jl` automatically yielded sparse output even in the absence of any `SparseArray` argument.

source

`SparseArrays.sparse_hvcat` – Function.

```
| sparse_hvcat(rows::Tuple{Vararg{Int}}, values...)
```

Sparse horizontal and vertical concatenation in one call. This function is called for block matrix syntax. The first argument specifies the number of arguments to concatenate in each block row.

Julia 1.8

This method was added in Julia 1.8. It mimics previous concatenation behavior, where the concatenation with specialized "sparse" matrix types from `LinearAlgebra.jl` automatically yielded sparse output even in the absence of any `SparseArray` argument.

source

`SparseArrays.blockdiag` – Function.

```
| blockdiag(A...)
```

Concatenate matrices block-diagonally. Currently only implemented for sparse matrices.

Examples

```
julia> blockdiag(sparse(2I, 3, 3), sparse(4I, 2, 2))
5×5 SparseMatrixCSC{Int64, Int64} with 5 stored entries:
 2  .  .  .  .
 .  2  .  .  .
 .  .  2  .  .
 .  .  .  4  .
 .  .  .  .  4
```

[source](#)

`SparseArrays.sprand` – Function.

```
| sprand([rng], [T::Type], m, [n], p::AbstractFloat)
| sprand([rng], m, [n], p::AbstractFloat, [rfn=rand])
```

Create a random length `m` sparse vector or `m` by `n` sparse matrix, in which the probability of any element being nonzero is independently given by `p` (and hence the mean density of nonzeros is also exactly `p`). The optional `rng` argument specifies a random number generator, see [Random Numbers](#). The optional `T` argument specifies the element type, which defaults to `Float64`.

By default, nonzero values are sampled from a uniform distribution using the `rand` function, i.e. by `rand(T)`, or `rand(rng, T)` if `rng` is supplied; for the default `T=Float64`, this corresponds to nonzero values sampled uniformly in `[0,1)`.

You can sample nonzero values from a different distribution by passing a custom `rfn` function instead of `rand`. This should be a function `rfn(k)` that returns an array of `k` random numbers sampled from the desired distribution; alternatively, if `rng` is supplied, it should instead be a function `rfn(rng, k)`.

Examples

```
| julia> sprand(Bool, 2, 2, 0.5)
| 2×2 SparseMatrixCSC{Bool, Int64} with 2 stored entries:
|  1  1
|  .  .
|
| julia> sprand(Float64, 3, 0.75)
| 3-element SparseVector{Float64, Int64} with 2 stored entries:
| [1] = 0.795547
| [2] = 0.49425
```

[source](#)

`SparseArrays.sprandn` – Function.

```
| sprandn([rng], [Type], m[, n], p::AbstractFloat)
```

Create a random sparse vector of length `m` or sparse matrix of size `m` by `n` with the specified (independent) probability `p` of any entry being nonzero, where nonzero values are sampled from the normal distribution. The optional `rng` argument specifies a random number generator, see [Random Numbers](#).

Julia 1.1

Specifying the output element type `Type` requires at least Julia 1.1.

Examples

```
| julia> sprandn(2, 2, 0.75)
| 2×2 SparseMatrixCSC{Float64, Int64} with 3 stored entries:
| -1.20577      .
| 0.311817  -0.234641
```

[source](#)

`SparseArrays.nonzeros` – Function.

```
| nonzero(A)
```

Return a vector of the structural nonzero values in sparse array A. This includes zeros that are explicitly stored in the sparse array. The returned vector points directly to the internal nonzero storage of A, and any modifications to the returned vector will mutate A as well. See [rowvals](#) and [nzrange](#).

Examples

```
julia> A = sparse(2I, 3, 3)
3×3 SparseMatrixCSC{Int64, Int64} with 3 stored entries:
 2  .  .
 .  2  .
 .  .  2

julia> nonzero(A)
3-element Vector{Int64}:
 2
 2
 2
```

[source](#)

`SparseArrays.rowvals` – Function.

```
| rowvals(A::AbstractSparseMatrixCSC)
```

Return a vector of the row indices of A. Any modifications to the returned vector will mutate A as well. Providing access to how the row indices are stored internally can be useful in conjunction with iterating over structural nonzero values. See also [nonzeros](#) and [nzrange](#).

Examples

```
julia> A = sparse(2I, 3, 3)
3×3 SparseMatrixCSC{Int64, Int64} with 3 stored entries:
 2  .  .
 .  2  .
 .  .  2

julia> rowvals(A)
3-element Vector{Int64}:
 1
 2
 3
```

[source](#)

`SparseArrays.nzrange` – Function.

```
| nzrange(A::AbstractSparseMatrixCSC, col::Integer)
```

Return the range of indices to the structural nonzero values of a sparse matrix column. In conjunction with [nonzeros](#) and [rowvals](#), this allows for convenient iterating over a sparse matrix :

```

A = sparse(I,J,V)
rows = rowvals(A)
vals = nonzeros(A)
m, n = size(A)
for j = 1:n
    for i in nzrange(A, j)
        row = rows[i]
        val = vals[i]
        # perform sparse wizardry...
    end
end
end

```

Warning

Adding or removing nonzero elements to the matrix may invalidate the `nzrange`, one should not mutate the matrix while iterating.

source

```
| nzrange(x::SparseVectorUnion, col)
```

Give the range of indices to the structural nonzero values of a sparse vector. The column index `col` is ignored (assumed to be 1).

source

`SparseArrays.droptol!` – Function.

```
| droptol!(A::AbstractSparseMatrixCSC, tol)
```

Removes stored values from `A` whose absolute value is less than or equal to `tol`.

source

```
| droptol!(x::AbstractCompressedVector, tol)
```

Removes stored values from `x` whose absolute value is less than or equal to `tol`.

source

`SparseArrays.dropzeros!` – Function.

```
| dropzeros!(x::AbstractCompressedVector)
```

Removes stored numerical zeros from `x`.

For an out-of-place version, see [dropzeros](#). For algorithmic information, see [fkeep!](#).

source

`SparseArrays.dropzeros` – Function.

```
| dropzeros(A::AbstractSparseMatrixCSC;)
```

Generates a copy of `A` and removes stored numerical zeros from that copy.

For an in-place version and algorithmic information, see [dropzeros!](#).

Examples

```
julia> A = sparse([1, 2, 3], [1, 2, 3], [1.0, 0.0, 1.0])
3×3 SparseMatrixCSC{Float64, Int64} with 3 stored entries:
 1.0  .  .
 .  0.0  .
 .  .  1.0

julia> dropzeros(A)
3×3 SparseMatrixCSC{Float64, Int64} with 2 stored entries:
 1.0  .  .
 .  .  .
 .  .  1.0
```

[source](#)

```
dropzeros(x::AbstractCompressedVector)
```

Generates a copy of `x` and removes numerical zeros from that copy.

For an in-place version and algorithmic information, see [dropzeros!](#).

Examples

```
julia> A = sparsevec([1, 2, 3], [1.0, 0.0, 1.0])
3-element SparseVector{Float64, Int64} with 3 stored entries:
 [1] = 1.0
 [2] = 0.0
 [3] = 1.0

julia> dropzeros(A)
3-element SparseVector{Float64, Int64} with 2 stored entries:
 [1] = 1.0
 [3] = 1.0
```

[source](#)

`SparseArrays.permute` – Function.

```
permute(A::AbstractSparseMatrixCSC{Tv,Ti}, p::AbstractVector{<:Integer},
        q::AbstractVector{<:Integer}) where {Tv,Ti}
```

Bilaterally permute `A`, returning `PAQ` (`A[p,q]`). Column-permutation `q`'s length must match `A`'s column count (`length(q) == size(A, 2)`). Row-permutation `p`'s length must match `A`'s row count (`length(p) == size(A, 1)`).

For expert drivers and additional information, see [permute!](#).

Examples

```
julia> A = spdiagm(0 => [1, 2, 3, 4], 1 => [5, 6, 7])
4×4 SparseMatrixCSC{Int64, Int64} with 7 stored entries:
 1  5  .  .
 .  2  6  .
 .  .  3  7
 .  .  .  4
```

```
julia> permute(A, [4, 3, 2, 1], [1, 2, 3, 4])
4×4 SparseMatrixCSC{Int64, Int64} with 7 stored entries:
 .  .  .  4
 .  .  3  7
 .  2  6  .
 1  5  .  .

julia> permute(A, [1, 2, 3, 4], [4, 3, 2, 1])
4×4 SparseMatrixCSC{Int64, Int64} with 7 stored entries:
 .  .  5  1
 .  6  2  .
 7  3  .  .
 4  .  .  .
```

[source](#)

Base.permute! – Method.

```
permute!(X::AbstractSparseMatrixCSC{Tv,Ti}, A::AbstractSparseMatrixCSC{Tv,Ti},
         p::AbstractVector{<:Integer}, q::AbstractVector{<:Integer},
         [C::AbstractSparseMatrixCSC{Tv,Ti}]) where {Tv,Ti}
```

Bilaterally permute A, storing result PAQ ($A[p, q]$) in X. Stores intermediate result $(AQ)^T$ (transpose($A[:, q]$)) in optional argument C if present. Requires that none of X, A, and, if present, C alias each other; to store result PAQ back into A, use the following method lacking X:

```
permute!(A::AbstractSparseMatrixCSC{Tv,Ti}, p::AbstractVector{<:Integer},
         q::AbstractVector{<:Integer}[, C::AbstractSparseMatrixCSC{Tv,Ti},
         [workcolptr::Vector{Ti}]] where {Tv,Ti}
```

X's dimensions must match those of A ($\text{size}(X, 1) == \text{size}(A, 1)$ and $\text{size}(X, 2) == \text{size}(A, 2)$), and X must have enough storage to accommodate all allocated entries in A ($\text{length}(\text{rowvals}(X)) \geq \text{nnz}(A)$ and $\text{length}(\text{nonzeros}(X)) \geq \text{nnz}(A)$). Column-permutation q's length must match A's column count ($\text{length}(q) == \text{size}(A, 2)$). Row-permutation p's length must match A's row count ($\text{length}(p) == \text{size}(A, 1)$).

C's dimensions must match those of transpose(A) ($\text{size}(C, 1) == \text{size}(A, 2)$ and $\text{size}(C, 2) == \text{size}(A, 1)$), and C must have enough storage to accommodate all allocated entries in A ($\text{length}(\text{rowvals}(C)) \geq \text{nnz}(A)$ and $\text{length}(\text{nonzeros}(C)) \geq \text{nnz}(A)$).

For additional (algorithmic) information, and for versions of these methods that forgo argument checking, see (unexported) parent methods `unchecked_noalias_permute!` and `unchecked_aliasing_permute!`.

See also [permute](#).

[source](#)

SparseArrays.halfperm! – Function.

```
halfperm!(X::AbstractSparseMatrixCSC{Tv,Ti}, A::AbstractSparseMatrixCSC{TvA,Ti},
          q::AbstractVector{<:Integer}, f::Function = identity) where {Tv,TvA,Ti}
```

Column-permute and transpose A, simultaneously applying f to each entry of A, storing the result $(f(A)Q)^T$ ($\text{map}(f, \text{transpose}(A[:, q]))$) in X.

Element type T_v of X must match $f(::T_vA)$, where T_vA is the element type of A . X 's dimensions must match those of $\text{transpose}(A)$ ($\text{size}(X, 1) == \text{size}(A, 2)$ and $\text{size}(X, 2) == \text{size}(A, 1)$), and X must have enough storage to accommodate all allocated entries in A ($\text{length}(\text{rowvals}(X)) \geq \text{nnz}(A)$ and $\text{length}(\text{nonzeros}(X)) \geq \text{nnz}(A)$). Column-permutation q 's length must match A 's column count ($\text{length}(q) == \text{size}(A, 2)$).

This method is the parent of several methods performing transposition and permutation operations on `SparseMatrixCSCs`. As this method performs no argument checking, prefer the safer child methods (`[c]transpose[!]`, `permute[!]`) to direct use.

This method implements the HALFPERM algorithm described in F. Gustavson, "Two fast algorithms for sparse matrices: multiplication and permuted transposition," ACM TOMS 4(3), 250-269 (1978). The algorithm runs in $O(\text{size}(A, 1), \text{size}(A, 2), \text{nnz}(A))$ time and requires no space beyond that passed in.

[source](#)

`SparseArrays.ftranspose!` – Function.

```
ftranspose!(X::AbstractSparseMatrixCSC{Tv,Ti}, A::AbstractSparseMatrixCSC{Tv,Ti},
↳ f::Function) where {Tv,Ti}
```

Transpose A and store it in X while applying the function f to the non-zero elements. Does not remove the zeros created by f . $\text{size}(X)$ must be equal to $\text{size}(\text{transpose}(A))$. No additional memory is allocated other than resizing the `rowval` and `nzval` of X , if needed.

See `halfperm!`

[source](#)

Chapter 95

Noteworthy external packages

Several other Julia packages provide sparse matrix implementations that should be mentioned:

1. [SuiteSparseGraphBLAS.jl](#) is a wrapper over the fast, multithreaded SuiteSparse:GraphBLAS C library. On CPU this is typically the fastest option, often significantly outperforming MKLSparse.
2. [CUDA.jl](#) exposes the [CUSPARSE](#) library for GPU sparse matrix operations.
3. [SparseMatricesCSR.jl](#) provides a Julia native implementation of the Compressed Sparse Rows (CSR) format.
4. [MKLSparse.jl](#) accelerates SparseArrays sparse-dense matrix operations using Intel's MKL library.
5. [SparseArrayKit.jl](#) available for multidimensional sparse arrays.
6. [LuxurySparse.jl](#) provides static sparse array formats, as well as a coordinate format.
7. [ExtendableSparse.jl](#) enables fast insertion into sparse matrices using a lazy approach to new stored indices.

Chapter 96

Statistics

The Statistics standard library module contains basic statistics functionality.

Statistics.std - Function.

```
| std(itr; corrected:Bool=true, mean=nothing[, dims])
```

Compute the sample standard deviation of collection itr.

The algorithm returns an estimator of the generative distribution's standard deviation under the assumption that each entry of itr is a sample drawn from the same unknown distribution, with the samples uncorrelated. For arrays, this computation is equivalent to calculating $\sqrt{\text{sum}((\text{itr} - \text{mean}(\text{itr}))^2) / (\text{length}(\text{itr}) - 1)}$. If corrected is true, then the sum is scaled with n-1, whereas the sum is scaled with n if corrected is false with n the number of elements in itr.

If itr is an AbstractArray, dims can be provided to compute the standard deviation over dimensions.

A pre-computed mean may be provided. When dims is specified, mean must be an array with the same shape as mean(itr, dims=dims) (additional trailing singleton dimensions are allowed).

Note

If array contains NaN or missing values, the result is also NaN or missing (missing takes precedence if array contains both). Use the skipmissing function to omit missing entries and compute the standard deviation of non-missing values.

source

Statistics.stdm - Function.

```
| stdm(itr, mean; corrected:Bool=true[, dims])
```

Compute the sample standard deviation of collection itr, with known mean(s) mean.

The algorithm returns an estimator of the generative distribution's standard deviation under the assumption that each entry of itr is a sample drawn from the same unknown distribution, with the samples uncorrelated. For arrays, this computation is equivalent to calculating $\sqrt{\text{sum}((\text{itr} - \text{mean}(\text{itr}))^2) / (\text{length}(\text{itr}) - 1)}$. If corrected is true, then the sum is scaled with n-1, whereas the sum is scaled with n if corrected is false with n the number of elements in itr.

If `itr` is an `AbstractArray`, `dims` can be provided to compute the standard deviation over dimensions. In that case, `mean` must be an array with the same shape as `mean(itr, dims=dims)` (additional trailing singleton dimensions are allowed).

Note

If array contains NaN or `missing` values, the result is also NaN or `missing` (`missing` takes precedence if array contains both). Use the `skipmissing` function to omit missing entries and compute the standard deviation of non-missing values.

source

`Statistics.var` – Function.

```
| var(itr; corrected::Bool=true, mean=nothing[, dims])
```

Compute the sample variance of collection `itr`.

The algorithm returns an estimator of the generative distribution's variance under the assumption that each entry of `itr` is a sample drawn from the same unknown distribution, with the samples uncorrelated. For arrays, this computation is equivalent to calculating $\text{sum}((\text{itr} .- \text{mean}(\text{itr}))^2) / (\text{length}(\text{itr}) - 1)$. If `corrected` is `true`, then the sum is scaled with $n-1$, whereas the sum is scaled with n if `corrected` is `false` where n is the number of elements in `itr`.

If `itr` is an `AbstractArray`, `dims` can be provided to compute the variance over dimensions.

A pre-computed mean may be provided. When `dims` is specified, `mean` must be an array with the same shape as `mean(itr, dims=dims)` (additional trailing singleton dimensions are allowed).

Note

If array contains NaN or `missing` values, the result is also NaN or `missing` (`missing` takes precedence if array contains both). Use the `skipmissing` function to omit missing entries and compute the variance of non-missing values.

source

`Statistics.varm` – Function.

```
| varm(itr, mean; dims, corrected::Bool=true)
```

Compute the sample variance of collection `itr`, with known mean(s) `mean`.

The algorithm returns an estimator of the generative distribution's variance under the assumption that each entry of `itr` is a sample drawn from the same unknown distribution, with the samples uncorrelated. For arrays, this computation is equivalent to calculating $\text{sum}((\text{itr} .- \text{mean}(\text{itr}))^2) / (\text{length}(\text{itr}) - 1)$. If `corrected` is `true`, then the sum is scaled with $n-1$, whereas the sum is scaled with n if `corrected` is `false` with n the number of elements in `itr`.

If `itr` is an `AbstractArray`, `dims` can be provided to compute the variance over dimensions. In that case, `mean` must be an array with the same shape as `mean(itr, dims=dims)` (additional trailing singleton dimensions are allowed).

Note

If array contains NaN or `missing` values, the result is also NaN or `missing` (`missing` takes precedence if array contains both). Use the `skipmissing` function to omit missing entries and compute the variance of non-missing values.

[source](#)

Statistics.cor – Function.

```
| cor(x::AbstractVector)
```

Return the number one.

[source](#)

```
| cor(X::AbstractMatrix; dims::Int=1)
```

Compute the Pearson correlation matrix of the matrix X along the dimension dims.

[source](#)

```
| cor(x::AbstractVector, y::AbstractVector)
```

Compute the Pearson correlation between the vectors x and y.

[source](#)

```
| cor(X::AbstractVecOrMat, Y::AbstractVecOrMat; dims=1)
```

Compute the Pearson correlation between the vectors or matrices X and Y along the dimension dims.

[source](#)

Statistics.cov – Function.

```
| cov(x::AbstractVector; corrected::Bool=true)
```

Compute the variance of the vector x. If corrected is true (the default) then the sum is scaled with n-1, whereas the sum is scaled with n if corrected is false where $n = \text{length}(x)$.

[source](#)

```
| cov(X::AbstractMatrix; dims::Int=1, corrected::Bool=true)
```

Compute the covariance matrix of the matrix X along the dimension dims. If corrected is true (the default) then the sum is scaled with n-1, whereas the sum is scaled with n if corrected is false where $n = \text{size}(X, \text{dims})$.

[source](#)

```
| cov(x::AbstractVector, y::AbstractVector; corrected::Bool=true)
```

Compute the covariance between the vectors x and y. If corrected is true (the default), computes $\frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})^*$ where * denotes the complex conjugate and $n = \text{length}(x) = \text{length}(y)$. If corrected is false, computes $\frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})^*$.

[source](#)

```
| cov(X::AbstractVecOrMat, Y::AbstractVecOrMat; dims::Int=1, corrected::Bool=true)
```

Compute the covariance between the vectors or matrices X and Y along the dimension dims. If corrected is true (the default) then the sum is scaled with n-1, whereas the sum is scaled with n if corrected is false where $n = \text{size}(X, \text{dims}) = \text{size}(Y, \text{dims})$.

[source](#)

Statistics.mean! – Function.

```
| mean!(r, v)
```

Compute the mean of *v* over the singleton dimensions of *r*, and write results to *r*.

Examples

```
julia> using Statistics

julia> v = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> mean!([1., 1.], v)
2-element Vector{Float64}:
 1.5
 3.5

julia> mean!([1. 1.], v)
1×2 Matrix{Float64}:
 2.0  3.0
```

[source](#)

Statistics.mean – Function.

```
| mean(itr)
```

Compute the mean of all elements in a collection.

Note

If *itr* contains NaN or [missing](#) values, the result is also NaN or missing (missing takes precedence if array contains both). Use the [skipmissing](#) function to omit missing entries and compute the mean of non-missing values.

Examples

```
julia> using Statistics

julia> mean(1:20)
10.5

julia> mean([1, missing, 3])
missing

julia> mean(skipmissing([1, missing, 3]))
2.0
```

[source](#)

```
| mean(f, itr)
```

Apply the function `f` to each element of collection `itr` and take the mean.

```
julia> using Statistics

julia> mean(√, [1, 2, 3])
1.3820881233139908

julia> mean([√1, √2, √3])
1.3820881233139908
```

[source](#)

```
mean(f, A::AbstractArray; dims)
```

Apply the function `f` to each element of array `A` and take the mean over dimensions `dims`.

Julia 1.3

This method requires at least Julia 1.3.

```
julia> using Statistics

julia> mean(√, [1, 2, 3])
1.3820881233139908

julia> mean([√1, √2, √3])
1.3820881233139908

julia> mean(√, [1 2 3; 4 5 6], dims=2)
2×1 Matrix{Float64}:
 1.3820881233139908
 2.285192400943226
```

[source](#)

```
mean(A::AbstractArray; dims)
```

Compute the mean of an array over the given dimensions.

Julia 1.1

`mean` for empty arrays requires at least Julia 1.1.

Examples

```
julia> using Statistics

julia> A = [1 2; 3 4]
2×2 Matrix{Int64}:
 1  2
 3  4

julia> mean(A, dims=1)
1×2 Matrix{Float64}:
 2.0  3.0
```

```
julia> mean(A, dims=2)
2×1 Matrix{Float64}:
 1.5
 3.5
```

[source](#)

Statistics.median! - Function.

```
median!(v)
```

Like [median](#), but may overwrite the input vector.

[source](#)

Statistics.median - Function.

```
median(itr)
```

Compute the median of all elements in a collection. For an even number of elements no exact median element exists, so the result is equivalent to calculating mean of two median elements.

Note

If `itr` contains NaN or [missing](#) values, the result is also NaN or missing (missing takes precedence if `itr` contains both). Use the [skipmissing](#) function to omit missing entries and compute the median of non-missing values.

Examples

```
julia> using Statistics

julia> median([1, 2, 3])
2.0

julia> median([1, 2, 3, 4])
2.5

julia> median([1, 2, missing, 4])
missing

julia> median(skipmissing([1, 2, missing, 4]))
2.0
```

[source](#)

```
median(A::AbstractArray; dims)
```

Compute the median of an array along the given dimensions.

Examples

```
julia> using Statistics

julia> median([1 2; 3 4], dims=1)
1×2 Matrix{Float64}:
 2.0  3.0
```

[source](#)

Statistics.middle – Function.

```
| middle(x)
```

Compute the middle of a scalar value, which is equivalent to x itself, but of the type of `middle(x, x)` for consistency.

[source](#)

```
| middle(x, y)
```

Compute the middle of two numbers x and y , which is equivalent in both value and type to computing their mean $((x + y) / 2)$.

[source](#)

```
| middle(a::AbstractArray)
```

Compute the middle of an array a , which consists of finding its extrema and then computing their mean.

```
julia> using Statistics

julia> middle(1:10)
5.5

julia> a = [1,2,3.6,10.9]
4-element Vector{Float64}:
 1.0
 2.0
 3.6
10.9

julia> middle(a)
5.95
```

[source](#)

Statistics.quantile! – Function.

```
| quantile!([q::AbstractArray, ] v::AbstractVector, p; sorted=false, alpha::Real=1.0,
↪ beta::Real=alpha)
```

Compute the quantile(s) of a vector v at a specified probability or vector or tuple of probabilities p on the interval $[0,1]$. If p is a vector, an optional output array q may also be specified. (If not provided, a new output array is created.) The keyword argument `sorted` indicates whether v can be assumed to be sorted; if `false` (the default), then the elements of v will be partially sorted in-place.

Samples quantile are defined by $Q(p) = (1-\gamma)*x[j] + \gamma*x[j+1]$, where $x[j]$ is the j -th order statistic of v , $j = \text{floor}(n*p + m)$, $m = \alpha + p*(1 - \alpha - \beta)$ and $\gamma = n*p + m - j$.

By default ($\alpha = \beta = 1$), quantiles are computed via linear interpolation between the points $((k-1)/(n-1), x[k])$, for $k = 1:n$ where $n = \text{length}(v)$. This corresponds to Definition 7 of Hyndman and Fan (1996), and is the same as the R and NumPy default.

The keyword arguments α and β correspond to the same parameters in Hyndman and Fan, setting them to different values allows to calculate quantiles with any of the methods 4-9 defined in this paper:

- Def. 4: $\alpha=0, \beta=1$
- Def. 5: $\alpha=0.5, \beta=0.5$
- Def. 6: $\alpha=0, \beta=0$ (Excel PERCENTILE.EXC, Python default, Stata `altdf`)
- Def. 7: $\alpha=1, \beta=1$ (Julia, R and NumPy default, Excel PERCENTILE and PERCENTILE.INC, Python 'inclusive')
- Def. 8: $\alpha=1/3, \beta=1/3$
- Def. 9: $\alpha=3/8, \beta=3/8$

Note

An `ArgumentError` is thrown if v contains NaN or `missing` values.

References

- Hyndman, R.J and Fan, Y. (1996) "Sample Quantiles in Statistical Packages", The American Statistician, Vol. 50, No. 4, pp. 361-365
- [Quantile on Wikipedia](#) details the different quantile definitions

Examples

```
julia> using Statistics

julia> x = [3, 2, 1];

julia> quantile!(x, 0.5)
2.0

julia> x
3-element Vector{Int64}:
 1
 2
 3

julia> y = zeros(3);

julia> quantile!(y, x, [0.1, 0.5, 0.9]) == y
true

julia> y
3-element Vector{Float64}:
```

```
1.20000000000000002
2.0
2.8000000000000003
```

[source](#)

Statistics.quantile - Function.

```
quantile(itr, p; sorted=false, alpha::Real=1.0, beta::Real=alpha)
```

Compute the quantile(s) of a collection `itr` at a specified probability or vector or tuple of probabilities `p` on the interval `[0,1]`. The keyword argument `sorted` indicates whether `itr` can be assumed to be sorted.

Samples quantile are defined by $Q(p) = (1-\gamma)*x[j] + \gamma*x[j+1]$, where $x[j]$ is the j -th order statistic of `itr`, $j = \text{floor}(n*p + m)$, $m = \text{alpha} + p*(1 - \text{alpha} - \text{beta})$ and $\gamma = n*p + m - j$.

By default (`alpha = beta = 1`), quantiles are computed via linear interpolation between the points $((k-1)/(n-1), x[k])$, for $k = 1:n$ where $n = \text{length}(itr)$. This corresponds to Definition 7 of Hyndman and Fan (1996), and is the same as the R and NumPy default.

The keyword arguments `alpha` and `beta` correspond to the same parameters in Hyndman and Fan, setting them to different values allows to calculate quantiles with any of the methods 4-9 defined in this paper:

- Def. 4: `alpha=0, beta=1`
- Def. 5: `alpha=0.5, beta=0.5`
- Def. 6: `alpha=0, beta=0` (Excel PERCENTILE.EXC, Python default, Stata `altdf`)
- Def. 7: `alpha=1, beta=1` (Julia, R and NumPy default, Excel PERCENTILE and PERCENTILE.INC, Python 'inclusive')
- Def. 8: `alpha=1/3, beta=1/3`
- Def. 9: `alpha=3/8, beta=3/8`

Note

An `ArgumentError` is thrown if `v` contains `NaN` or `missing` values. Use the `skipmissing` function to omit missing entries and compute the quantiles of non-missing values.

References

- Hyndman, R.J and Fan, Y. (1996) "Sample Quantiles in Statistical Packages", The American Statistician, Vol. 50, No. 4, pp. 361-365
- [Quantile on Wikipedia](#) details the different quantile definitions

Examples

```
julia> using Statistics

julia> quantile(0:20, 0.5)
10.0
```

```
julia> quantile(0:20, [0.1, 0.5, 0.9])
3-element Vector{Float64}:
 2.0
10.0
18.000000000000004

julia> quantile(skipmissing([1, 10, missing]), 0.5)
5.5
```

[source](#)

Chapter 97

TOML

TOML.jl is a Julia standard library for parsing and writing [TOML v1.0](#) files.

97.1 Parsing TOML data

```
julia> using TOML

julia> data = """
    [database]
    server = "192.168.1.1"
    ports = [ 8001, 8001, 8002 ]
    """;

julia> TOML.parse(data)
Dict{String, Any} with 1 entry:
  "database" => Dict{String, Any}("server"=>"192.168.1.1", "ports"=>[8001, 8001...
```

To parse a file, use [TOML.parsefile](#). If the file has a syntax error, an exception is thrown:

```
julia> using TOML

julia> TOML.parse("""
    value = 0.0.0
    """)
ERROR: TOML Parser error:
none:1:16 error: failed to parse value
    value = 0.0.0
              ^
[...]
```

There are other versions of the parse functions ([TOML.tryparse](#) and [TOML.tryparsefile](#)) that instead of throwing exceptions on parser error returns a [TOML.ParserError](#) with information:

```
julia> using TOML

julia> err = TOML.tryparse("""
```

```

        value = 0.0.0
        """);

julia> err.type
ErrGenericValueError::ErrorType = 14

julia> err.line
1

julia> err.column
16

```

97.2 Exporting data to TOML file

The `TOML.print` function is used to print (or serialize) data into TOML format.

```

julia> using TOML

julia> data = Dict{
    "names" => ["Julia", "Julio"],
    "age" => [10, 20],
};

julia> TOML.print(data)
names = ["Julia", "Julio"]
age = [10, 20]

julia> fname = tempname();

julia> open(fname, "w") do io
    TOML.print(io, data)
end

julia> TOML.parsefile(fname)
Dict{String, Any} with 2 entries:
  "names" => ["Julia", "Julio"]
  "age"   => [10, 20]

```

Keys can be sorted according to some value

```

julia> using TOML

julia> TOML.print(Dict{
    "abc" => 1,
    "ab"  => 2,
    "abcd" => 3,
}; sorted=true, by=length)
ab = 2
abc = 1
abcd = 3

```

For custom structs, pass a function that converts the struct to a supported type

```
julia> using TOML

julia> struct MyStruct
    a::Int
    b::String
end

julia> TOML.print(Dict{"foo" => MyStruct(5, "bar")}) do x
    x isa MyStruct && return [x.a, x.b]
    error("unhandled type $(typeof(x))")
end
foo = [5, "bar"]
```

97.3 References

TOML.parse – Function.

```
parse(x::Union{AbstractString, IO})
parse(p::Parser, x::Union{AbstractString, IO})
```

Parse the string or stream x, and return the resulting table (dictionary). Throw a [ParserError](#) upon failure.

See also [TOML.tryparse](#).

TOML.parsefile – Function.

```
parsefile(f::AbstractString)
parsefile(p::Parser, f::AbstractString)
```

Parse file f and return the resulting table (dictionary). Throw a [ParserError](#) upon failure.

See also [TOML.tryparsefile](#).

TOML.tryparse – Function.

```
tryparse(x::Union{AbstractString, IO})
tryparse(p::Parser, x::Union{AbstractString, IO})
```

Parse the string or stream x, and return the resulting table (dictionary). Return a [ParserError](#) upon failure.

See also [TOML.parse](#).

TOML.tryparsefile – Function.

```
tryparsefile(f::AbstractString)
tryparsefile(p::Parser, f::AbstractString)
```

Parse file f and return the resulting table (dictionary). Return a [ParserError](#) upon failure.

See also [TOML.parsefile](#).

TOML.print – Function.

```
print([to_toml::Function], io::IO [=stdout], data::AbstractDict; sorted=false, by=identity)
```

Write data as TOML syntax to the stream `io`. If the keyword argument `sorted` is set to `true`, sort tables according to the function given by the keyword argument `by`.

The following data types are supported: `AbstractDict`, `AbstractVector`, `AbstractString`, `Integer`, `AbstractFloat`, `Bool`, `Dates.DateTime`, `Dates.Time`, `Dates.Date`. Note that the integers and floats need to be convertible to `Float64` and `Int64` respectively. For other data types, pass the function `to_toml` that takes the data types and returns a value of a supported type.

`TOML.Parser` – Type.

| `Parser()`

Constructor for a TOML Parser. Note that in most cases one does not need to explicitly create a `Parser` but instead one directly use `TOML.parsefile` or `TOML.parse`. Using an explicit parser will however reuse some internal data structures which can be beneficial for performance if a larger number of small files are parsed.

`TOML.ParserError` – Type.

| `ParserError`

Type that is returned from `tryparse` and `tryparsefile` when parsing fails. It contains (among others) the following fields:

- `pos`, the position in the string when the error happened
- `table`, the result that so far was successfully parsed
- `type`, an error type, different for different types of errors

Chapter 98

Tar

Tar.create - Function.

```
create(
  [ predicate, ] dir, [ tarball ];
  [ skeleton, ] [ portable = false ]
) -> tarball

predicate :: String --> Bool
dir       :: AbstractString
tarball   :: Union{AbstractString, AbstractCmd, IO}
skeleton  :: Union{AbstractString, AbstractCmd, IO}
portable  :: Bool
```

Create a tar archive ("tarball") of the directory `dir`. The resulting archive is written to the path `tarball` or if no path is specified, a temporary path is created and returned by the function call. If `tarball` is an IO object then the tarball content is written to that handle instead (the handle is left open).

If a predicate function is passed, it is called on each system path that is encountered while recursively searching `dir` and path is only included in the tarball if `predicate(path)` is true. If `predicate(path)` returns false for a directory, then the directory is excluded entirely: nothing under that directory will be included in the archive.

If the `skeleton` keyword is passed then the file or IO handle given is used as a "skeleton" to generate the tarball. You create a skeleton file by passing the `skeleton` keyword to the `extract` command. If `create` is called with that skeleton file and the extracted files haven't changed, an identical tarball is recreated. The `skeleton` and `predicate` arguments cannot be used together.

If the `portable` flag is true then path names are checked for validity on Windows, which ensures that they don't contain illegal characters or have names that are reserved. See <https://stackoverflow.com/a/31976060/659248> for details.

Tar.extract - Function.

```
extract(
  [ predicate, ] tarball, [ dir ];
  [ skeleton = <none>, ]
  [ copy_symlinks = <auto>, ]
  [ set_permissions = true, ]
) -> dir
```

```

predicate      :: Header --> Bool
tarball        :: Union{AbstractString, AbstractCmd, IO}
dir            :: AbstractString
skeleton       :: Union{AbstractString, AbstractCmd, IO}
copy_symlinks  :: Bool
set_permissions :: Bool

```

Extract a tar archive ("tarball") located at the path `tarball` into the directory `dir`. If `tarball` is an IO object instead of a path, then the archive contents will be read from that IO stream. The archive is extracted to `dir` which must either be an existing empty directory or a non-existent path which can be created as a new directory. If `dir` is not specified, the archive is extracted into a temporary directory which is returned by `extract`.

If a predicate function is passed, it is called on each Header object that is encountered while extracting `tarball` and the entry is only extracted if the `predicate(hdr)` is true. This can be used to selectively extract only parts of an archive, to skip entries that cause `extract` to throw an error, or to record what is extracted during the extraction process.

Before it is passed to the predicate function, the Header object is somewhat modified from the raw header in the tarball: the path field is normalized to remove `.` entries and replace multiple consecutive slashes with a single slash. If the entry has type `:hardlink`, the link target path is normalized the same way so that it will match the path of the target entry; the size field is set to the size of the target path (which must be an already-seen file).

If the `skeleton` keyword is passed then a "skeleton" of the extracted tarball is written to the file or IO handle given. This skeleton file can be used to recreate an identical tarball by passing the `skeleton` keyword to the `create` function. The `skeleton` and `predicate` arguments cannot be used together.

If `copy_symlinks` is true then instead of extracting symbolic links as such, they will be extracted as copies of what they link to if they are internal to the tarball and if it is possible to do so. Non-internal symlinks, such as a link to `/etc/passwd` will not be copied. Symlinks which are in any way cyclic will also not be copied and will instead be skipped. By default, `extract` will detect whether symlinks can be created in `dir` or not and will automatically copy symlinks if they cannot be created.

If `set_permissions` is false, no permissions are set on the extracted files.

Tar.list - Function.

```

list(tarball; [ strict = true ]) -> Vector{Header}
list(callback, tarball; [ strict = true ])

callback  :: Header, [ <data> ] --> Any
tarball   :: Union{AbstractString, AbstractCmd, IO}
strict    :: Bool

```

List the contents of a tar archive ("tarball") located at the path `tarball`. If `tarball` is an IO handle, read the tar contents from that stream. Returns a vector of Header structs. See [Header](#) for details.

If a callback is provided then instead of returning a vector of headers, the callback is called on each Header. This can be useful if the number of items in the tarball is large or if you want examine items prior to an error in the tarball. If the callback function can accept a second argument of either type `Vector{UInt8}` or `Vector{Pair{Symbol, String}}` then it will be called with a representation of the

raw header data either as a single byte vector or as a vector of pairs mapping field names to the raw data for that field (if these fields are concatenated together, the result is the raw data of the header).

By default `list` will error if it encounters any tarball contents which the `extract` function would refuse to extract. With `strict=false` it will skip these checks and list all the contents of the tar file whether `extract` would extract them or not. Beware that malicious tarballs can do all sorts of crafty and unexpected things to try to trick you into doing something bad.

If the `tarball` argument is a skeleton file (see `extract` and `create`) then `list` will detect that from the file header and appropriately list or iterate the headers of the skeleton file.

`Tar.rewrite` - Function.

```
rewrite(
  [ predicate, ] old_tarball, [ new_tarball ];
  [ portable = false, ]
) -> new_tarball

predicate  :: Header -> Bool
old_tarball :: Union{AbstractString, AbstractCmd, IO}
new_tarball :: Union{AbstractString, AbstractCmd, IO}
portable   :: Bool
```

Rewrite `old_tarball` to the standard format that `create` generates, while also checking that it doesn't contain anything that would cause `extract` to raise an error. This is functionally equivalent to doing

```
Tar.create(Tar.extract(predicate, old_tarball), new_tarball)
```

However, it never extracts anything to disk and instead uses the `seek` function to navigate the old tarball's data. If no `new_tarball` argument is passed, the new tarball is written to a temporary file whose path is returned.

If a predicate function is passed, it is called on each `Header` object that is encountered while extracting `old_tarball` and the entry is skipped unless `predicate(hdr)` is true. This can be used to selectively rewrite only parts of an archive, to skip entries that would cause `extract` to throw an error, or to record what content is encountered during the rewrite process.

Before it is passed to the predicate function, the `Header` object is somewhat modified from the raw header in the tarball: the `path` field is normalized to remove `.` entries and replace multiple consecutive slashes with a single slash. If the entry has type `:hardlink`, the link target path is normalized the same way so that it will match the path of the target entry; the `size` field is set to the size of the target path (which must be an already-seen file).

If the `portable` flag is true then path names are checked for validity on Windows, which ensures that they don't contain illegal characters or have names that are reserved. See <https://stackoverflow.com/a/31976060/659248> for details.

`Tar.tree_hash` - Function.

```
tree_hash([ predicate, ] tarball;
  [ algorithm = "git-sha1", ]
  [ skip_empty = false ]) -> hash::String

predicate  :: Header -> Bool
tarball    :: Union{AbstractString, AbstractCmd, IO}
```

```

algorithm :: AbstractString
skip_empty :: Bool

```

Compute a tree hash value for the file tree that the tarball contains. By default, this uses git's tree hashing algorithm with the SHA1 secure hash function (like current versions of git). This means that for any tarball whose file tree git can represent—i.e. one with only files, symlinks and non-empty directories—the hash value computed by this function will be the same as the hash value git would compute for that file tree. Note that tarballs can represent file trees with empty directories, which git cannot store, and this function can generate hashes for those, which will, by default (see `skip_empty` below for how to change this behavior), differ from the hash of a tarball which omits those empty directories. In short, the hash function agrees with git on all trees which git can represent, but extends (in a consistent way) the domain of hashable trees to other trees which git cannot represent.

If a predicate function is passed, it is called on each Header object that is encountered while processing tarball and an entry is only hashed if `predicate(hdr)` is true. This can be used to selectively hash only parts of an archive, to skip entries that cause extract to throw an error, or to record what is extracted during the hashing process.

Before it is passed to the predicate function, the Header object is somewhat modified from the raw header in the tarball: the path field is normalized to remove . entries and replace multiple consecutive slashes with a single slash. If the entry has type `:hardlink`, the link target path is normalized the same way so that it will match the path of the target entry; the size field is set to the size of the target path (which must be an already-seen file).

Currently supported values for `algorithm` are `git-sha1` (the default) and `git-sha256`, which uses the same basic algorithm as `git-sha1` but replaces the SHA1 hash function with SHA2-256, the hash function that git will transition to using in the future (due to known attacks on SHA1). Support for other file tree hashing algorithms may be added in the future.

The `skip_empty` option controls whether directories in the tarball which recursively contain no files or symlinks are included in the hash or ignored. In general, if you are hashing the content of a tarball or a file tree, you care about all directories, not just non-empty ones, so including these in the computed hash is the default. So why does this function even provide the option to skip empty directories? Because git refuses to store empty directories and will ignore them if you try to add them to a repo. So if you compute a reference tree hash by adding files to a git repo and then asking git for the tree hash, the hash value that you get will match the hash value computed by `tree_hash` with `skip_empty=true`. In other words, this option allows `tree_hash` to emulate how git would hash a tree with empty directories. If you are hashing trees that may contain empty directories (i.e. do not come from a git repo), however, it is recommended that you hash them using a tool (such as this one) that does not ignore empty directories.

Tar.Header - Type.

The Header type is a struct representing the essential metadata for a single record in a tar file with this definition:

```

struct Header
  path :: String # path relative to the root
  type :: Symbol # type indicator (see below)
  mode :: UInt16 # mode/permissions (best viewed in octal)
  size :: Int64  # size of record data in bytes
  link :: String # target path of a symlink
end

```

Types are represented with the following symbols: file, hardlink, symlink, chardev, blockdev, directory, fifo, or for unknown types, the typeflag character as a symbol. Note that `extract` refuses to extract records types other than file, symlink and directory; `list` will only list other kinds of records if called with `strict=false`.

The tar format includes various other metadata about records, including user and group IDs, user and group names, and timestamps. The Tar package, by design, completely ignores these. When creating tar files, these fields are always set to zero/empty. When reading tar files, these fields are ignored aside from verifying header checksums for each header record for all fields.

Chapter 99

Unit Testing

99.1 Testing Base Julia

Julia is under rapid development and has an extensive test suite to verify functionality across multiple platforms. If you build Julia from source, you can run this test suite with `make test`. In a binary install, you can run the test suite using `Base.runtests()`.

`Base.runtests` – Function.

```
Base.runtests(tests=["all"]; ncores=ceil{Int, Sys.CPU_THREADS / 2},
              exit_on_error=false, revise=false, [seed])
```

Run the Julia unit tests listed in `tests`, which can be either a string or an array of strings, using `ncores` processors. If `exit_on_error` is `false`, when one test fails, all remaining tests in other files will still be run; they are otherwise discarded, when `exit_on_error == true`. If `revise` is `true`, the `Revise` package is used to load any modifications to Base or to the standard libraries before running the tests. If a seed is provided via the keyword argument, it is used to seed the global RNG in the context where the tests are run; otherwise the seed is chosen randomly.

[source](#)

99.2 Basic Unit Tests

The `Test` module provides simple unit testing functionality. Unit testing is a way to see if your code is correct by checking that the results are what you expect. It can be helpful to ensure your code still works after you make changes, and can be used when developing as a way of specifying the behaviors your code should have when complete. You may also want to look at the documentation for [adding tests to your Julia Package](#).

Simple unit testing can be performed with the `@test` and `@test_throws` macros:

`Test.@test` – Macro.

```
@test ex
@test f(args...) key=val ...
@test ex broken=true
@test ex skip=true
```

Test that the expression `ex` evaluates to `true`. If executed inside a `@testset`, return a `Pass Result` if it does, a `Fail Result` if it is false, and an `Error Result` if it could not be evaluated. If executed outside a `@testset`, throw an exception instead of returning `Fail` or `Error`.

Examples

```
julia> @test true
Test Passed

julia> @test [1, 2] + [2, 1] == [3, 3]
Test Passed
```

The `@test f(args...) key=val...` form is equivalent to writing `@test f(args..., key=val...)` which can be useful when the expression is a call using infix syntax such as approximate comparisons:

```
julia> @test π ≈ 3.14 atol=0.01
Test Passed
```

This is equivalent to the uglier test `@test ≈(π, 3.14, atol=0.01)`. It is an error to supply more than one expression unless the first is a call expression and the rest are assignments (`k=v`).

You can use any key for the `key=val` arguments, except for `broken` and `skip`, which have special meanings in the context of `@test`:

- `broken=cond` indicates a test that should pass but currently consistently fails when `cond==true`. Tests that the expression `ex` evaluates to false or causes an exception. Returns a `Broken Result` if it does, or an `Error Result` if the expression evaluates to `true`. Regular `@test ex` is evaluated when `cond==false`.
- `skip=cond` marks a test that should not be executed but should be included in test summary reporting as `Broken`, when `cond==true`. This can be useful for tests that intermittently fail, or tests of not-yet-implemented functionality. Regular `@test ex` is evaluated when `cond==false`.

Examples

```
julia> @test 2 + 2 ≈ 6 atol=1 broken=true
Test Broken
Expression: ≈(2 + 2, 6, atol = 1)

julia> @test 2 + 2 ≈ 5 atol=1 broken=false
Test Passed

julia> @test 2 + 2 == 5 skip=true
Test Broken
Skipped: 2 + 2 == 5

julia> @test 2 + 2 == 4 skip=false
Test Passed
```

Julia 1.7

The `broken` and `skip` keyword arguments require at least Julia 1.7.

[source](#)

Test.@test_throws – Macro.

```
| @test_throws exception expr
```

Tests that the expression `expr` throws exception. The exception may specify either a type, a string, regular expression, or list of strings occurring in the displayed error message, a matching function, or a value (which will be tested for equality by comparing fields). Note that `@test_throws` does not support a trailing keyword form.

Julia 1.8

The ability to specify anything other than a type or a value as exception requires Julia v1.8 or later.

Examples

```
julia> @test_throws BoundsError [1, 2, 3][4]
Test Passed
  Thrown: BoundsError

julia> @test_throws DimensionMismatch [1, 2, 3] + [1, 2]
Test Passed
  Thrown: DimensionMismatch

julia> @test_throws "Try sqrt(Complex" sqrt(-1)
Test Passed
  Message: "DomainError with -1.0:\nsqrt was called with a negative real argument but will
↪ only return a complex result if called with a complex argument. Try sqrt(Complex(x))."
```

In the final example, instead of matching a single string it could alternatively have been performed with:

- `["Try", "Complex"]` (a list of strings)
- `r"Try sqrt\[Cc]omplex"` (a regular expression)
- `str -> occursin("complex", str)` (a matching function)

source

For example, suppose we want to check our new function `foo(x)` works as expected:

```
julia> using Test

julia> foo(x) = length(x)^2
foo (generic function with 1 method)
```

If the condition is true, a Pass is returned:

```
julia> @test foo("bar") == 9
Test Passed

julia> @test foo("fizz") >= 10
Test Passed
```

If the condition is false, then a Fail is returned and an exception is thrown:

```
julia> @test foo("f") == 20
Test Failed at none:1
  Expression: foo("f") == 20
    Evaluated: 1 == 20

ERROR: There was an error during testing
```

If the condition could not be evaluated because an exception was thrown, which occurs in this case because `length` is not defined for symbols, an Error object is returned and an exception is thrown:

```
julia> @test foo(:cat) == 1
Error During Test
  Test threw an exception of type MethodError
  Expression: foo(:cat) == 1
  MethodError: no method matching length(::Symbol)
  Closest candidates are:
    length(::SimpleVector) at essentials.jl:256
    length(::Base.MethodList) at reflection.jl:521
    length(::MethodTable) at reflection.jl:597
  ...
  Stacktrace:
  [...]

ERROR: There was an error during testing
```

If we expect that evaluating an expression should throw an exception, then we can use `@test_throws` to check that this occurs:

```
julia> @test_throws MethodError foo(:cat)
Test Passed
  Thrown: MethodError
```

99.3 Working with Test Sets

Typically a large number of tests are used to make sure functions work correctly over a range of inputs. In the event a test fails, the default behavior is to throw an exception immediately. However, it is normally preferable to run the rest of the tests first to get a better picture of how many errors there are in the code being tested.

Note

The `@testset` will create a local scope of its own when running the tests in it.

The `@testset` macro can be used to group tests into sets. All the tests in a test set will be run, and at the end of the test set a summary will be printed. If any of the tests failed, or could not be evaluated due to an error, the test set will then throw a `TestSetException`.

Test.@testset – Macro.

```

@testset [CustomTestSet] [options...] ["description"] begin test_ex end
@testset [CustomTestSet] [options...] ["description $v"] for v in itr test_ex end
@testset [CustomTestSet] [options...] ["description $v, $w"] for v in itr_v, w in itr_w test_ex
↳ end
@testset [CustomTestSet] [options...] ["description"] test_func()
@testset let v = v, w = w; test_ex; end

```

With begin/end or function call

When `@testset` is used, with `begin/end` or a single function call, the macro starts a new test set in which to evaluate the given expression.

If no custom testset type is given it defaults to creating a `DefaultTestSet`. `DefaultTestSet` records all the results and, if there are any Fails or Errors, throws an exception at the end of the top-level (non-nested) test set, along with a summary of the test results.

Any custom testset type (subtype of `AbstractTestSet`) can be given and it will also be used for any nested `@testset` invocations. The given options are only applied to the test set where they are given. The default test set type accepts three boolean options:

- `verbose`: if true, the result summary of the nested testsets is shown even when they all pass (the default is false).
- `showtiming`: if true, the duration of each displayed testset is shown (the default is true).
- `failfast`: if true, any test failure or error will cause the testset and any child testsets to return immediately (the default is false). This can also be set globally via the env var `JULIA_TEST_FAILFAST`.

Julia 1.8

`@testset test_func()` requires at least Julia 1.8.

Julia 1.9

`failfast` requires at least Julia 1.9.

The description string accepts interpolation from the loop indices. If no description is provided, one is constructed based on the variables. If a function call is provided, its name will be used. Explicit description strings override this behavior.

By default the `@testset` macro will return the testset object itself, though this behavior can be customized in other testset types. If a `for` loop is used then the macro collects and returns a list of the return values of the `finish` method, which by default will return a list of the testset objects used in each iteration.

Before the execution of the body of a `@testset`, there is an implicit call to `Random.seed!(seed)` where `seed` is the current seed of the global RNG. Moreover, after the execution of the body, the state of the global RNG is restored to what it was before the `@testset`. This is meant to ease reproducibility in case of failure, and to allow seamless re-arrangements of `@testsets` regardless of their side-effect on the global RNG state.

Examples

```

julia> @testset "trigonometric identities" begin
    θ = 2/3*π
    @test sin(-θ) ≈ -sin(θ)
end

```

```

        @test cos(-θ) ≈ cos(θ)
        @test sin(2θ) ≈ 2*sin(θ)*cos(θ)
        @test cos(2θ) ≈ cos(θ)^2 - sin(θ)^2
    end;
Test Summary:          | Pass  Total  Time
trigonometric identities |    4      4  0.2s

```

@testset for

When `@testset for` is used, the macro starts a new test for each iteration of the provided loop. The semantics of each test set are otherwise identical to that of that `begin/end` case (as if used for each loop iteration).

@testset let

When `@testset let` is used, the macro starts a transparent test set with the given object added as a context object to any failing test contained therein. This is useful when performing a set of related tests on one larger object and it is desirable to print this larger object when any of the individual tests fail. Transparent test sets do not introduce additional levels of nesting in the test set hierarchy and are passed through directly to the parent test set (with the context object appended to any failing tests.)

Julia 1.9

`@testset let` requires at least Julia 1.9.

Julia 1.10

Multiple `let` assignments are supported since Julia 1.10.

Examples

```

julia> @testset let logi = log(im)
        @test imag(logi) == π/2
        @test !iszero(real(logi))
    end
Test Failed at none:3
Expression: !(iszero(real(logi)))
Context: logi = 0.0 + 1.5707963267948966im

ERROR: There was an error during testing

julia> @testset let logi = log(im), op = !iszero
        @test imag(logi) == π/2
        @test op(real(logi))
    end
Test Failed at none:3
Expression: op(real(logi))
Context: logi = 0.0 + 1.5707963267948966im
        op = !iszero

ERROR: There was an error during testing

```

[source](#)

`Test.TestSetException` – Type.

| TestSetException

Thrown when a test set finishes and not all tests passed.

[source](#)

We can put our tests for the `foo(x)` function in a test set:

```
julia> @testset "Foo Tests" begin
    @test foo("a") == 1
    @test foo("ab") == 4
    @test foo("abc") == 9
end;
Test Summary: | Pass  Total  Time
Foo Tests    |     3     3  0.0s
```

Test sets can also be nested:

```
julia> @testset "Foo Tests" begin
    @testset "Animals" begin
        @test foo("cat") == 9
        @test foo("dog") == foo("cat")
    end
    @testset "Arrays $i" for i in 1:3
        @test foo(zeros(i)) == i^2
        @test foo(fill(1.0, i)) == i^2
    end
end;
Test Summary: | Pass  Total  Time
Foo Tests    |     8     8  0.0s
```

As well as call functions:

```
julia> f(x) = @test isone(x)
f (generic function with 1 method)

julia> @testset f(1);
Test Summary: | Pass  Total  Time
f             |     1     1  0.0s
```

This can be used to allow for factorization of test sets, making it easier to run individual test sets by running the associated functions instead. Note that in the case of functions, the test set will be given the name of the called function. In the event that a nested test set has no failures, as happened here, it will be hidden in the summary, unless the `verbose=true` option is passed:

```
julia> @testset verbose = true "Foo Tests" begin
    @testset "Animals" begin
        @test foo("cat") == 9
        @test foo("dog") == foo("cat")
    end
end
```

```

        @testset "Arrays $i" for i in 1:3
            @test foo(zeros(i)) == i^2
            @test foo(fill(1.0, i)) == i^2
        end
    end;

```

| | | | | |
|---------------|--|------|-------|------|
| Test Summary: | | Pass | Total | Time |
| Foo Tests | | 8 | 8 | 0.0s |
| Animals | | 2 | 2 | 0.0s |
| Arrays 1 | | 2 | 2 | 0.0s |
| Arrays 2 | | 2 | 2 | 0.0s |
| Arrays 3 | | 2 | 2 | 0.0s |

If we do have a test failure, only the details for the failed test sets will be shown:

```

julia> @testset "Foo Tests" begin
    @testset "Animals" begin
        @testset "Felines" begin
            @test foo("cat") == 9
        end
        @testset "Canines" begin
            @test foo("dog") == 9
        end
    end
    @testset "Arrays" begin
        @test foo(zeros(2)) == 4
        @test foo(fill(1.0, 4)) == 15
    end
end

```

Arrays: Test Failed
 Expression: `foo(fill(1.0, 4)) == 15`
 Evaluated: `16 == 15`

[...]

| | | | | | |
|---------------|--|------|------|-------|------|
| Test Summary: | | Pass | Fail | Total | Time |
| Foo Tests | | 3 | 1 | 4 | 0.0s |
| Animals | | 2 | | 2 | 0.0s |
| Arrays | | 1 | 1 | 2 | 0.0s |

ERROR: Some tests did not pass: 3 passed, 1 failed, 0 errored, 0 broken.

99.4 Testing Log Statements

One can use the `@test_logs` macro to test log statements, or use a [TestLogger](#).

Test.@test_logs - Macro.

```
| @test_logs [log_patterns...] [keywords] expression
```

Collect a list of log records generated by expression using `collect_test_logs`, check that they match the sequence `log_patterns`, and return the value of expression. The keywords provide some simple filtering of log records: the `min_level` keyword controls the minimum log level which will be collected for the test, the `match_mode` keyword defines how matching will be performed (the default `:all` checks that all logs and patterns match pairwise; use `:any` to check that the pattern matches at least once somewhere in the sequence.)

The most useful log pattern is a simple tuple of the form `(level,message)`. A different number of tuple elements may be used to match other log metadata, corresponding to the arguments to passed to `AbstractLogger` via the `handle_message` function: `(level,message,module,group,id,file,line)`. Elements which are present will be matched pairwise with the log record fields using `==` by default, with the special cases that Symbols may be used for the standard log levels, and Regexp in the pattern will match string or Symbol fields using `occursin`.

Examples

Consider a function which logs a warning, and several debug messages:

```
function foo(n)
  @info "Doing foo with n=$n"
  for i=1:n
    @debug "Iteration $i"
  end
  42
end
```

We can test the info message using

```
@test_logs (:info,"Doing foo with n=2") foo(2)
```

If we also wanted to test the debug messages, these need to be enabled with the `min_level` keyword:

```
using Logging
@test_logs (:info,"Doing foo with n=2") (:debug,"Iteration 1") (:debug,"Iteration 2")
      min_level=Logging.Debug foo(2)
```

If you want to test that some particular messages are generated while ignoring the rest, you can set the keyword `match_mode=:any`:

```
using Logging
@test_logs (:info,) (:debug,"Iteration 42") min_level=Logging.Debug match_mode=:any foo(100)
```

The macro may be chained with `@test` to also test the returned value:

```
@test (@test_logs (:info,"Doing foo with n=2") foo(2)) == 42
```

If you want to test for the absence of warnings, you can omit specifying log patterns and set the `min_level` accordingly:

```
# test that the expression logs no messages when the logger level is warn:
@test_logs min_level=Logging.Warn @info("Some information") # passes
@test_logs min_level=Logging.Warn @warn("Some information") # fails
```

If you want to test the absence of warnings (or error messages) in `stderr` which are not generated by `@warn`, see `@test_nowarn`.

[source](#)

`Test.TestLogger` - Type.

```
TestLogger(; min_level=Info, catch_exceptions=false)
```

Create a `TestLogger` which captures logged messages in its `logs::Vector{LogRecord}` field.

Set `min_level` to control the `LogLevel`, `catch_exceptions` for whether or not exceptions thrown as part of log event generation should be caught, and `respect_maxlog` for whether or not to follow the convention of logging messages with `maxlog=n` for some integer `n` at most `n` times.

See also: [LogRecord](#).

Example

```
julia> using Test, Logging

julia> f() = @info "Hi" number=5;

julia> test_logger = TestLogger();

julia> with_logger(test_logger) do
    f()
    @info "Bye!"
end

julia> @test test_logger.logs[1].message == "Hi"
Test Passed

julia> @test test_logger.logs[1].kwargs[:number] == 5
Test Passed

julia> @test test_logger.logs[2].message == "Bye!"
Test Passed
```

[source](#)

`Test.LogRecord` – Type.

| `LogRecord`

Stores the results of a single log event. Fields:

- `level`: the [LogLevel](#) of the log message
- `message`: the textual content of the log message
- `_module`: the module of the log event
- `group`: the logging group (by default, the name of the file containing the log event)
- `id`: the ID of the log event
- `file`: the file containing the log event
- `line`: the line within the file of the log event
- `kwargs`: any keyword arguments passed to the log event

[source](#)

99.5 Other Test Macros

As calculations on floating-point values can be imprecise, you can perform approximate equality checks using either `@test a ≈ b` (where `≈`, typed via tab completion of `\approx`, is the `isapprox` function) or use `isapprox` directly.

```
julia> @test 1 ≈ 0.999999999
Test Passed

julia> @test 1 ≈ 0.999999
Test Failed at none:1
Expression: 1 ≈ 0.999999
Evaluated: 1 ≈ 0.999999

ERROR: There was an error during testing
```

You can specify relative and absolute tolerances by setting the `rtol` and `atol` keyword arguments of `isapprox`, respectively, after the `≈` comparison:

```
julia> @test 1 ≈ 0.999999 rtol=1e-5
Test Passed
```

Note that this is not a specific feature of the `≈` but rather a general feature of the `@test` macro: `@test a <op> b key=val` is transformed by the macro into `@test op(a, b, key=val)`. It is, however, particularly useful for `≈` tests.

Test.@inferred – Macro.

```
| @inferred [AllowedType] f(x)
```

Tests that the call expression `f(x)` returns a value of the same type inferred by the compiler. It is useful to check for type stability.

`f(x)` can be any call expression. Returns the result of `f(x)` if the types match, and an `Error Result` if it finds different types.

Optionally, `AllowedType` relaxes the test, by making it pass when either the type of `f(x)` matches the inferred type modulo `AllowedType`, or when the return type is a subtype of `AllowedType`. This is useful when testing type stability of functions returning a small union such as `Union{Nothing, T}` or `Union{Missing, T}`.

```
julia> f(a) = a > 1 ? 1 : 1.0
f (generic function with 1 method)

julia> typeof(f(2))
Int64

julia> @code_warntype f(2)
MethodInstance for f{::Int64}
  from f(a) @ Main none:1
Arguments
  #self#::Core.Const(f)
```

```

    a::Int64
Body::UNION{FLOAT64, INT64}
1 - %1 = (a > 1)::Bool
└─      goto #3 if not %1
2 -      return 1
3 -      return 1.0

julia> @inferred f(2)
ERROR: return type Int64 does not match inferred return type Union{Float64, Int64}
[...]

julia> @inferred max(1, 2)
2

julia> g(a) = a < 10 ? missing : 1.0
g (generic function with 1 method)

julia> @inferred g(20)
ERROR: return type Float64 does not match inferred return type Union{Missing, Float64}
[...]

julia> @inferred Missing g(20)
1.0

julia> h(a) = a < 10 ? missing : f(a)
h (generic function with 1 method)

julia> @inferred Missing h(20)
ERROR: return type Int64 does not match inferred return type Union{Missing, Float64, Int64}
[...]
```

[source](#)

Test.@test_deprecated – Macro.

```
| @test_deprecated [pattern] expression
```

When --depwarn=yes, test that expression emits a deprecation warning and return the value of expression. The log message string will be matched against pattern which defaults to r"deprecated".

When --depwarn=no, simply return the result of executing expression. When --depwarn=error, check that an `ErrorException` is thrown.

Examples

```

# Deprecated in julia 0.7
@test_deprecated num2hex(1)

# The returned value can be tested by chaining with @test:
@test (@test_deprecated num2hex(1)) == "0000000000000001"
```

[source](#)

Test.@test_warn – Macro.

```
| @test_warn msg expr
```

Test whether evaluating `expr` results in `stderr` output that contains the `msg` string or matches the `msg` regular expression. If `msg` is a boolean function, tests whether `msg(output)` returns `true`. If `msg` is a tuple or array, checks that the error output contains/matches each item in `msg`. Returns the result of evaluating `expr`.

See also `@test_nowarn` to check for the absence of error output.

Note: Warnings generated by `@warn` cannot be tested with this macro. Use `@test_logs` instead.

[source](#)

Test.`@test_nowarn` - Macro.

```
| @test_nowarn expr
```

Test whether evaluating `expr` results in empty `stderr` output (no warnings or other messages). Returns the result of evaluating `expr`.

Note: The absence of warnings generated by `@warn` cannot be tested with this macro. Use `@test_logs` instead.

[source](#)

99.6 Broken Tests

If a test fails consistently it can be changed to use the `@test_broken` macro. This will denote the test as Broken if the test continues to fail and alerts the user via an Error if the test succeeds.

Test.`@test_broken` - Macro.

```
| @test_broken ex
| @test_broken f(args...) key=val ...
```

Indicates a test that should pass but currently consistently fails. Tests that the expression `ex` evaluates to `false` or causes an exception. Returns a `Broken Result` if it does, or an `Error Result` if the expression evaluates to `true`. This is equivalent to `@test ex broken=true`.

The `@test_broken f(args...) key=val...` form works as for the `@test` macro.

Examples

```
julia> @test_broken 1 == 2
Test Broken
Expression: 1 == 2

julia> @test_broken 1 == 2 atol=0.1
Test Broken
Expression: ==(1, 2, atol = 0.1)
```

[source](#)

`@test_skip` is also available to skip a test without evaluation, but counting the skipped test in the test set reporting. The test will not run but gives a `Broken Result`.

Test.`@test_skip` - Macro.

```
| @test_skip ex
| @test_skip f(args...) key=val ...
```

Marks a test that should not be executed but should be included in test summary reporting as Broken. This can be useful for tests that intermittently fail, or tests of not-yet-implemented functionality. This is equivalent to `@test ex skip=true`.

The `@test_skip f(args...) key=val...` form works as for the `@test` macro.

Examples

```
| julia> @test_skip 1 == 2
| Test Broken
| Skipped: 1 == 2
|
| julia> @test_skip 1 == 2 atol=0.1
| Test Broken
| Skipped: ==(1, 2, atol = 0.1)
```

[source](#)

99.7 Test result types

`Test.Result` – Type.

```
| Test.Result
```

All tests produce a result object. This object may or may not be stored, depending on whether the test is part of a test set.

[source](#)

`Test.Pass` – Type.

```
| Test.Pass <: Test.Result
```

The test condition was true, i.e. the expression evaluated to true or the correct exception was thrown.

[source](#)

`Test.Fail` – Type.

```
| Test.Fail <: Test.Result
```

The test condition was false, i.e. the expression evaluated to false or the correct exception was not thrown.

[source](#)

`Test.Error` – Type.

```
| Test.Error <: Test.Result
```

The test condition couldn't be evaluated due to an exception, or it evaluated to something other than a `Bool`. In the case of `@test_broken` it is used to indicate that an unexpected `Pass Result` occurred.

[source](#)

Test.Broken – Type.

```
| Test.Broken <: Test.Result
```

The test condition is the expected (failed) result of a broken test, or was explicitly skipped with `@test_skip`.

[source](#)

99.8 Creating Custom AbstractTestSet Types

Packages can create their own `AbstractTestSet` subtypes by implementing the `record` and `finish` methods. The subtype should have a one-argument constructor taking a description string, with any options passed in as keyword arguments.

Test.record – Function.

```
| record(ts::AbstractTestSet, res::Result)
```

Record a result to a testset. This function is called by the `@testset` infrastructure each time a contained `@test` macro completes, and is given the test result (which could be an `Error`). This will also be called with an `Error` if an exception is thrown inside the test block but outside of a `@test` context.

[source](#)

Test.finish – Function.

```
| finish(ts::AbstractTestSet)
```

Do any final processing necessary for the given testset. This is called by the `@testset` infrastructure after a test block executes.

Custom `AbstractTestSet` subtypes should call `record` on their parent (if there is one) to add themselves to the tree of test results. This might be implemented as:

```
| if get_testset_depth() != 0
|   # Attach this test set to the parent test set
|   parent_ts = get_testset()
|   record(parent_ts, self)
|   return self
| end
```

[source](#)

Test takes responsibility for maintaining a stack of nested testsets as they are executed, but any result accumulation is the responsibility of the `AbstractTestSet` subtype. You can access this stack with the `get_testset` and `get_testset_depth` methods. Note that these functions are not exported.

Test.get_testset – Function.

```
| get_testset()
```

Retrieve the active test set from the task's local storage. If no test set is active, use the fallback default test set.

[source](#)

Test.get_testset_depth - Function.

```
| get_testset_depth()
```

Return the number of active test sets, not including the default test set

[source](#)

Test also makes sure that nested @testset invocations use the same AbstractTestSet subtype as their parent unless it is set explicitly. It does not propagate any properties of the testset. Option inheritance behavior can be implemented by packages using the stack infrastructure that Test provides.

Defining a basic AbstractTestSet subtype might look like:

```
import Test: Test, record, finish
using Test: AbstractTestSet, Result, Pass, Fail, Error
using Test: get_testset_depth, get_testset
struct CustomTestSet <: Test.AbstractTestSet
    description::AbstractString
    foo::Int
    results::Vector
    # constructor takes a description string and options keyword arguments
    CustomTestSet(desc; foo=1) = new(desc, foo, [])
end

record(ts::CustomTestSet, child::AbstractTestSet) = push!(ts.results, child)
record(ts::CustomTestSet, res::Result) = push!(ts.results, res)
function finish(ts::CustomTestSet)
    # just record if we're not the top-level parent
    if get_testset_depth() > 0
        record(get_testset(), ts)
    end
    ts
end
```

And using that testset looks like:

```
@testset CustomTestSet foo=4 "custom testset inner 2" begin
    # this testset should inherit the type, but not the argument.
    @testset "custom testset inner" begin
        @test true
    end
end
```

99.9 Test utilities

Test.GenericArray - Type.

The GenericArray can be used to test generic array APIs that program to the AbstractArray interface, in order to ensure that functions can work with array types besides the standard Array type.

[source](#)

Test.GenericDict – Type.

The GenericDict can be used to test generic dict APIs that program to the AbstractDict interface, in order to ensure that functions can work with associative types besides the standard Dict type.

[source](#)

Test.GenericOrder – Type.

The GenericOrder can be used to test APIs for their support of generic ordered types.

[source](#)

Test.GenericSet – Type.

The GenericSet can be used to test generic set APIs that program to the AbstractSet interface, in order to ensure that functions can work with set types besides the standard Set and BitSet types.

[source](#)

Test.GenericString – Type.

The GenericString can be used to test generic string APIs that program to the AbstractString interface, in order to ensure that functions can work with string types besides the standard String type.

[source](#)

Test.detect_ambiguities – Function.

```
detect_ambiguities(mod1, mod2...; recursive=false,
                  ambiguous_bottom=false,
                  allowed_undefineds=nothing)
```

Return a vector of (Method,Method) pairs of ambiguous methods defined in the specified modules. Use recursive=true to test in all submodules.

ambiguous_bottom controls whether ambiguities triggered only by Union{} type parameters are included; in most cases you probably want to set this to false. See [Base.isambiguous](#).

See [Test.detect_unbound_args](#) for an explanation of allowed_undefineds.

Julia 1.8

allowed_undefineds requires at least Julia 1.8.

[source](#)

Test.detect_unbound_args – Function.

```
detect_unbound_args(mod1, mod2...; recursive=false, allowed_undefineds=nothing)
```

Return a vector of Methods which may have unbound type parameters. Use recursive=true to test in all submodules.

By default, any undefined symbols trigger a warning. This warning can be suppressed by supplying a collection of GlobalRefs for which the warning can be skipped. For example, setting

```
allowed_undefineds = Set([GlobalRef(Base, :active_repl),
                          GlobalRef(Base, :active_repl_backend)])
```

would suppress warnings about `Base.active_repl` and `Base.active_repl_backend`.

Julia 1.8

`allowed_undefs` requires at least Julia 1.8.

[source](#)

99.10 Workflow for Testing Packages

Using the tools available to us in the previous sections, here is a potential workflow of creating a package and adding tests to it.

Generating an Example Package

For this workflow, we will create a package called `Example`:

```
pkg> generate Example
shell> cd Example
shell> mkdir test
pkg> activate .
```

Creating Sample Functions

The number one requirement for testing a package is to have functionality to test. For that, we will add some simple functions to `Example` that we can test. Add the following to `src/Example.jl`:

```
module Example

function greet()
    "Hello world!"
end

function simple_add(a, b)
    a + b
end

function type_multiply(a::Float64, b::Float64)
    a * b
end

end
```

Creating a Test Environment

From within the root of the `Example` package, navigate to the `test` directory, activate a new environment there, and add the `Test` package to the environment:

```
shell> cd test
pkg> activate .
(test) pkg> add Test
```

Testing Our Package

Now, we are ready to add tests to Example. It is standard practice to create a file within the test directory called `runtests.jl` which contains the test sets we want to run. Go ahead and create that file within the test directory and add the following code to it:

```
using Example
using Test

@testset "Example tests" begin

    @testset "Math tests" begin
        include("math_tests.jl")
    end

    @testset "Greeting tests" begin
        include("greeting_tests.jl")
    end
end
```

We will need to create those two included files, `math_tests.jl` and `greeting_tests.jl`, and add some tests to them.

Note: Notice how we did not have to specify add Example into the test environment's Project.toml. This is a benefit of Julia's testing system that you could [read about more here](#).

Writing Tests for `math_tests.jl`

Using our knowledge of Test.jl, here are some example tests we could add to `math_tests.jl`:

```
@testset "Testset 1" begin
    @test 2 == simple_add(1, 1)
    @test 3.5 == simple_add(1, 2.5)
    @test_throws MethodError simple_add(1, "A")
    @test_throws MethodError simple_add(1, 2, 3)
end

@testset "Testset 2" begin
    @test 1.0 == type_multiply(1.0, 1.0)
    @test isa(type_multiply(2.0, 2.0), Float64)
    @test_throws MethodError type_multiply(1, 2.5)
end
```

Writing Tests for `greeting_tests.jl`

Using our knowledge of Test.jl, here are some example tests we could add to `math_tests.jl`:

```
@testset "Testset 3" begin
    @test "Hello world!" == greet()
    @test_throws MethodError greet("Antonia")
end
```

Testing Our Package

Now that we have added our tests and our `runtests.jl` script in `test`, we can test our Example package by going back to the root of the Example package environment and reactivating the Example environment:

```
shell> cd ..
pkg> activate .
```

From there, we can finally run our test suite as follows:

```
(Example) pkg> test
  Testing Example
    Status `~/tmp/jl_Yngpv/Project.toml`
[fa318bd2] Example v0.1.0 `~/home/src/Projects/tmp/errata/Example`
[8dfed614] Test `@stdlib/Test`
    Status `~/tmp/jl_Yngpv/Manifest.toml`
[fa318bd2] Example v0.1.0 `~/home/src/Projects/tmp/errata/Example`
[2a0f44e3] Base64 `@stdlib/Base64`
[b77e0a4c] InteractiveUtils `@stdlib/InteractiveUtils`
[56ddb016] Logging `@stdlib/Logging`
[d6f4376e] Markdown `@stdlib/Markdown`
[9a3f8284] Random `@stdlib/Random`
[ea8e919c] SHA `@stdlib/SHA`
[9e88b42a] Serialization `@stdlib/Serialization`
[8dfed614] Test `@stdlib/Test`
  Testing Running tests...
Test Summary: | Pass  Total
Example tests |    9    9
  Testing Example tests passed
```

And if all went correctly, you should see a similar output as above. Using `Test.jl`, more complicated tests can be added for packages but this should ideally point developers in the direction of how to get started with testing their own created packages.

Chapter 100

UUIDs

UUIDs.uuid1 – Function.

```
| uuid1([rng::AbstractRNG]) -> UUID
```

Generates a version 1 (time-based) universally unique identifier (UUID), as specified by RFC 4122. Note that the Node ID is randomly generated (does not identify the host) according to section 4.5 of the RFC.

The default rng used by uuid1 is not GLOBAL_RNG and every invocation of uuid1() without an argument should be expected to return a unique identifier. Importantly, the outputs of uuid1 do not repeat even when Random.seed!(seed) is called. Currently (as of Julia 1.6), uuid1 uses Random.RandomDevice as the default rng. However, this is an implementation detail that may change in the future.

Julia 1.6

The output of uuid1 does not depend on GLOBAL_RNG as of Julia 1.6.

Examples

```
| julia> rng = MersenneTwister(1234);  
  
| julia> uuid1(rng)  
| UUID("cfc395e8-590f-11e8-1f13-43a2532b2fa8")
```

UUIDs.uuid4 – Function.

```
| uuid4([rng::AbstractRNG]) -> UUID
```

Generates a version 4 (random or pseudo-random) universally unique identifier (UUID), as specified by RFC 4122.

The default rng used by uuid4 is not GLOBAL_RNG and every invocation of uuid4() without an argument should be expected to return a unique identifier. Importantly, the outputs of uuid4 do not repeat even when Random.seed!(seed) is called. Currently (as of Julia 1.6), uuid4 uses Random.RandomDevice as the default rng. However, this is an implementation detail that may change in the future.

Julia 1.6

The output of uuid4 does not depend on GLOBAL_RNG as of Julia 1.6.

Examples

```
julia> rng = MersenneTwister(1234);  
  
julia> uuid4(rng)  
UUID("7a052949-c101-4ca3-9a7e-43a2532b2fa8")
```

UUIDs.uuid5 – Function.

```
uuid5(ns::UUID, name::String) -> UUID
```

Generates a version 5 (namespace and domain-based) universally unique identifier (UUID), as specified by RFC 4122.

Julia 1.1

This function requires at least Julia 1.1.

Examples

```
julia> rng = MersenneTwister(1234);  
  
julia> u4 = uuid4(rng)  
UUID("7a052949-c101-4ca3-9a7e-43a2532b2fa8")  
  
julia> u5 = uuid5(u4, "julia")  
UUID("086cc5bb-2461-57d8-8068-0aed7f5b5cd1")
```

UUIDs.uuid_version – Function.

```
uuid_version(u::UUID) -> Int
```

Inspects the given UUID and returns its version (see [RFC 4122](#)).

Examples

```
julia> uuid_version(uuid4())  
4
```

Chapter 101

Unicode

Unicode.julia_chartransform - Function.

```
Unicode.julia_chartransform(c::Union{Char,Integer})
```

Map the Unicode character (Char) or codepoint (Integer) *c* to the corresponding "equivalent" character or codepoint, respectively, according to the custom equivalence used within the Julia parser (in addition to NFC normalization).

For example, 'μ' (U+00B5 micro) is treated as equivalent to 'µ' (U+03BC mu) by Julia's parser, so `julia_chartransform` performs this transformation while leaving other characters unchanged:

```
julia> Unicode.julia_chartransform('μ')
'μ': Unicode U+03BC (category Ll: Letter, lowercase)

julia> Unicode.julia_chartransform('x')
'x': ASCII/Unicode U+0078 (category Ll: Letter, lowercase)
```

`julia_chartransform` is mainly useful for passing to the `Unicode.normalize` function in order to mimic the normalization used by the Julia parser:

```
julia> s = "μö "
"μö "

julia> s2 = Unicode.normalize(s, compose=true, stable=true,
↪ chartransform=Unicode.julia_chartransform)
"μö "

julia> collect(s2)
2-element Vector{Char}:
 'μ': Unicode U+03BC (category Ll: Letter, lowercase)
 'ö': Unicode U+00F6 (category Ll: Letter, lowercase)

julia> s2 == string(Meta.parse(s))
true
```

Julia 1.8

This function was introduced in Julia 1.8.

Unicode.isassigned – Function.

```
Unicode.isassigned(c) -> Bool
```

Return true if the given char or integer is an assigned Unicode code point.

Examples

```
julia> Unicode.isassigned(101)
true

julia> Unicode.isassigned('\x01')
true
```

Unicode.isequal_normalized – Function.

```
isequal_normalized(s1::AbstractString, s2::AbstractString; casefold=false, stripmark=false,
↳ chartransform=identity)
```

Return whether s1 and s2 are canonically equivalent Unicode strings. If casefold=true, ignores case (performs Unicode case-folding); if stripmark=true, strips diacritical marks and other combining characters.

As with [Unicode.normalize](#), you can also pass an arbitrary function via the chartransform keyword (mapping Integer codepoints to codepoints) to perform custom normalizations, such as [Unicode.julia_chartransform](#).

Julia 1.8

The isequal_normalized function was added in Julia 1.8.

Examples

For example, the string "noël" can be constructed in two canonically equivalent ways in Unicode, depending on whether "ë" is formed from a single codepoint U+00EB or from the ASCII character 'e' followed by the U+0308 combining-diaeresis character.

```
julia> s1 = "noël"
"noël"

julia> s2 = "noë l"
"noë l"

julia> s1 == s2
false

julia> isequal_normalized(s1, s2)
true

julia> isequal_normalized(s1, "noel", stripmark=true)
true

julia> isequal_normalized(s1, "NOËL", casefold=true)
true
```

Unicode.normalize – Function.

```
Unicode.normalize(s::AbstractString; keywords...)
Unicode.normalize(s::AbstractString, normalform::Symbol)
```

Normalize the string `s`. By default, canonical composition (`compose=true`) is performed without ensuring Unicode versioning stability (`compat=false`), which produces the shortest possible equivalent string but may introduce composition characters not present in earlier Unicode versions.

Alternatively, one of the four "normal forms" of the Unicode standard can be specified: `normalform` can be `:NFC`, `:NFD`, `:NFKC`, or `:NFKD`. Normal forms C (canonical composition) and D (canonical decomposition) convert different visually identical representations of the same abstract string into a single canonical form, with form C being more compact. Normal forms KC and KD additionally canonicalize "compatibility equivalents": they convert characters that are abstractly similar but visually distinct into a single canonical choice (e.g. they expand ligatures into the individual characters), with form KC being more compact.

Alternatively, finer control and additional transformations may be obtained by calling `Unicode.normalize(s; keywords...)`, where any number of the following boolean keywords options (which all default to `false` except for `compose`) are specified:

- `compose=false`: do not perform canonical composition
- `decompose=true`: do canonical decomposition instead of canonical composition (`compose=true` is ignored if present)
- `compat=true`: compatibility equivalents are canonicalized
- `casefold=true`: perform Unicode case folding, e.g. for case-insensitive string comparison
- `newline2lf=true`, `newline2ls=true`, or `newline2ps=true`: convert various newline sequences (LF, CRLF, CR, NEL) into a linefeed (LF), line-separation (LS), or paragraph-separation (PS) character, respectively
- `stripmark=true`: strip diacritical marks (e.g. accents)
- `stripignore=true`: strip Unicode's "default ignorable" characters (e.g. the soft hyphen or the left-to-right marker)
- `stripccc=true`: strip control characters; horizontal tabs and form feeds are converted to spaces; newlines are also converted to spaces unless a newline-conversion flag was specified
- `rejectna=true`: throw an error if unassigned code points are found
- `stable=true`: enforce Unicode versioning stability (never introduce characters missing from earlier Unicode versions)

You can also use the `chartransform` keyword (which defaults to `identity`) to pass an arbitrary function mapping Integer codepoints to codepoints, which is called on each character in `s` as it is processed, in order to perform arbitrary additional normalizations. For example, by passing `chartransform=Unicode.julia_chartransform` you can apply a few Julia-specific character normalizations that are performed by Julia when parsing identifiers (in addition to NFC normalization: `compose=true`, `stable=true`).

For example, NFKC corresponds to the options `compose=true`, `compat=true`, `stable=true`.

Examples

```
julia> "é" == Unicode.normalize("é") #LHS: Unicode U+00e9, RHS: U+0065 & U+0301
true
```

```
julia> "μ" == Unicode.normalize("μ", compat=true) #LHS: Unicode U+03bc, RHS: Unicode U+00b5
true

julia> Unicode.normalize("JuLiA", casefold=true)
"julia"

julia> Unicode.normalize("JúLiA", stripmark=true)
"JuLiA"
```

Julia 1.8

The `chartransform` keyword argument requires Julia 1.8.

Unicode.graphemes – Function.

```
| graphemes(s::AbstractString) -> GraphemeIterator
```

Return an iterator over substrings of `s` that correspond to the extended graphemes in the string, as defined by Unicode UAX #29. (Roughly, these are what users would perceive as single characters, even though they may contain more than one codepoint; for example a letter combined with an accent mark is a single grapheme.)

```
| graphemes(s::AbstractString, m:n) -> SubString
```

Returns a [SubString](#) of `s` consisting of the `m`-th through `n`-th graphemes of the string `s`, where the second argument `m:n` is an integer-valued [AbstractUnitRange](#).

Loosely speaking, this corresponds to the `m:n`-th user-perceived "characters" in the string. For example:

```
julia> s = graphemes("exposé ", 3:6)
"posé "

julia> collect(s)
5-element Vector{Char}:
 'p': ASCII/Unicode U+0070 (category Ll: Letter, lowercase)
 'o': ASCII/Unicode U+006F (category Ll: Letter, lowercase)
 's': ASCII/Unicode U+0073 (category Ll: Letter, lowercase)
 'e': ASCII/Unicode U+0065 (category Ll: Letter, lowercase)
 ' ': Unicode U+0301 (category Mn: Mark, nonspacing)
```

This consists of the 3rd to 7th codepoints ([Chars](#)) in "exposé ", because the grapheme "é " is actually two Unicode codepoints (an 'e' followed by an acute-accent combining character U+0301).

Because finding grapheme boundaries requires iteration over the string contents, the `graphemes(s, m:n)` function requires time proportional to the length of the string (number of codepoints) before the end of the substring.

Julia 1.9

The `m:n` argument of `graphemes` requires Julia 1.9.

Part IV

Developer Documentation

Chapter 102

Documentation of Julia's Internals

102.1 Initialization of the Julia runtime

How does the Julia runtime execute `julia -e 'println("Hello World!")'`?

`main()`

Execution starts at `main()` in `cli/loader_exe.c`, which calls `jl_load_repl()` in `cli/loader_lib.c` which loads a few libraries, eventually calling `jl_repl_entrypoint()` in `src/jlapi.c`.

`jl_repl_entrypoint()` calls `libsupport_init()` to set the C library locale and to initialize the "ios" library (see `ios_init_stdstreams()` and [Legacy ios.c library](#)).

Next `jl_parse_opts()` is called to process command line options. Note that `jl_parse_opts()` only deals with options that affect code generation or early initialization. Other options are handled later by `exec_options()` in `base/client.jl`.

`jl_parse_opts()` stores command line options in the [global `jl_options` struct](#).

`julia_init()`

`julia_init()` in `init.c` is called by `main()` and calls `_julia_init()` in `init.c`.

`_julia_init()` begins by calling `libsupport_init()` again (it does nothing the second time).

`restore_signals()` is called to zero the signal handler mask.

`jl_resolve_sysimg_location()` searches configured paths for the base system image. See [Building the Julia system image](#).

`jl_gc_init()` sets up allocation pools and lists for weak refs, preserved values and finalization.

`jl_init_frontend()` loads and initializes a pre-compiled femtolisp image containing the scanner/parser.

`jl_init_types()` creates `jl_datatype_t` type description objects for the [built-in types defined in `julia.h`](#). e.g.

```
jl_any_type = jl_new_abstracttype(jl_symbol("Any"), core, NULL, jl_emptyvec);
jl_any_type->super = jl_any_type;

jl_type_type = jl_new_abstracttype(jl_symbol("Type"), core, jl_any_type, jl_emptyvec);
```

```
jl_int32_type = jl_new_primitivetype(jl_symbol("Int32"), core,
                                     jl_any_type, jl_emptyvec, 32);
```

`jl_init_tasks()` creates the `jl_datatype_t*` `jl_task_type` object; initializes the global `jl_root_task` struct; and sets `jl_current_task` to the root task.

`jl_init_codegen()` initializes the LLVM library.

`jl_init_serializer()` initializes 8-bit serialization tags for builtin `jl_value_t` values.

If there is no sysimg file (`!jl_options.image_file`) then the Core and Main modules are created and `boot.jl` is evaluated:

`jl_core_module = jl_new_module(jl_symbol("Core"))` creates the Julia Core module.

`jl_init_intrinsic_functions()` creates a new Julia module `Intrinsics` containing constant `jl_intrinsic_type` symbols. These define an integer code for each `intrinsic function`. `emit_intrinsic()` translates these symbols into LLVM instructions during code generation.

`jl_init_primitives()` hooks C functions up to Julia function symbols. e.g. the symbol `Core.:(==)()` is bound to C function pointer `jl_f_is()` by calling `add_builtin_func("==", jl_f_is)`.

`jl_new_main_module()` creates the global "Main" module and sets `jl_current_task->current_module = jl_main_module`.

Note: `_julia_init()` then sets `jl_root_task->current_module = jl_core_module`. `jl_root_task` is an alias of `jl_current_task` at this point, so the `current_module` set by `jl_new_main_module()` above is overwritten.

`jl_load("boot.jl", sizeof("boot.jl"))` calls `jl_parse_eval_all` which repeatedly calls `jl_toplevel_eval_flex()` to execute `boot.jl`. <!-- TODO - drill down into eval? -->

`jl_get_builtin_hooks()` initializes global C pointers to Julia globals defined in `boot.jl`.

`jl_init_box_caches()` pre-allocates global boxed integer value objects for values up to 1024. This speeds up allocation of boxed ints later on. e.g.:

```
jl_value_t *jl_box_uint8(uint8_t x)
{
    return boxed_uint8_cache[(uint8_t)x];
}
```

`_julia_init()` iterates over the `jl_core_module->bindings.table` looking for `jl_datatype_t` values and sets the type name's module prefix to `jl_core_module`.

`jl_add_standard_imports(jl_main_module)` does "using Base" in the "Main" module.

Note: `_julia_init()` now reverts to `jl_root_task->current_module = jl_main_module` as it was before being set to `jl_core_module` above.

Platform specific signal handlers are initialized for SIGSEGV (OSX, Linux), and SIGFPE (Windows).

Other signals (SIGINFO, SIGBUS, SIGILL, SIGTERM, SIGABRT, SIGQUIT, SIGSYS and SIGPIPE) are hooked up to `sigdie_handler()` which prints a backtrace.

`jl_init_restored_module()` calls `jl_module_run_initializer()` for each deserialized module to run the `__init__()` function.

Finally `sigint_handler()` is hooked up to SIGINT and calls `jl_throw(jl_interrupt_exception)`.
`_julia_init()` then returns `back_to_main()` in `cli/loader_exe.c` and `main()` calls `repl_entrypoint(argc, (char**)argv)`.

sysimg

If there is a sysimg file, it contains a pre-cooked image of the Core and Main modules (and whatever else is created by `boot.jl`). See [Building the Julia system image](#).

`jl_restore_system_image()` deserializes the saved sysimg into the current Julia runtime environment and initialization continues after `jl_init_box_caches()` below...

Note: `jl_restore_system_image()` (and `staticdata.c` in general) uses the [Legacy ios.c library](#).

repl_entrypoint()

`repl_entrypoint()` loads the contents of `argv[]` into `Base.ARGS`.

If a `.jl "program"` file was supplied on the command line, then `exec_program()` calls `jl_load(program, len)` which calls `jl_parse_eval_all` which repeatedly calls `jl_toplevel_eval_flex()` to execute the program.

However, in our example (`julia -e 'println("Hello World!")'`), `jl_get_global(jl_base_module, jl_symbol("_start"))` looks up `Base._start` and `jl_apply()` executes it.

Base._start

`Base._start` calls `Base.exec_options` which calls `jl_parse_input_line("println(\"Hello World!\")")` to create an expression object and `Core.eval(Main, ex)` to execute the parsed expression `ex` in the module context of `Main`.

Core.eval

`Core.eval(Main, ex)` calls `jl_toplevel_eval_in(m, ex)`, which calls `jl_toplevel_eval_flex`. `jl_toplevel_eval_flex` implements a simple heuristic to decide whether to compile a given code thunk or run it by interpreter. When given `println("Hello World!")`, it would usually decide to run the code by interpreter, in which case it calls `jl_interpret_toplevel_thunk`, which then calls `eval_body`.

The stack dump below shows how the interpreter works its way through various methods of `Base.println()` and `Base.print()` before arriving at `write(s::IO, a::Array{T})` where `T` which does `ccall(jl_uv_write())`.

`jl_uv_write()` calls `uv_write()` to write "Hello World!" to `JL_STDOUT`. See [Libuv wrappers for stdio](#):

```
| Hello World!
```

Since our example has just one function call, which has done its job of printing "Hello World!", the stack now rapidly unwinds back to `main()`.

jl_atexit_hook()

`main()` calls `jl_atexit_hook()`. This calls `Base._atexit`, then calls `jl_gc_run_all_finalizers()` and cleans up libuv handles.

| Stack frame | Source code | Notes |
|-----------------------------|---------------|---|
| jl_uv_write() | jl_uv.c | called though <code>ccall</code> |
| julia_write_282942 | stream.jl | function <code>write!(s::IO, a::Array{T})</code> where <code>T</code> |
| julia_print_284639 | ascii.jl | <code>print(io::IO, s::String) = (write(io, s); nothing)</code> |
| jlcall_print_284639 | | |
| jl_apply() | julia.h | |
| jl_trampoline() | builtins.c | |
| jl_apply() | julia.h | |
| jl_apply_generic() | gf.c | <code>Base.print(Base.TTY, String)</code> |
| jl_apply() | julia.h | |
| jl_trampoline() | builtins.c | |
| jl_apply() | julia.h | |
| jl_apply_generic() | gf.c | <code>Base.print(Base.TTY, String, Char, Char...)</code> |
| jl_apply() | julia.h | |
| jl_f_apply() | builtins.c | |
| jl_apply() | julia.h | |
| jl_trampoline() | builtins.c | |
| jl_apply() | julia.h | |
| jl_apply_generic() | gf.c | <code>Base.println(Base.TTY, String, String...)</code> |
| jl_apply() | julia.h | |
| jl_trampoline() | builtins.c | |
| jl_apply() | julia.h | |
| jl_apply_generic() | gf.c | <code>Base.println(String,)</code> |
| jl_apply() | julia.h | |
| do_call() | interpreter.c | |
| eval_body() | interpreter.c | |
| jl_interpret_toplevel_thunk | interpreter.c | |
| jl_toplevel_eval_flex | toplevel.c | |
| jl_toplevel_eval_in | toplevel.c | |
| Core.eval | boot.jl | |

jl_save()

Finally, `main()` calls `jl_save()`, which if requested on the command line, saves the runtime state to a new system image. See `jl_compile_all()` and `jl_save_system_image()`.

102.2 Julia ASTs

Julia has two representations of code. First there is a surface syntax AST returned by the parser (e.g. the `Meta.parse` function), and manipulated by macros. It is a structured representation of code as it is written, constructed by `julia-parser.scm` from a character stream. Next there is a lowered form, or IR (intermediate representation), which is used by type inference and code generation. In the lowered form there are fewer types of nodes, all macros are expanded, and all control flow is converted to explicit branches and sequences of statements. The lowered form is constructed by `julia-syntax.scm`.

First we will focus on the AST, since it is needed to write macros.

Surface syntax AST

Front end ASTs consist almost entirely of [Exprs](#) and atoms (e.g. symbols, numbers). There is generally a different expression head for each visually distinct syntactic form. Examples will be given in s-expression syntax. Each parenthesized list corresponds to an Expr, where the first element is the head. For example (call f x) corresponds to Expr(:call, :f, :x) in Julia.

Calls

| Input | AST |
|----------------|----------------------------------|
| f(x) | (call f x) |
| f(x, y=1, z=2) | (call f x (kw y 1) (kw z 2)) |
| f(x; y=1) | (call f (parameters (kw y 1)) x) |
| f(x...) | (call f (... x)) |

do syntax:

```
f(x) do a,b
    body
end
```

parses as (do (call f x) (-> (tuple a b) (block body))).

Operators

Most uses of operators are just function calls, so they are parsed with the head call. However some operators are special forms (not necessarily function calls), and in those cases the operator itself is the expression head. In julia-parser.scm these are referred to as "syntactic operators". Some operators (+ and *) use N-ary parsing; chained calls are parsed as a single N-argument call. Finally, chains of comparisons have their own special expression structure.

| Input | AST |
|-----------|-------------------------|
| x+y | (call + x y) |
| a+b+c+d | (call + a b c d) |
| 2x | (call * 2 x) |
| a&&b | (&& a b) |
| x += 1 | (+= x 1) |
| a ? 1 : 2 | (if a 1 2) |
| a,b | (tuple a b) |
| a==b | (call == a b) |
| 1<i<=n | (comparison 1 < i <= n) |
| a.b | (. a (quote b)) |
| a.(b) | (. a (tuple b)) |

Bracketed forms

Macros

Strings

Doc string syntax:

| Input | AST |
|-------------------------------------|--|
| <code>a[i]</code> | <code>(ref a i)</code> |
| <code>t[i;j]</code> | <code>(typed_vcat t i j)</code> |
| <code>t[i j]</code> | <code>(typed_hcat t i j)</code> |
| <code>t[a b; c d]</code> | <code>(typed_vcat t (row a b) (row c d))</code> |
| <code>t[a b;;; c d]</code> | <code>(typed_ncat t 3 (row a b) (row c d))</code> |
| <code>a{b}</code> | <code>(curly a b)</code> |
| <code>a{b;c}</code> | <code>(curly a (parameters c) b)</code> |
| <code>[x]</code> | <code>(vect x)</code> |
| <code>[x,y]</code> | <code>(vect x y)</code> |
| <code>[x;y]</code> | <code>(vcat x y)</code> |
| <code>[x y]</code> | <code>(hcat x y)</code> |
| <code>[x y; z t]</code> | <code>(vcat (row x y) (row z t))</code> |
| <code>[x;y;; z;t;;;]</code> | <code>(ncat 3 (nrow 2 (nrow 1 x y) (nrow 1 z t)))</code> |
| <code>[x for y in z, a in b]</code> | <code>(comprehension (generator x (= y z) (= a b)))</code> |
| <code>T[x for y in z]</code> | <code>(typed_comprehension T (generator x (= y z)))</code> |
| <code>(a, b, c)</code> | <code>(tuple a b c)</code> |
| <code>(a; b; c)</code> | <code>(block a b c)</code> |

| Input | AST |
|--------------------------|---|
| <code>@m x y</code> | <code>(macrocall @m (line) x y)</code> |
| <code>Base.@m x y</code> | <code>(macrocall (. Base (quote @m)) (line) x y)</code> |
| <code>@Base.m x y</code> | <code>(macrocall (. Base (quote @m)) (line) x y)</code> |

| Input | AST |
|------------------------|--|
| <code>"a"</code> | <code>"a"</code> |
| <code>x"y"</code> | <code>(macrocall @x_str (line) "y")</code> |
| <code>x"y"z</code> | <code>(macrocall @x_str (line) "y" "z")</code> |
| <code>"x = \$x"</code> | <code>(string "x = " x)</code> |
| <code>`a b c`</code> | <code>(macrocall @cmd (line) "a b c")</code> |

```
"some docs"
f(x) = x
```

parses as `(macrocall (|. Core '@doc) (line) "some docs" (= (call f x) (block x)))`.

Imports and such

| Input | AST |
|--------------------------------|--|
| <code>import a</code> | <code>(import (. a))</code> |
| <code>import a.b.c</code> | <code>(import (. a b c))</code> |
| <code>import ...a</code> | <code>(import (. . . . a))</code> |
| <code>import a.b, c.d</code> | <code>(import (. a b) (. c d))</code> |
| <code>import Base: x</code> | <code>(import (: (. Base) (. x)))</code> |
| <code>import Base: x, y</code> | <code>(import (: (. Base) (. x) (. y)))</code> |
| <code>export a, b</code> | <code>(export a b)</code> |

using has the same representation as import, but with expression head :using instead of :import.

Numbers

Julia supports more number types than many scheme implementations, so not all numbers are represented directly as scheme numbers in the AST.

| Input | AST |
|-----------------------|--|
| 11111111111111111111 | (macrocall @int128_str nothing "11111111111111111111") |
| 0xfffffffffffffffffff | (macrocall @uint128_str nothing "0xfffffffffffffffffff") |
| 1111...many digits... | (macrocall @big_str nothing "1111...") |

Block forms

A block of statements is parsed as (block stmt1 stmt2 ...).

If statement:

```

if a
  b
elseif c
  d
else
  e
end

```

parses as:

```

(if a (block (line 2) b)
    (elseif (block (line 3) c) (block (line 4) d)
            (block (line 6) e)))

```

A while loop parses as (while condition body).

A for loop parses as (for (= var iter) body). If there is more than one iteration specification, they are parsed as a block: (for (block (= v1 iter1) (= v2 iter2)) body).

break and continue are parsed as 0-argument expressions (break) and (continue).

let is parsed as (let (= var val) body) or (let (block (= var1 val1) (= var2 val2) ...) body), like for loops.

A basic function definition is parsed as (function (call f x) body). A more complex example:

```

function f(x::T; k = 1) where T
  return x+1
end

```

parses as:

```

(function (where (call f (parameters (kw k 1))
                                (:: x T))
          T)
  (block (line 2) (return (call + x 1))))

```

Type definition:

```
mutable struct Foo{T<:S}
    x::T
end
```

parses as:

```
(struct true (curly Foo (<: T S))
  (block (line 2) (: x T)))
```

The first argument is a boolean telling whether the type is mutable.

try blocks parse as (try try_block var catch_block finally_block). If no variable is present after catch, var is #f. If there is no finally clause, then the last argument is not present.

Quote expressions

Julia source syntax forms for code quoting (quote and `: ()`) support interpolation with `$`. In Lisp terminology, this means they are actually "backquote" or "quasiquote" forms. Internally, there is also a need for code quoting without interpolation. In Julia's scheme code, non-interpolating quote is represented with the expression head `inert`.

`inert` expressions are converted to Julia `QuoteNode` objects. These objects wrap a single value of any type, and when evaluated simply return that value.

A quote expression whose argument is an atom also gets converted to a `QuoteNode`.

Line numbers

Source location information is represented as `(line line_num file_name)` where the third component is optional (and omitted when the current line number, but not file name, changes).

These expressions are represented as `LineNumberNodes` in Julia.

Macros

Macro hygiene is represented through the expression head pair `escape` and `hygienic-scope`. The result of a macro expansion is automatically wrapped in `(hygienic-scope block module)`, to represent the result of the new scope. The user can insert `(escape block)` inside to interpolate code from the caller.

Lowered form

Lowered form (IR) is more important to the compiler, since it is used for type inference, optimizations like inlining, and code generation. It is also less obvious to the human, since it results from a significant rearrangement of the input syntax.

In addition to `Symbols` and some number types, the following data types exist in lowered form:

- `Expr`

Has a node type indicated by the head field, and an `args` field which is a `Vector{Any}` of subexpressions. While almost every part of a surface AST is represented by an `Expr`, the IR uses only a limited number of `Exprs`, mostly for calls and some top-level-only forms.

- `SlotNumber`

Identifies arguments and local variables by consecutive numbering. It has an integer-valued `id` field giving the slot index. The types of these slots can be found in the `slottypes` field of their `CodeInfo` object. When a slot has different types at different uses and thus requires per-use type annotations, they are converted to temporary `Core.Compiler.TypedSlot` object. This object has an additional `typ` field as well as the `id` field. Note that `Core.Compiler.TypedSlot` only appears in an unoptimized lowered form that is scheduled for optimization, and it never appears elsewhere.

- `Argument`

The same as `SlotNumber`, but appears only post-optimization. Indicates that the referenced slot is an argument of the enclosing function.

- `CodeInfo`

Wraps the IR of a group of statements. Its `code` field is an array of expressions to execute.

- `GotoNode`

Unconditional branch. The argument is the branch target, represented as an index in the code array to jump to.

- `GotoIfNot`

Conditional branch. If the `cond` field evaluates to false, goes to the index identified by the `dest` field.

- `ReturnNode`

Returns its argument (the `val` field) as the value of the enclosing function. If the `val` field is undefined, then this represents an unreachable statement.

- `QuoteNode`

Wraps an arbitrary value to reference as data. For example, the function `f() = :a` contains a `QuoteNode` whose `value` field is the symbol `a`, in order to return the symbol itself instead of evaluating it.

- `GlobalRef`

Refers to global variable name in module `mod`.

- `SSAValue`

Refers to a consecutively-numbered (starting at 1) static single assignment (SSA) variable inserted by the compiler. The number (`id`) of an `SSAValue` is the code array index of the expression whose value it represents.

- `NewvarNode`

Marks a point where a variable (slot) is created. This has the effect of resetting a variable to undefined.

Expr types

These symbols appear in the head field of [Exprs](#) in lowered form.

- `call`

Function call (dynamic dispatch). `args[1]` is the function to call, `args[2:end]` are the arguments.

- `invoke`

Function call (static dispatch). `args[1]` is the `MethodInstance` to call, `args[2:end]` are the arguments (including the function that is being called, at `args[2]`).

- `static_parameter`

Reference a static parameter by index.

- `=`

Assignment. In the IR, the first argument is always a `SlotNumber` or a `GlobalRef`.

- `method`

Adds a method to a generic function and assigns the result if necessary.

Has a 1-argument form and a 3-argument form. The 1-argument form arises from the syntax function `foo end`. In the 1-argument form, the argument is a symbol. If this symbol already names a function in the current scope, nothing happens. If the symbol is undefined, a new function is created and assigned to the identifier specified by the symbol. If the symbol is defined but names a non-function, an error is raised. The definition of "names a function" is that the binding is constant, and refers to an object of singleton type. The rationale for this is that an instance of a singleton type uniquely identifies the type to add the method to. When the type has fields, it wouldn't be clear whether the method was being added to the instance or its type.

The 3-argument form has the following arguments:

- `args[1]`

A function name, or nothing if unknown or unneeded. If a symbol, then the expression first behaves like the 1-argument form above. This argument is ignored from then on. It can be nothing when methods are added strictly by type, $(::T)(x) = x$, or when a method is being added to an existing function, `MyModule.f(x) = x`.

- `args[2]`

A `SimpleVector` of argument type data. `args[2][1]` is a `SimpleVector` of the argument types, and `args[2][2]` is a `SimpleVector` of type variables corresponding to the method's static parameters.

- `args[3]`

A `CodeInfo` of the method itself. For "out of scope" method definitions (adding a method to a function that also has methods defined in different scopes) this is an expression that evaluates to a `:lambda` expression.

- `struct_type`

A 7-argument expression that defines a new struct:

- `args[1]`

The name of the struct

- `args[2]`

A call expression that creates a `SimpleVector` specifying its parameters

- `args[3]`

A call expression that creates a `SimpleVector` specifying its fieldnames

- `args[4]`
A `Symbol`, `GlobalRef`, or `Expr` specifying the supertype (e.g., `:Integer`, `GlobalRef(Core, :Any)`, or `:(Core.apply_type(AbstractArray, T, N))`)
 - `args[5]`
A call expression that creates a `SimpleVector` specifying its fieldtypes
 - `args[6]`
A `Bool`, true if mutable
 - `args[7]`
The number of arguments to initialize. This will be the number of fields, or the minimum number of fields called by an inner constructor's `new` statement.
- `abstract_type`
A 3-argument expression that defines a new abstract type. The arguments are the same as arguments 1, 2, and 4 of `struct_type` expressions.
 - `primitive_type`
A 4-argument expression that defines a new primitive type. Arguments 1, 2, and 4 are the same as `struct_type`. Argument 3 is the number of bits.
- Julia 1.5**
`struct_type`, `abstract_type`, and `primitive_type` were removed in Julia 1.5 and replaced by calls to new builtins.
- `global`
Declares a global binding.
 - `const`
Declares a (global) variable as constant.
 - `new`
Allocates a new struct-like object. First argument is the type. The `new` pseudo-function is lowered to this, and the type is always inserted by the compiler. This is very much an internal-only feature, and does no checking. Evaluating arbitrary `new` expressions can easily segfault.
 - `splatnew`
Similar to `new`, except field values are passed as a single tuple. Works similarly to `splat(new)` if `new` were a first-class function, hence the name.
 - `isdefined`
`Expr(:isdefined, :x)` returns a `Bool` indicating whether `x` has already been defined in the current scope.
 - `the_exception`
Yields the caught exception inside a `catch` block, as returned by `jl_current_exception()`.
 - `enter`
Enters an exception handler (`setjmp`). `args[1]` is the label of the `catch` block to jump to on error. Yields a token which is consumed by `pop_exception`.

- `leave`
Pop exception handlers. `args[1]` is the number of handlers to pop.
- `pop_exception`
Pop the stack of current exceptions back to the state at the associated enter when leaving a catch block. `args[1]` contains the token from the associated enter.

Julia 1.1

`pop_exception` is new in Julia 1.1.

- `inbounds`
Controls turning bounds checks on or off. A stack is maintained; if the first argument of this expression is true or false (true means bounds checks are disabled), it is pushed onto the stack. If the first argument is `:pop`, the stack is popped.
- `boundscheck`
Has the value `false` if inlined into a section of code marked with `@inbounds`, otherwise has the value `true`.
- `loopinfo`
Marks the end of the a loop. Contains metadata that is passed to `LowerSimdLoop` to either mark the inner loop of `@simd` expression, or to propagate information to LLVM loop passes.
- `copyast`
Part of the implementation of quasi-quote. The argument is a surface syntax AST that is simply copied recursively and returned at run time.
- `meta`
Metadata. `args[1]` is typically a symbol specifying the kind of metadata, and the rest of the arguments are free-form. The following kinds of metadata are commonly used:
 - `:inline` and `:noinline`: Inlining hints.
- `foreigncall`
Statically-computed container for `ccall` information. The fields are:
 - `args[1] : name`
The expression that'll be parsed for the foreign function.
 - `args[2]::Type : RT`
The (literal) return type, computed statically when the containing method was defined.
 - `args[3]::SimpleVector{of Types} : AT`
The (literal) vector of argument types, computed statically when the containing method was defined.
 - `args[4]::Int : nreq`
The number of required arguments for a varargs function definition.
 - `args[5]::QuoteNode{Symbol} : calling convention`
The calling convention for the call.

- `args[6:5+length(args[3])]` : arguments
The values for all the arguments (with types of each given in `args[3]`).
- `args[6+length(args[3])+1:end]` : gc-roots
The additional objects that may need to be gc-rooted for the duration of the call. See [Working with LLVM](#) for where these are derived from and how they get handled.

- `new_opaque_closure`

Constructs a new opaque closure. The fields are:

- `args[1]` : signature
The function signature of the opaque closure. Opaque closures don't participate in dispatch, but the input types can be restricted.
- `args[2]` : `isva`
Indicates whether the closure accepts varargs.
- `args[3]` : `lb`
Lower bound on the output type. (Defaults to `Union{}`)
- `args[4]` : `ub`
Upper bound on the output type. (Defaults to `Any`)
- `args[5]` : `method`
The actual method as an `opaque_closure_method` expression.
- `args[6:end]` : `captures`
The values captured by the opaque closure.

Julia 1.7

Opaque closures were added in Julia 1.7

Method

A unique'd container describing the shared metadata for a single method.

- `name, module, file, line, sig`
Metadata to uniquely identify the method for the computer and the human.
- `ambig`
Cache of other methods that may be ambiguous with this one.
- `specializations`
Cache of all `MethodInstance` ever created for this `Method`, used to ensure uniqueness. Uniqueness is required for efficiency, especially for incremental precompile and tracking of method invalidation.
- `source`
The original source code (if available, usually compressed).
- `generator`
A callable object which can be executed to get specialized source for a specific method signature.

- `roots`
Pointers to non-AST things that have been interpolated into the AST, required by compression of the AST, type-inference, or the generation of native code.
- `nargs`, `isva`, `called`, `is_for_opaque_closure`,
Descriptive bit-fields for the source code of this Method.
- `primary_world`
The world age that "owns" this Method.

MethodInstance

A unique'd container describing a single callable signature for a Method. See especially [Proper maintenance and care of multi-threading locks](#) for important details on how to modify these fields safely.

- `specTypes`
The primary key for this MethodInstance. Uniqueness is guaranteed through a `def.specializations` lookup.
- `def`
The Method that this function describes a specialization of. Or a Module, if this is a top-level Lambda expanded in Module, and which is not part of a Method.
- `sparam_vals`
The values of the static parameters in `specTypes` indexed by `def.sparam_syms`. For the MethodInstance at `Method.unspecialized`, this is the empty SimpleVector. But for a runtime MethodInstance from the MethodTable cache, this will always be defined and indexable.
- `uninferred`
The uncompressed source code for a toplevel thunk. Additionally, for a generated function, this is one of many places that the source code might be found.
- `backedges`
We store the reverse-list of cache dependencies for efficient tracking of incremental reanalysis/re-compilation work that may be needed after a new method definitions. This works by keeping a list of the other MethodInstance that have been inferred or optimized to contain a possible call to this MethodInstance. Those optimization results might be stored somewhere in the cache, or it might have been the result of something we didn't want to cache, such as constant propagation. Thus we merge all of those backedges to various cache entries here (there's almost always only the one applicable cache entry with a sentinel value for `max_world` anyways).
- `cache`
Cache of CodeInstance objects that share this template instantiation.

CodeInstance

- **def**
The MethodInstance that this cache entry is derived from.
- **rettype/rettype_const**
The inferred return type for the `specFunctionObject` field, which (in most cases) is also the computed return type for the function in general.
- **inferred**
May contain a cache of the inferred source for this function, or it could be set to `nothing` to just indicate `rettype` is inferred.
- **ftpr**
The generic `jllcall` entry point.
- **jllcall_api**
The ABI to use when calling `ftpr`. Some significant ones include:
 - 0 - Not compiled yet
 - 1 - `JL_CALLABLE jl_value_t (*)(jl_function_t *f, jl_value_t *args[nargs], uint32_t nargs)`
 - 2 - Constant (value stored in `rettype_const`)
 - 3 - With Static-parameters forwarded `jl_value_t (*)(jl_svec_t *sparams, jl_function_t *f, jl_value_t *args[nargs], uint32_t nargs)`
 - 4 - Run in interpreter `jl_value_t (*)(jl_method_instance_t *meth, jl_function_t *f, jl_value_t *args[nargs], uint32_t nargs)`
- **min_world / max_world**
The range of world ages for which this method instance is valid to be called. If `max_world` is the special token value `-1`, the value is not yet known. It may continue to be used until we encounter a backedge that requires us to reconsider.

CodeInfo

A (usually temporary) container for holding lowered source code.

- **code**
An Any array of statements
- **slotnames**
An array of symbols giving names for each slot (argument or local variable).
- **slotflags**
A `UInt8` array of slot properties, represented as bit flags:
 - `0x02` - assigned (only false if there are no assignment statements with this var on the left)

- 0x08 - used (if there is any read or write of the slot)
- 0x10 - statically assigned once
- 0x20 - might be used before assigned. This flag is only valid after type inference.

- `ssavaluetypes`

Either an array or an Int.

If an Int, it gives the number of compiler-inserted temporary locations in the function (the length of code array). If an array, specifies a type for each location.

- `ssaflags`

Statement-level flags for each expression in the function. Many of these are reserved, but not yet implemented:

- $0x01 \ll 0$ = statement is marked as `@inbounds`
- $0x01 \ll 1$ = statement is marked as `@inline`
- $0x01 \ll 2$ = statement is marked as `@noinline`
- $0x01 \ll 3$ = statement is within a block that leads to throw call
- $0x01 \ll 4$ = statement may be removed if its result is unused, in particular it is thus be both pure and effect free
- $0x01 \ll 5-6$ = `<unused>`
- $0x01 \ll 7$ = `<reserved>` has out-of-band info

- `linetable`

An array of source location objects

- `codelocs`

An array of integer indices into the `linetable`, giving the location associated with each statement.

Optional Fields:

- `slottypes`

An array of types for the slots.

- `rettype`

The inferred return type of the lowered form (IR). Default value is Any.

- `method_for_inference_limit_heuristics`

The `method_for_inference_heuristics` will expand the given method's generator if necessary during inference.

- `parent`

The `MethodInstance` that "owns" this object (if applicable).

- `edges`

Forward edges to method instances that must be invalidated.

- `min_world/max_world`

The range of world ages for which this code was valid at the time when it had been inferred.

Boolean properties:

- `inferred`

Whether this has been produced by type inference.

- `inlineable`

Whether this should be eligible for inlining.

- `propagate_inbounds`

Whether this should propagate `@inbounds` when inlined for the purpose of eliding `@boundscheck` blocks.

UInt8 settings:

- `constprop`

- 0 = use heuristic

- 1 = aggressive

- 2 = none

- `purity` Constructed from 5 bit flags:

- `0x01 << 0` = this method is guaranteed to return or terminate consistently (`:consistent`)

- `0x01 << 1` = this method is free from externally semantically visible side effects (`:effect_free`)

- `0x01 << 2` = this method is guaranteed to not throw an exception (`:nothrow`)

- `0x01 << 3` = this method is guaranteed to terminate (`:terminates_globally`)

- `0x01 << 4` = the syntactic control flow within this method is guaranteed to terminate (`:terminates_locally`)

See the documentation of `Base.@assume_effects` for more details.

102.3 More about types

If you've used Julia for a while, you understand the fundamental role that types play. Here we try to get under the hood, focusing particularly on [Parametric Types](#).

Types and sets (and Any and Union{}/Bottom)

It's perhaps easiest to conceive of Julia's type system in terms of sets. While programs manipulate individual values, a type refers to a set of values. This is not the same thing as a collection; for example a [Set](#) of values is itself a single Set value. Rather, a type describes a set of possible values, expressing uncertainty about which value we have.

A concrete type *T* describes the set of values whose direct tag, as returned by the [typeof](#) function, is *T*. An abstract type describes some possibly-larger set of values.

[Any](#) describes the entire universe of possible values. [Integer](#) is a subset of Any that includes [Int](#), [Int8](#), and other concrete types. Internally, Julia also makes heavy use of another type known as Bottom, which can also be written as [Union{}](#). This corresponds to the empty set.

Julia's types support the standard operations of set theory: you can ask whether *T1* is a "subset" (subtype) of *T2* with *T1* <: *T2*. Likewise, you intersect two types using [typeintersect](#), take their union with [Union](#), and compute a type that contains their union with [typejoin](#):

```
julia> typeintersect(Int, Float64)
Union{}

julia> Union{Int, Float64}
Union{Float64, Int64}

julia> typejoin(Int, Float64)
Real

julia> typeintersect(Signed, Union{UInt8, Int8})
Int8

julia> Union{Signed, Union{UInt8, Int8}}
Union{UInt8, Signed}

julia> typejoin(Signed, Union{UInt8, Int8})
Integer

julia> typeintersect(Tuple{Integer, Float64}, Tuple{Int, Real})
Tuple{Int64, Float64}

julia> Union{Tuple{Integer, Float64}, Tuple{Int, Real}}
Union{Tuple{Int64, Real}, Tuple{Integer, Float64}}

julia> typejoin(Tuple{Integer, Float64}, Tuple{Int, Real})
Tuple{Integer, Real}
```

While these operations may seem abstract, they lie at the heart of Julia. For example, method dispatch is implemented by stepping through the items in a method list until reaching one for which the type of the argument tuple is a subtype of the method signature. For this algorithm to work, it's important that methods be sorted by their specificity, and that the search begins with the most specific methods. Consequently, Julia also implements a partial order on types; this is achieved by functionality that is similar to <:, but with differences that will be discussed below.

UnionAll types

Julia's type system can also express an iterated union of types: a union of types over all values of some variable. This is needed to describe parametric types where the values of some parameters are not known.

For example, `Array` has two parameters as in `Array{Int, 2}`. If we did not know the element type, we could write `Array{T, 2}` where `T`, which is the union of `Array{T, 2}` for all values of `T`: `Union{Array{Int8, 2}, Array{Int16, 2}, ...}`.

Such a type is represented by a `UnionAll` object, which contains a variable (`T` in this example, of type `TypeVar`), and a wrapped type (`Array{T, 2}` in this example).

Consider the following methods:

```
f1(A::Array) = 1
f2(A::Array{Int}) = 2
f3(A::Array{T}) where {T<:Any} = 3
f4(A::Array{Any}) = 4
```

The signature - as described in [Function calls](#) - of `f3` is a `UnionAll` type wrapping a tuple type: `Tuple{typeof(f3), Array{T}}` where `T`. All but `f4` can be called with `a = [1, 2]`; all but `f2` can be called with `b = Any[1, 2]`.

Let's look at these types a little more closely:

```
julia> dump(Array)
UnionAll
  var: TypeVar
    name: Symbol T
    lb: Union{}
    ub: Any
  body: UnionAll
    var: TypeVar
      name: Symbol N
      lb: Union{}
      ub: Any
    body: Array{T, N} <: DenseArray{T, N}
```

This indicates that `Array` actually names a `UnionAll` type. There is one `UnionAll` type for each parameter, nested. The syntax `Array{Int, 2}` is equivalent to `Array{Int}{2}`; internally each `UnionAll` is instantiated with a particular variable value, one at a time, outermost-first. This gives a natural meaning to the omission of trailing type parameters; `Array{Int}` gives a type equivalent to `Array{Int, N}` where `N`.

A `TypeVar` is not itself a type, but rather should be considered part of the structure of a `UnionAll` type. Type variables have lower and upper bounds on their values (in the fields `lb` and `ub`). The symbol name is purely cosmetic. Internally, `TypeVars` are compared by address, so they are defined as mutable types to ensure that "different" type variables can be distinguished. However, by convention they should not be mutated.

One can construct `TypeVars` manually:

```
julia> TypeVar(:V, Signed, Real)
Signed<:V<:Real
```

There are convenience versions that allow you to omit any of these arguments except the name symbol.

The syntax `Array{T}` where `T<:Integer` is lowered to

```
let T = TypeVar(:T,Integer)
    UnionAll(T, Array{T})
end
```

so it is seldom necessary to construct a `TypeVar` manually (indeed, this is to be avoided).

Free variables

The concept of a free type variable is extremely important in the type system. We say that a variable `V` is free in type `T` if `T` does not contain the `UnionAll` that introduces variable `V`. For example, the type `Array{Array{V}}` where `V<:Integer` has no free variables, but the `Array{V}` part inside of it does have a free variable, `V`.

A type with free variables is, in some sense, not really a type at all. Consider the type `Array{Array{T}}` where `T`, which refers to all homogeneous arrays of arrays. The inner type `Array{T}`, seen by itself, might seem to refer to any kind of array. However, every element of the outer array must have the same array type, so `Array{T}` cannot refer to just any old array. One could say that `Array{T}` effectively "occurs" multiple times, and `T` must have the same value each "time".

For this reason, the function `j1_has_free_typevars` in the C API is very important. Types for which it returns true will not give meaningful answers in subtyping and other type functions.

TypeNames

The following two `Array` types are functionally equivalent, yet print differently:

```
julia> TV, NV = TypeVar(:T), TypeVar(:N)
(T, N)

julia> Array
Array

julia> Array{TV, NV}
Array{T, N}
```

These can be distinguished by examining the name field of the type, which is an object of type `TypeName`:

```
julia> dump(Array{Int,1}.name)
TypeName
  name: Symbol Array
  module: Module Core
  names: empty SimpleVector
  wrapper: UnionAll
    var: TypeVar
      name: Symbol T
      lb: Union{}
      ub: Any
```

```

    body: UnionAll
    var: TypeVar
        name: Symbol N
        lb: Union{}
        ub: Any
    body: Array{T, N} <: DenseArray{T, N}
cache: SimpleVector
...

linearcache: SimpleVector
...

hash: Int64 -7900426068641098781
mt: MethodTable
    name: Symbol Array
    defs: Nothing nothing
    cache: Nothing nothing
    max_args: Int64 0
    module: Module Core
    : Int64 0
    : Int64 0

```

In this case, the relevant field is `wrapper`, which holds a reference to the top-level type used to make new `Array` types.

```

julia> pointer_from_objref(Array)
Ptr{Cvoid} @0x00007fcc7de64850

julia> pointer_from_objref(Array.body.body.name.wrapper)
Ptr{Cvoid} @0x00007fcc7de64850

julia> pointer_from_objref(Array{TV,NV})
Ptr{Cvoid} @0x00007fcc80c4d930

julia> pointer_from_objref(Array{TV,NV}.name.wrapper)
Ptr{Cvoid} @0x00007fcc7de64850

```

The `wrapper` field of `Array` points to itself, but for `Array{TV,NV}` it points back to the original definition of the type.

What about the other fields? `hash` assigns an integer to each type. To examine the `cache` field, it's helpful to pick a type that is less heavily used than `Array`. Let's first create our own type:

```

julia> struct MyType{T,N} end

julia> MyType{Int,2}
MyType{Int64, 2}

julia> MyType{Float32, 5}
MyType{Float32, 5}

```

When you instantiate a parametric type, each concrete type gets saved in a type cache (`MyType.body.body.name.cache`). However, instances containing free type variables are not cached.

Tuple types

Tuple types constitute an interesting special case. For dispatch to work on declarations like `x::Tuple`, the type has to be able to accommodate any tuple. Let's check the parameters:

```
julia> Tuple
Tuple

julia> Tuple.parameters
svec{Vararg{Any}}
```

Unlike other types, tuple types are covariant in their parameters, so this definition permits `Tuple` to match any type of tuple:

```
julia> typeintersect(Tuple, Tuple{Int,Float64})
Tuple{Int64, Float64}

julia> typeintersect(Tuple{Vararg{Any}}, Tuple{Int,Float64})
Tuple{Int64, Float64}
```

However, if a variadic (`Vararg`) tuple type has free variables it can describe different kinds of tuples:

```
julia> typeintersect(Tuple{Vararg{T} where T}, Tuple{Int,Float64})
Tuple{Int64, Float64}

julia> typeintersect(Tuple{Vararg{T}} where T, Tuple{Int,Float64})
Union{}
```

Notice that when `T` is free with respect to the `Tuple` type (i.e. its binding `UnionAll` type is outside the `Tuple` type), only one `T` value must work over the whole type. Therefore a heterogeneous tuple does not match.

Finally, it's worth noting that `Tuple{}` is distinct:

```
julia> Tuple{}
Tuple{}

julia> Tuple{}.parameters
svec()

julia> typeintersect(Tuple{}, Tuple{Int})
Union{}
```

What is the "primary" tuple-type?

```
julia> pointer_from_objref(Tuple)
Ptr{Cvoid} @0x00007f5998a04370

julia> pointer_from_objref(Tuple{})
Ptr{Cvoid} @0x00007f5998a570d0
```

```
julia> pointer_from_objref(Tuple.name.wrapper)
Ptr{Cvoid} @0x00007f5998a04370

julia> pointer_from_objref(Tuple{}.name.wrapper)
Ptr{Cvoid} @0x00007f5998a04370
```

so `Tuple == Tuple{Vararg{Any}}` is indeed the primary type.

Diagonal types

Consider the type `Tuple{T,T}` where `T`. A method with this signature would look like:

```
f(x::T, y::T) where {T} = ...
```

According to the usual interpretation of a `UnionAll` type, this `T` ranges over all types, including `Any`, so this type should be equivalent to `Tuple{Any,Any}`. However, this interpretation causes some practical problems.

First, a value of `T` needs to be available inside the method definition. For a call like `f(1, 1.0)`, it's not clear what `T` should be. It could be `Union{Int,Float64}`, or perhaps `Real`. Intuitively, we expect the declaration `x::T` to mean `T === typeof(x)`. To make sure that invariant holds, we need `typeof(x) === typeof(y) === T` in this method. That implies the method should only be called for arguments of the exact same type.

It turns out that being able to dispatch on whether two values have the same type is very useful (this is used by the promotion system for example), so we have multiple reasons to want a different interpretation of `Tuple{T,T}` where `T`. To make this work we add the following rule to subtyping: if a variable occurs more than once in covariant position, it is restricted to ranging over only concrete types. ("Covariant position" means that only `Tuple` and `Union` types occur between an occurrence of a variable and the `UnionAll` type that introduces it.) Such variables are called "diagonal variables" or "concrete variables".

So for example, `Tuple{T,T}` where `T` can be seen as `Union{Tuple{Int8,Int8}, Tuple{Int16,Int16}, ...}`, where `T` ranges over all concrete types. This gives rise to some interesting subtyping results. For example `Tuple{Real,Real}` is not a subtype of `Tuple{T,T}` where `T`, because it includes some types like `Tuple{Int8,Int16}` where the two elements have different types. `Tuple{Real,Real}` and `Tuple{T,T}` where `T` have the non-trivial intersection `Tuple{T,T}` where `T <: Real`. However, `Tuple{Real}` is a subtype of `Tuple{T}` where `T`, because in that case `T` occurs only once and so is not diagonal.

Next consider a signature like the following:

```
f(a::Array{T}, x::T, y::T) where {T} = ...
```

In this case, `T` occurs in invariant position inside `Array{T}`. That means whatever type of array is passed unambiguously determines the value of `T` – we say `T` has an equality constraint on it. Therefore in this case the diagonal rule is not really necessary, since the array determines `T` and we can then allow `x` and `y` to be of any subtypes of `T`. So variables that occur in invariant position are never considered diagonal. This choice of behavior is slightly controversial – some feel this definition should be written as

```
f(a::Array{T}, x::S, y::S) where {T, S<:T} = ...
```

to clarify whether x and y need to have the same type. In this version of the signature they would, or we could introduce a third variable for the type of y if x and y can have different types.

The next complication is the interaction of unions and diagonal variables, e.g.

```
| f(x::Union{Nothing,T}, y::T) where {T} = ...
```

Consider what this declaration means. y has type T . x then can have either the same type T , or else be of type `Nothing`. So all of the following calls should match:

```
| f(1, 1)
| f("", "")
| f(2.0, 2.0)
| f(nothing, 1)
| f(nothing, "")
| f(nothing, 2.0)
```

These examples are telling us something: when x is `nothing::Nothing`, there are no extra constraints on y . It is as if the method signature had $y::Any$. Indeed, we have the following type equivalence:

```
| (Tuple{Union{Nothing,T},T} where T) == Union{Tuple{Nothing,Any}, Tuple{T,T} where T}
```

The general rule is: a concrete variable in covariant position acts like it's not concrete if the subtyping algorithm only uses it once. When x has type `Nothing`, we don't need to use the T in `Union{Nothing,T}`; we only use it in the second slot. This arises naturally from the observation that in `Tuple{T}` where T restricting T to concrete types makes no difference; the type is equal to `Tuple{Any}` either way.

However, appearing in invariant position disqualifies a variable from being concrete whether that appearance of the variable is used or not. Otherwise types can behave differently depending on which other types they are compared to, making subtyping not transitive. For example, consider

```
| Tuple{Int,Int8,Vector{Integer}} <: Tuple{T,T,Vector{Union{Integer,T}}} where T
```

If the T inside the `Union` is ignored, then T is concrete and the answer is "false" since the first two types aren't the same. But consider instead

```
| Tuple{Int,Int8,Vector{Any}} <: Tuple{T,T,Vector{Union{Integer,T}}} where T
```

Now we cannot ignore the T in the `Union` (we must have $T == Any$), so T is not concrete and the answer is "true". That would make the concreteness of T depend on the other type, which is not acceptable since a type must have a clear meaning on its own. Therefore the appearance of T inside `Vector` is considered in both cases.

Subtyping diagonal variables

The subtyping algorithm for diagonal variables has two components: (1) identifying variable occurrences, and (2) ensuring that diagonal variables range over concrete types only.

The first task is accomplished by keeping counters `occurs_inv` and `occurs_cov` (in `src/subtype.c`) for each variable in the environment, tracking the number of invariant and covariant occurrences, respectively. A variable is diagonal when `occurs_inv == 0 && occurs_cov > 1`.

The second task is accomplished by imposing a condition on a variable's lower bound. As the subtyping algorithm runs, it narrows the bounds of each variable (raising lower bounds and lowering upper bounds) to keep track of the range of variable values for which the subtype relation would hold. When we are done evaluating the body of a `UnionAll` type whose variable is diagonal, we look at the final values of the bounds. Since the variable must be concrete, a contradiction occurs if its lower bound could not be a subtype of a concrete type. For example, an abstract type like `AbstractArray` cannot be a subtype of a concrete type, but a concrete type like `Int` can be, and the empty type `Bottom` can be as well. If a lower bound fails this test the algorithm stops with the answer `false`.

For example, in the problem `Tuple{Int,String} <: Tuple{T,T}` where `T`, we derive that this would be true if `T` were a supertype of `Union{Int,String}`. However, `Union{Int,String}` is an abstract type, so the relation does not hold.

This concreteness test is done by the function `is_leaf_bound`. Note that this test is slightly different from `jl_is_leaf_type`, since it also returns `true` for `Bottom`. Currently this function is heuristic, and does not catch all possible concrete types. The difficulty is that whether a lower bound is concrete might depend on the values of other type variable bounds. For example, `Vector{T}` is equivalent to the concrete type `Vector{Int}` only if both the upper and lower bounds of `T` equal `Int`. We have not yet worked out a complete algorithm for this.

Introduction to the internal machinery

Most operations for dealing with types are found in the files `jltypes.c` and `subtype.c`. A good way to start is to watch subtyping in action. Build Julia with `make debug` and fire up Julia within a debugger. [gdb debugging tips](#) has some tips which may be useful.

Because the subtyping code is used heavily in the REPL itself – and hence breakpoints in this code get triggered often – it will be easiest if you make the following definition:

```
julia> function mysubtype(a,b)
    ccall(:jl_breakpoint, Cvoid, (Any,), nothing)
    a <: b
end
```

and then set a breakpoint in `jl_breakpoint`. Once this breakpoint gets triggered, you can set breakpoints in other functions.

As a warm-up, try the following:

```
|mysubtype(Tuple{Int, Float64}, Tuple{Integer, Real})
```

We can make it more interesting by trying a more complex case:

```
|mysubtype(Tuple{Array{Int,2}, Int8}, Tuple{Array{T}, T} where T)
```

Subtyping and method sorting

The `type_morespecific` functions are used for imposing a partial order on functions in method tables (from most-to-least specific). Specificity is strict; if `a` is more specific than `b`, then `a` does not equal `b` and `b` is not more specific than `a`.

If `a` is a strict subtype of `b`, then it is automatically considered more specific. From there, `type_morespecific` employs some less formal rules. For example, subtype is sensitive to the number of arguments, but `type_morespecific` may not be. In particular, `Tuple{Int, AbstractFloat}` is more specific than `Tuple{Integer}`, even though it is not a subtype. (Of `Tuple{Int, AbstractFloat}` and `Tuple{Integer, Float64}`, neither is more specific than the other.) Likewise, `Tuple{Int, Vararg{Int}}` is not a subtype of `Tuple{Integer}`, but it is considered more specific. However, `morespecific` does get a bonus for length: in particular, `Tuple{Int, Int}` is more specific than `Tuple{Int, Vararg{Int}}`.

If you're debugging how methods get sorted, it can be convenient to define the function:

```
| type_morespecific(a, b) = ccall(:jl_type_morespecific, Cint, (Any, Any), a, b)
```

which allows you to test whether tuple type `a` is more specific than tuple type `b`.

102.4 Memory layout of Julia Objects

Object layout (`jl_value_t`)

The `jl_value_t` struct is the name for a block of memory owned by the Julia Garbage Collector, representing the data associated with a Julia object in memory. Absent any type information, it is simply an opaque pointer:

```
| typedef struct jl_value_t* jl_pvalue_t;
```

Each `jl_value_t` struct is contained in a `jl_typedtag_t` struct that contains metadata information about the Julia object, such as its type and garbage collector (gc) reachability:

```
| typedef struct {
|     opaque metadata;
|     jl_value_t value;
| } jl_typedtag_t;
```

The type of any Julia object is an instance of a leaf `jl_datatype_t` object. The `jl_typeof()` function can be used to query for it:

```
| jl_value_t *jl_typeof(jl_value_t *v);
```

The layout of the object depends on its type. Reflection methods can be used to inspect that layout. A field can be accessed by calling one of the get-field methods:

```
| jl_value_t *jl_get_nth_field_checked(jl_value_t *v, size_t i);
| jl_value_t *jl_get_field(jl_value_t *o, char *fld);
```

If the field types are known, a priori, to be all pointers, the values can also be extracted directly as an array access:

```
| jl_value_t *v = value->fieldptr[n];
```

As an example, a "boxed" `uint16_t` is stored as follows:

```
struct {
    opaque metadata;
    struct {
        uint16_t data;          // -- 2 bytes
    } jl_value_t;
};
```

This object is created by `jl_box_uint16()`. Note that the `jl_value_t` pointer references the data portion, not the metadata at the top of the struct.

A value may be stored "unboxed" in many circumstances (just the data, without the metadata, and possibly not even stored but just kept in registers), so it is unsafe to assume that the address of a box is a unique identifier. The "egal" test (corresponding to the `===` function in Julia), should instead be used to compare two unknown objects for equivalence:

```
int jl_egal(jl_value_t *a, jl_value_t *b);
```

This optimization should be relatively transparent to the API, since the object will be "boxed" on-demand, whenever a `jl_value_t` pointer is needed.

Note that modification of a `jl_value_t` pointer in memory is permitted only if the object is mutable. Otherwise, modification of the value may corrupt the program and the result will be undefined. The mutability property of a value can be queried for with:

```
int jl_is_mutable(jl_value_t *v);
```

If the object being stored is a `jl_value_t`, the Julia garbage collector must be notified also:

```
void jl_gc_wb(jl_value_t *parent, jl_value_t *ptr);
```

However, the [Embedding Julia](#) section of the manual is also required reading at this point, for covering other details of boxing and unboxing various types, and understanding the gc interactions.

Mirror structs for some of the built-in types are [defined in julia.h](#). The corresponding global `jl_datatype_t` objects are created by [jl_init_types in jltypes.c](#).

Garbage collector mark bits

The garbage collector uses several bits from the metadata portion of the `jl_ttypetag_t` to track each object in the system. Further details about this algorithm can be found in the comments of the [garbage collector implementation in gc.c](#).

Object allocation

Most new objects are allocated by `jl_new_structv()`:

```
jl_value_t *jl_new_struct(jl_datatype_t *type, ...);
jl_value_t *jl_new_structv(jl_datatype_t *type, jl_value_t **args, uint32_t na);
```

Although, [isbits](#) objects can be also constructed directly from memory:

```
jl_value_t *jl_new_bits(jl_value_t *bt, void *data)
```

And some objects have special constructors that must be used instead of the above functions:

Types:

```
jl_datatype_t *jl_apply_type(jl_datatype_t *tc, jl_tuple_t *params);
jl_datatype_t *jl_apply_array_type(jl_datatype_t *type, size_t dim);
```

While these are the most commonly used options, there are more low-level constructors too, which you can find declared in `julia.h`. These are used in `jl_init_types()` to create the initial types needed to bootstrap the creation of the Julia system image.

Tuples:

```
jl_tuple_t *jl_tuple(size_t n, ...);
jl_tuple_t *jl_tuplev(size_t n, jl_value_t **v);
jl_tuple_t *jl_alloc_tuple(size_t n);
```

The representation of tuples is highly unique in the Julia object representation ecosystem. In some cases, a `Base.tuple()` object may be an array of pointers to the objects contained by the tuple equivalent to:

```
typedef struct {
    size_t length;
    jl_value_t *data[length];
} jl_tuple_t;
```

However, in other cases, the tuple may be converted to an anonymous `isbits` type and stored unboxed, or it may not be stored at all (if it is not being used in a generic context as a `jl_value_t*`).

Symbols:

```
jl_sym_t *jl_symbol(const char *str);
```

Functions and MethodInstance:

```
jl_function_t *jl_new_generic_function(jl_sym_t *name);
jl_method_instance_t *jl_new_method_instance(jl_value_t *ast, jl_tuple_t *sparams);
```

Arrays:

```
jl_array_t *jl_new_array(jl_value_t *atype, jl_tuple_t *dims);
jl_array_t *jl_new_arrayv(jl_value_t *atype, ...);
jl_array_t *jl_alloc_array_1d(jl_value_t *atype, size_t nr);
jl_array_t *jl_alloc_array_2d(jl_value_t *atype, size_t nr, size_t nc);
jl_array_t *jl_alloc_array_3d(jl_value_t *atype, size_t nr, size_t nc, size_t z);
jl_array_t *jl_alloc_vec_any(size_t n);
```

Note that many of these have alternative allocation functions for various special-purposes. The list here reflects the more common usages, but a more complete list can be found by reading the `julia.h` header file.

Internal to Julia, storage is typically allocated by `newstruct()` (or `newobj()` for the special types):

```
jl_value_t *newstruct(jl_value_t *type);
jl_value_t *newobj(jl_value_t *type, size_t nfields);
```

And at the lowest level, memory is getting allocated by a call to the garbage collector (in `gc.c`), then tagged with its type:

```
jl_value_t *jl_gc_allocobj(size_t nbytes);
void jl_set_typeof(jl_value_t *v, jl_datatype_t *type);
```

Out of date Warning

The documentation and usage for the function `jl_gc_allocobj` may be out of date

Note that all objects are allocated in multiples of 4 bytes and aligned to the platform pointer size. Memory is allocated from a pool for smaller objects, or directly with `malloc()` for large objects.

Singleton Types

Singleton types have only one instance and no data fields. Singleton instances have a size of 0 bytes, and consist only of their metadata. e.g. `nothing::Nothing`.

See [Singleton Types](#) and [Nothingness and missing values](#)

102.5 Eval of Julia code

One of the hardest parts about learning how the Julia Language runs code is learning how all of the pieces work together to execute a block of code.

Each chunk of code typically makes a trip through many steps with potentially unfamiliar names, such as (in no particular order): `flisp`, `AST`, `C++`, `LLVM`, `eval`, `typeinf`, `macroexpand`, `sysimg` (or system image), bootstrapping, `compile`, `parse`, `execute`, `JIT`, `interpret`, `box`, `unbox`, `intrinsic function`, and `primitive function`, before turning into the desired result (hopefully).

Definitions

- **REPL**
REPL stands for Read-Eval-Print Loop. It's just what we call the command line environment for short.
- **AST**
Abstract Syntax Tree The AST is the digital representation of the code structure. In this form the code has been tokenized for meaning so that it is more suitable for manipulation and execution.

Julia Execution

The 10,000 foot view of the whole process is as follows:

1. The user starts `julia`.
2. The C function `main()` from `cli/loader_exe.c` gets called. This function processes the command line arguments, filling in the `jl_options` struct and setting the variable `ARGS`. It then initializes Julia (by calling `julia_init` in `init.c`, which may load a previously compiled `sysimg`). Finally, it passes off control to Julia by calling `Base._start()`.

Figure 102.1: Diagram of the compiler flow

- When `_start()` takes over control, the subsequent sequence of commands depends on the command line arguments given. For example, if a filename was supplied, it will proceed to execute that file. Otherwise, it will start an interactive REPL.
- Skipping the details about how the REPL interacts with the user, let's just say the program ends up with a block of code that it wants to run.
- If the block of code to run is in a file, `julia_load(char *filename)` gets invoked to load the file and `parse` it. Each fragment of code is then passed to `eval` to execute.
- Each fragment of code (or AST), is handed off to `eval()` to turn into results.
- `eval()` takes each code fragment and tries to run it in `julia_toplevel_eval_flex()`.
- `julia_toplevel_eval_flex()` decides whether the code is a "toplevel" action (such as using or module), which would be invalid inside a function. If so, it passes off the code to the toplevel interpreter.
- `julia_toplevel_eval_flex()` then `expands` the code to eliminate any macros and to "lower" the AST to make it simpler to execute.
- `julia_toplevel_eval_flex()` then uses some simple heuristics to decide whether to JIT compile the AST or to interpret it directly.

11. The bulk of the work to interpret code is handled by `eval` in `interpreter.c`.
12. If instead, the code is compiled, the bulk of the work is handled by `codegen.cpp`. Whenever a Julia function is called for the first time with a given set of argument types, `type inference` will be run on that function. This information is used by the `codegen` step to generate faster code.
13. Eventually, the user quits the REPL, or the end of the program is reached, and the `_start()` method returns.
14. Just before exiting, `main()` calls `jl_atexit_hook(exit_code)`. This calls `Base._atexit()` (which calls any functions registered to `atexit()` inside Julia). Then it calls `jl_gc_run_all_finalizers()`. Finally, it gracefully cleans up all `libuv` handles and waits for them to flush and close.

Parsing

The Julia parser is a small lisp program written in `femtolisp`, the source-code for which is distributed inside Julia in `src/flisp`.

The interface functions for this are primarily defined in `jlfrontend.scm`. The code in `ast.c` handles this handoff on the Julia side.

The other relevant files at this stage are `julia-parser.scm`, which handles tokenizing Julia code and turning it into an AST, and `julia-syntax.scm`, which handles transforming complex AST representations into simpler, "lowered" AST representations which are more suitable for analysis and execution.

If you want to test the parser without re-building Julia in its entirety, you can run the frontend on its own as follows:

```
$ cd src
$ flisp/flisp
> (load "jlfrontend.scm")
> (jl-parse-file "<filename>")
```

Macro Expansion

When `eval()` encounters a macro, it expands that AST node before attempting to evaluate the expression. Macro expansion involves a handoff from `eval()` (in Julia), to the parser function `jl_macroexpand()` (written in `flisp`) to the Julia macro itself (written in - what else - Julia) via `fl_invoke_julia_macro()`, and back.

Typically, macro expansion is invoked as a first step during a call to `Meta.lower()/jl_expand()`, although it can also be invoked directly by a call to `macroexpand()/jl_macroexpand()`.

Type Inference

Type inference is implemented in Julia by `typeinf()` in `compiler/typeinfer.jl`. Type inference is the process of examining a Julia function and determining bounds for the types of each of its variables, as well as bounds on the type of the return value from the function. This enables many future optimizations, such as unboxing of known immutable values, and compile-time hoisting of various run-time operations such as computing field offsets and function pointers. Type inference may also include other steps such as constant propagation and inlining.

More Definitions

- **JIT**
Just-In-Time Compilation The process of generating native-machine code into memory right when it is needed.
- **LLVM**
Low-Level Virtual Machine (a compiler) The Julia JIT compiler is a program/library called libLLVM. Codegen in Julia refers both to the process of taking a Julia AST and turning it into LLVM instructions, and the process of LLVM optimizing that and turning it into native assembly instructions.
- **C++**
The programming language that LLVM is implemented in, which means that codegen is also implemented in this language. The rest of Julia's library is implemented in C, in part because its smaller feature set makes it more usable as a cross-language interface layer.
- **box**
This term is used to describe the process of taking a value and allocating a wrapper around the data that is tracked by the garbage collector (gc) and is tagged with the object's type.
- **unbox**
The reverse of boxing a value. This operation enables more efficient manipulation of data when the type of that data is fully known at compile-time (through type inference).
- **generic function**
A Julia function composed of multiple "methods" that are selected for dynamic dispatch based on the argument type-signature
- **anonymous function or "method"**
A Julia function without a name and without type-dispatch capabilities
- **primitive function**
A function implemented in C but exposed in Julia as a named function "method" (albeit without generic function dispatch capabilities, similar to an anonymous function)
- **intrinsic function**
A low-level operation exposed as a function in Julia. These pseudo-functions implement operations on raw bits such as add and sign extend that cannot be expressed directly in any other way. Since they operate on bits directly, they must be compiled into a function and surrounded by a call to `Core.Intrinsics.box(T, ...)` to reassign type information to the value.

JIT Code Generation

Codegen is the process of turning a Julia AST into native machine code.

The JIT environment is initialized by an early call to `julia_init_codegen` in `codegen.cpp`.

On demand, a Julia method is converted into a native function by the function `emit_function(jl_method_instance_t*)`. (note, when using the MCJIT (in LLVM v3.4+), each function must be JIT into a new module.) This function recursively calls `emit_expr()` until the entire function has been emitted.

Much of the remaining bulk of this file is devoted to various manual optimizations of specific code patterns. For example, `emit_known_call()` knows how to inline many of the primitive functions (defined in `builtins.c`) for various combinations of argument types.

Other parts of codegen are handled by various helper files:

- `debuginfo.cpp`
Handles backtraces for JIT functions
- `ccall.cpp`
Handles the ccall and llvmcall FFI, along with various `abi_*.cpp` files
- `intrinsics.cpp`
Handles the emission of various low-level intrinsic functions

Bootstrapping

The process of creating a new system image is called "bootstrapping".

The etymology of this word comes from the phrase "pulling oneself up by the bootstraps", and refers to the idea of starting from a very limited set of available functions and definitions and ending with the creation of a full-featured environment.

System Image

The system image is a precompiled archive of a set of Julia files. The `sys.ji` file distributed with Julia is one such system image, generated by executing the file `sysimg.jl`, and serializing the resulting environment (including Types, Functions, Modules, and all other defined values) into a file. Therefore, it contains a frozen version of the Main, Core, and Base modules (and whatever else was in the environment at the end of bootstrapping). This serializer/deserializer is implemented by `jl_save_system_image/jl_restore_system_image` in `staticdata.c`.

If there is no `sysimg` file (`jl_options.image_file == NULL`), this also implies that `--build` was given on the command line, so the final result should be a new `sysimg` file. During Julia initialization, minimal Core and Main modules are created. Then a file named `boot.jl` is evaluated from the current directory. Julia then evaluates any file given as a command line argument until it reaches the end. Finally, it saves the resulting environment to a "sysimg" file for use as a starting point for a future Julia run.

102.6 Calling Conventions

Julia uses three calling conventions for four distinct purposes:

| Name | Prefix | Purpose |
|---------|----------------------|----------------------------------|
| Native | <code>julia_</code> | Speed via specialized signatures |
| JL Call | <code>jlcall_</code> | Wrapper for generic calls |
| JL Call | <code>jl_</code> | Builtins |
| C ABI | <code>jlcall_</code> | Wrapper callable from C |

Julia Native Calling Convention

The native calling convention is designed for fast non-generic calls. It usually uses a specialized signature.

- LLVM ghosts (zero-length types) are omitted.
- LLVM scalars and vectors are passed by value.

- LLVM aggregates (arrays and structs) are passed by reference.

A small return values is returned as LLVM return values. A large return values is returned via the "structure return" (sret) convention, where the caller provides a pointer to a return slot.

An argument or return values that is a homogeneous tuple is sometimes represented as an LLVM vector instead of an LLVM array.

JL Call Convention

The JL Call convention is for builtins and generic dispatch. Hand-written functions using this convention are declared via the macro `JL_CALLABLE`. The convention uses exactly 3 parameters:

- `F` - Julia representation of function that is being applied
- `args` - pointer to array of pointers to boxes
- `nargs` - length of the array

The return value is a pointer to a box.

C ABI

C ABI wrappers enable calling Julia from C. The wrapper calls a function using the native calling convention.

Tuples are always represented as C arrays.

102.7 High-level Overview of the Native-Code Generation Process

Representation of Pointers

When emitting code to an object file, pointers will be emitted as relocations. The deserialization code will ensure any object that pointed to one of these constants gets recreated and contains the right runtime pointer.

Otherwise, they will be emitted as literal constants.

To emit one of these objects, call `literal_pointer_val`. It'll handle tracking the Julia value and the LLVM global, ensuring they are valid both for the current runtime and after deserialization.

When emitted into the object file, these globals are stored as references in a large `gvals` table. This allows the deserializer to reference them by index, and implement a custom manual mechanism similar to a Global Offset Table (GOT) to restore them.

Function pointers are handled similarly. They are stored as values in a large `fvals` table. Like globals, this allows the deserializer to reference them by index.

Note that extern functions are handled separately, with names, via the usual symbol resolution mechanism in the linker.

Note too that `ccall` functions are also handled separately, via a manual GOT and Procedure Linkage Table (PLT).

Representation of Intermediate Values

Values are passed around in a `jl_cgval_t` struct. This represents an R-value, and includes enough information to determine how to assign or pass it somewhere.

They are created via one of the helper constructors, usually: `mark_julia_type` (for immediate values) and `mark_julia_slot` (for pointers to values).

The function `convert_julia_type` can transform between any two types. It returns an R-value with `cgval.typ` set to `typ`. It'll cast the object to the requested representation, making heap boxes, allocating stack copies, and computing tagged unions as needed to change the representation.

By contrast `update_julia_type` will change `cgval.typ` to `typ`, only if it can be done at zero-cost (i.e. without emitting any code).

Union representation

Inferred union types may be stack allocated via a tagged type representation.

The primitive routines that need to be able to handle tagged unions are:

- `mark-type`
- `load-local`
- `store-local`
- `isa`
- `is`
- `emit_typeof`
- `emit_sizeof`
- `boxed`
- `unbox`
- `specialized cc-ret`

Everything else should be possible to handle in inference by using these primitives to implement union-splitting.

The representation of the tagged-union is as a pair of `< void* union, byte selector >`. The selector is fixed-size as `byte & 0x7f`, and will union-tag the first 126 isbits. It records the one-based depth-first count into the type-union of the isbits objects inside. An index of zero indicates that the `union*` is actually a tagged heap-allocated `jl_value_t*`, and needs to be treated as normal for a boxed object rather than as a tagged union.

The high bit of the selector (`byte & 0x80`) can be tested to determine if the `void*` is actually a heap-allocated (`jl_value_t*`) box, thus avoiding the cost of re-allocating a box, while maintaining the ability to efficiently handle union-splitting based on the low bits.

It is guaranteed that `byte & 0x7f` is an exact test for the type, if the value can be represented by a tag – it will never be marked `byte = 0x80`. It is not necessary to also test the type-tag when testing `isa`.

The union* memory region may be allocated at any size. The only constraint is that it is big enough to contain the data currently specified by selector. It might not be big enough to contain the union of all types that could be stored there according to the associated Union type field. Use appropriate care when copying.

Specialized Calling Convention Signature Representation

A `julia_returninfo_t` object describes the calling convention details of any callable.

If any of the arguments or return type of a method can be represented unboxed, and the method is not varargs, it'll be given an optimized calling convention signature based on its `specTypes` and `retType` fields.

The general principles are that:

- Primitive types get passed in int/float registers.
- Tuples of `VecElement` types get passed in vector registers.
- Structs get passed on the stack.
- Return values are handle similarly to arguments, with a size-cutoff at which they will instead be returned via a hidden `sret` argument.

The total logic for this is implemented by `get_specsig_function` and `deserves_sret`.

Additionally, if the return type is a union, it may be returned as a pair of values (a pointer and a tag). If the union values can be stack-allocated, then sufficient space to store them will also be passed as a hidden first argument. It is up to the callee whether the returned pointer will point to this space, a boxed object, or even other constant memory.

102.8 Julia Functions

This document will explain how functions, method definitions, and method tables work.

Method Tables

Every function in Julia is a generic function. A generic function is conceptually a single function, but consists of many definitions, or methods. The methods of a generic function are stored in a method table. Method tables (type `MethodTable`) are associated with `TypeName`s. A `TypeName` describes a family of parameterized types. For example `Complex{Float32}` and `Complex{Float64}` share the same `Complex` type name object.

All objects in Julia are potentially callable, because every object has a type, which in turn has a `TypeName`.

Function calls

Given the call `f(x,y)`, the following steps are performed: first, the method table to use is accessed as `typeof(f).name.mt`. Second, an argument tuple type is formed, `Tuple{typeof(f), typeof(x), typeof(y)}`. Note that the type of the function itself is the first element. This is because the type might have parameters, and so needs to take part in dispatch. This tuple type is looked up in the method table.

This dispatch process is performed by `julia_apply_generic`, which takes two arguments: a pointer to an array of the values `f`, `x`, and `y`, and the number of values (in this case 3).

Throughout the system, there are two kinds of APIs that handle functions and argument lists: those that accept the function and arguments separately, and those that accept a single argument structure. In the first kind of API, the "arguments" part does not contain information about the function, since that is passed separately. In the second kind of API, the function is the first element of the argument structure.

For example, the following function for performing a call accepts just an args pointer, so the first element of the args array will be the function to call:

```
| jl_value_t *jl_apply(jl_value_t **args, uint32_t nargs)
```

This entry point for the same functionality accepts the function separately, so the args array does not contain the function:

```
| jl_value_t *jl_call(jl_function_t *f, jl_value_t **args, int32_t nargs);
```

Adding methods

Given the above dispatch process, conceptually all that is needed to add a new method is (1) a tuple type, and (2) code for the body of the method. `jl_method_def` implements this operation. `jl_method_table_for` is called to extract the relevant method table from what would be the type of the first argument. This is much more complicated than the corresponding procedure during dispatch, since the argument tuple type might be abstract. For example, we can define:

```
| (::Union{Foo{Int}, Foo{Int8}})(x) = 0
```

which works since all possible matching methods would belong to the same method table.

Creating generic functions

Since every object is callable, nothing special is needed to create a generic function. Therefore `jl_new_generic_function` simply creates a new singleton (0 size) subtype of `Function` and returns its instance. A function can have a mnemonic "display name" which is used in debug info and when printing objects. For example the name of `Base.sin` is `sin`. By convention, the name of the created type is the same as the function name, with a `#` prepended. So `typeof(sin)` is `Base.#sin`.

Closures

A closure is simply a callable object with field names corresponding to captured variables. For example, the following code:

```
| function adder(x)
|     return y->x+y
| end
```

is lowered to (roughly):

```
| struct ##1{T}
|     x::T
| end
```

```

| (_::##1)(y) = _.x + y
|
| function adder(x)
|     return ##1(x)
| end

```

Constructors

A constructor call is just a call to a type. The method table for `Type` contains all constructor definitions. All subtypes of `Type` (`Type`, `UnionAll`, `Union`, and `DataType`) currently share a method table via special arrangement.

Builtins

The "builtin" functions, defined in the `Core` module, are:

```

| <: == _abstracttype _apply_iterate _apply_pure _call_in_world
| _call_in_world_total _call_latest _compute_sparams _equiv_typedef _expr
| _primitivetype _setsuper! _structtype _svec_ref _typebody! _typevar applicable
| apply_type arrayref arrayset arraysize compilerbarrier const_arrayref donotdelete
| fieldtype finalizer get_binding_type getfield getglobal ifelse invoke isa
| isdefined modifyfield! nfields replacefield! set_binding_type! setfield!
| setglobal! sizeof svec swapfield! throw tuple typeassert typeof

```

These are all singleton objects whose types are subtypes of `Builtin`, which is a subtype of `Function`. Their purpose is to expose entry points in the run time that use the "jlcall" calling convention:

```

| jl_value_t *(jl_value_t*, jl_value_t**, uint32_t)

```

The method tables of builtins are empty. Instead, they have a single catch-all method cache entry (`Tuple{Vararg{Any}}`) whose `jlcall` `fp` points to the correct function. This is kind of a hack but works reasonably well.

Keyword arguments

Keyword arguments work by adding methods to the `kwcall` function. This function is usually the "keyword argument sorter" or "keyword sorter", which then calls the inner body of the function (defined anonymously). Every definition in the `kwsorter` function has the same arguments as some definition in the normal method table, except with a single `NamedTuple` argument prepended, which gives the names and values of passed keyword arguments. The `kwsorter`'s job is to move keyword arguments into their canonical positions based on name, plus evaluate and substitute any needed default value expressions. The result is a normal positional argument list, which is then passed to yet another compiler-generated function.

The easiest way to understand the process is to look at how a keyword argument method definition is lowered. The code:

```

| function circle(center, radius; color = black, fill::Bool = true, options...)
|     # draw
| end

```

actually produces three method definitions. The first is a function that accepts all arguments (including keyword arguments) as positional arguments, and includes the code for the method body. It has an auto-generated name:

```
function #circle#1(color, fill::Bool, options, circle, center, radius)
    # draw
end
```

The second method is an ordinary definition for the original `circle` function, which handles the case where no keyword arguments are passed:

```
function circle(center, radius)
    #circle#1(black, true, pairs(NamedTuple{}), circle, center, radius)
end
```

This simply dispatches to the first method, passing along default values. `pairs` is applied to the named tuple of rest arguments to provide key-value pair iteration. Note that if the method doesn't accept rest keyword arguments then this argument is absent.

Finally there is the `kwsorter` definition:

```
function (::Core.kwftype(typeof(circle)))(kws, circle, center, radius)
    if haskey(kws, :color)
        color = kws.color
    else
        color = black
    end
    # etc.

    # put remaining kwargs in `options`
    options = structdiff(kws, NamedTuple{(:color, :fill)})

    # if the method doesn't accept rest keywords, throw an error
    # unless `options` is empty

    #circle#1(color, fill, pairs(options), circle, center, radius)
end
```

The function `Core.kwftype(t)` creates the field `t.name.mt.kwsorter` (if it hasn't been created yet), and returns the type of that function.

This design has the feature that call sites that don't use keyword arguments require no special handling; everything works as if they were not part of the language at all. Call sites that do use keyword arguments are dispatched directly to the called function's `kwsorter`. For example the call:

```
| circle((0,0), 1.0, color = red; other...)
```

is lowered to:

```
| kwcall(merge((color = red,), other), circle, (0,0), 1.0)
```

`kwcall` (also in `Core`) denotes a `kwcall` signature and dispatch. The keyword splatting operation (written as `other...`) calls the named tuple `merge` function. This function further unpacks each element of `other`, expecting each one to contain two values (a symbol and a value). Naturally, a more efficient implementation is available if all splatted arguments are named tuples. Notice that the original `circle` function is passed through, to handle closures.

Compiler efficiency issues

Generating a new type for every function has potentially serious consequences for compiler resource use when combined with Julia's "specialize on all arguments by default" design. Indeed, the initial implementation of this design suffered from much longer build and test times, higher memory use, and a system image nearly 2x larger than the baseline. In a naive implementation, the problem is bad enough to make the system nearly unusable. Several significant optimizations were needed to make the design practical.

The first issue is excessive specialization of functions for different values of function-valued arguments. Many functions simply "pass through" an argument to somewhere else, e.g. to another function or to a storage location. Such functions do not need to be specialized for every closure that might be passed in. Fortunately this case is easy to distinguish by simply considering whether a function calls one of its arguments (i.e. the argument appears in "head position" somewhere). Performance-critical higher-order functions like `map` certainly call their argument function and so will still be specialized as expected. This optimization is implemented by recording which arguments are called during the analyze-variables pass in the front end. When `cache_method` sees an argument in the Function type hierarchy passed to a slot declared as `Any` or `Function`, it behaves as if the `@nospecialize` annotation were applied. This heuristic seems to be extremely effective in practice.

The next issue concerns the structure of method cache hash tables. Empirical studies show that the vast majority of dynamically-dispatched calls involve one or two arguments. In turn, many of these cases can be resolved by considering only the first argument. (Aside: proponents of single dispatch would not be surprised by this at all. However, this argument means "multiple dispatch is easy to optimize in practice", and that we should therefore use it, not "we should use single dispatch"!) So the method cache uses the type of the first argument as its primary key. Note, however, that this corresponds to the second element of the tuple type for a function call (the first element being the type of the function itself). Typically, type variation in head position is extremely low – indeed, the majority of functions belong to singleton types with no parameters. However, this is not the case for constructors, where a single method table holds constructors for every type. Therefore the Type method table is special-cased to use the first tuple type element instead of the second.

The front end generates type declarations for all closures. Initially, this was implemented by generating normal type declarations. However, this produced an extremely large number of constructors, all of which were trivial (simply passing all arguments through to `new`). Since methods are partially ordered, inserting all of these methods is $O(n^2)$, plus there are just too many of them to keep around. This was optimized by generating `struct_type` expressions directly (bypassing default constructor generation), and using `new` directly to create closure instances. Not the prettiest thing ever, but you do what you gotta do.

The next problem was the `@test` macro, which generated a 0-argument closure for each test case. This is not really necessary, since each test case is simply run once in place. Therefore, `@test` was modified to expand to a try-catch block that records the test result (true, false, or exception raised) and calls the test suite handler on it.

102.9 Base.Cartesian

The (non-exported) Cartesian module provides macros that facilitate writing multidimensional algorithms. Most often you can write such algorithms with [straightforward techniques](#); however, there are a few cases where `Base.Cartesian` is still useful or necessary.

Principles of usage

A simple example of usage is:

```
@nloops 3 i A begin
    s += @nref 3 A i
end
```

which generates the following code:

```
for i_3 = axes(A, 3)
    for i_2 = axes(A, 2)
        for i_1 = axes(A, 1)
            s += A[i_1, i_2, i_3]
        end
    end
end
```

In general, Cartesian allows you to write generic code that contains repetitive elements, like the nested loops in this example. Other applications include repeated expressions (e.g., loop unwinding) or creating function calls with variable numbers of arguments without using the "splat" construct (`i...`).

Basic syntax

The (basic) syntax of `@nloops` is as follows:

- The first argument must be an integer (not a variable) specifying the number of loops.
- The second argument is the symbol-prefix used for the iterator variable. Here we used `i`, and variables `i_1`, `i_2`, `i_3` were generated.
- The third argument specifies the range for each iterator variable. If you use a variable (symbol) here, it's taken as `axes(A, dim)`. More flexibly, you can use the anonymous-function expression syntax described below.
- The last argument is the body of the loop. Here, that's what appears between the `begin...end`.

There are some additional features of `@nloops` described in the [reference section](#).

`@nref` follows a similar pattern, generating `A[i_1,i_2,i_3]` from `@nref 3 A i`. The general practice is to read from left to right, which is why `@nloops` is `@nloops 3 i A expr` (as in `for i_2 = axes(A, 2)`, where `i_2` is to the left and the range is to the right) whereas `@nref` is `@nref 3 A i` (as in `A[i_1,i_2,i_3]`, where the array comes first).

If you're developing code with Cartesian, you may find that debugging is easier when you examine the generated code, using `@macroexpand`:

```
julia> @macroexpand @nref 2 A i
:(A[i_1, i_2])
```

Supplying the number of expressions

The first argument to both of these macros is the number of expressions, which must be an integer. When you're writing a function that you intend to work in multiple dimensions, this may not be something you want to hard-code. The recommended approach is to use a `@generated` function. Here's an example:

```
@generated function mysum(A::Array{T,N}) where {T,N}
    quote
        s = zero(T)
        @nloops $N i A begin
            s += @nref $N A i
        end
        s
    end
end
```

Naturally, you can also prepare expressions or perform calculations before the quote block.

Anonymous-function expressions as macro arguments

Perhaps the single most powerful feature in Cartesian is the ability to supply anonymous-function expressions that get evaluated at parsing time. Let's consider a simple example:

```
@nexprs 2 j->(i_j = 1)
```

`@nexprs` generates `n` expressions that follow a pattern. This code would generate the following statements:

```
i_1 = 1
i_2 = 1
```

In each generated statement, an "isolated" `j` (the variable of the anonymous function) gets replaced by values in the range `1:2`. Generally speaking, Cartesian employs a LaTeX-like syntax. This allows you to do math on the index `j`. Here's an example computing the strides of an array:

```
s_1 = 1
@nexprs 3 j->(s_{j+1} = s_j * size(A, j))
```

would generate expressions

```
s_1 = 1
s_2 = s_1 * size(A, 1)
s_3 = s_2 * size(A, 2)
s_4 = s_3 * size(A, 3)
```

Anonymous-function expressions have many uses in practice.

Macro reference Base.Cartesian.@nloops - Macro.

```
@nloops N itersym rangeexpr bodyexpr
@nloops N itersym rangeexpr preexpr bodyexpr
@nloops N itersym rangeexpr preexpr postexpr bodyexpr
```

Generate N nested loops, using `itersym` as the prefix for the iteration variables. `rangeexpr` may be an anonymous-function expression, or a simple symbol `var` in which case the range is `axes(var, d)` for dimension `d`.

Optionally, you can provide "pre" and "post" expressions. These get executed first and last, respectively, in the body of each loop. For example:

```
@nloops 2 i A d -> j_d = min(i_d, 5) begin
    s += @nref 2 A j
end
```

would generate:

```
for i_2 = axes(A, 2)
    j_2 = min(i_2, 5)
    for i_1 = axes(A, 1)
        j_1 = min(i_1, 5)
        s += A[j_1, j_2]
    end
end
```

If you want just a post-expression, supply `nothing` for the pre-expression. Using parentheses and semicolons, you can supply multi-statement expressions.

[source](#)

Base.Cartesian.@nref - Macro.

```
@nref N A indexexpr
```

Generate expressions like `A[i_1, i_2, ...]`. `indexexpr` can either be an iteration-symbol prefix, or an anonymous-function expression.

Examples

```
julia> @macroexpand Base.Cartesian.@nref 3 A i
:(A[i_1, i_2, i_3])
```

[source](#)

Base.Cartesian.@nextextract - Macro.

```
@nextextract N esym isym
```

Generate N variables `esym_1`, `esym_2`, ..., `esym_N` to extract values from `isym`. `isym` can be either a Symbol or anonymous-function expression.

`@nextextract 2 x y` would generate

```
x_1 = y[1]
x_2 = y[2]
```

```
while @nextract 3 x d->y[2d-1] yields
```

```
| x_1 = y[1]
| x_2 = y[3]
| x_3 = y[5]
```

[source](#)

Base.Cartesian.@nexprs – Macro.

```
| @nexprs N expr
```

Generate N expressions. expr should be an anonymous-function expression.

Examples

```
| julia> @macroexpand Base.Cartesian.@nexprs 4 i -> y[i] = A[i+j]
| quote
|   y[1] = A[1 + j]
|   y[2] = A[2 + j]
|   y[3] = A[3 + j]
|   y[4] = A[4 + j]
| end
```

[source](#)

Base.Cartesian.@ncall – Macro.

```
| @ncall N f sym...
```

Generate a function call expression. sym represents any number of function arguments, the last of which may be an anonymous-function expression and is expanded into N arguments.

For example, @ncall 3 func a generates

```
| func(a_1, a_2, a_3)
```

```
while @ncall 2 func a b i->c[i] yields
```

```
| func(a, b, c[1], c[2])
```

[source](#)

Base.Cartesian.@ntuple – Macro.

```
| @ntuple N expr
```

Generates an N-tuple. @ntuple 2 i would generate (i_1, i_2), and @ntuple 2 k->k+1 would generate (2,3).

[source](#)

Base.Cartesian.@nall – Macro.

```
| @nall N expr
```

Check whether all of the expressions generated by the anonymous-function expression `expr` evaluate to true.

`@nall 3 d->(i_d > 1)` would generate the expression `(i_1 > 1 && i_2 > 1 && i_3 > 1)`. This can be convenient for bounds-checking.

[source](#)

Base.Cartesian.@nany – Macro.

```
| @nany N expr
```

Check whether any of the expressions generated by the anonymous-function expression `expr` evaluate to true.

`@nany 3 d->(i_d > 1)` would generate the expression `(i_1 > 1 || i_2 > 1 || i_3 > 1)`.

[source](#)

Base.Cartesian.@nif – Macro.

```
| @nif N conditionexpr expr
| @nif N conditionexpr expr elseexpr
```

Generates a sequence of `if ... elseif ... else ... end` statements. For example:

```
| @nif 3 d->(i_d >= size(A,d)) d->(error("Dimension ", d, " too big")) d->println("All OK")
```

would generate:

```
| if i_1 > size(A, 1)
|     error("Dimension ", 1, " too big")
| elseif i_2 > size(A, 2)
|     error("Dimension ", 2, " too big")
| else
|     println("All OK")
| end
```

102.10 Talking to the compiler (the `:meta` mechanism)

In some circumstances, one might wish to provide hints or instructions that a given block of code has special properties: you might always want to inline it, or you might want to turn on special compiler optimization passes. Starting with version 0.4, Julia has a convention that these instructions can be placed inside a `:meta` expression, which is typically (but not necessarily) the first expression in the body of a function.

`:meta` expressions are created with macros. As an example, consider the implementation of the `@inline` macro:

```
| macro inline(ex)
|     esc(isa(ex, Expr) ? pushmeta!(ex, :inline) : ex)
| end
```

Here, `ex` is expected to be an expression defining a function. A statement like this:

```
@inline function myfunction(x)
    x*(x+3)
end
```

gets turned into an expression like this:

```
quote
    function myfunction(x)
        Expr(:meta, :inline)
        x*(x+3)
    end
end
```

`Base.pushmeta!(ex, :symbol, args...)` appends `:symbol` to the end of the `:meta` expression, creating a new `:meta` expression if necessary. If `args` is specified, a nested expression containing `:symbol` and these arguments is appended instead, which can be used to specify additional information.

To use the metadata, you have to parse these `:meta` expressions. If your implementation can be performed within Julia, `Base.popmeta!` is very handy: `Base.popmeta!(body, :symbol)` will scan a function body expression (one without the function signature) for the first `:meta` expression containing `:symbol`, extract any arguments, and return a tuple `(found::Bool, args::Array{Any})`. If the metadata did not have any arguments, or `:symbol` was not found, the `args` array will be empty.

Not yet provided is a convenient infrastructure for parsing `:meta` expressions from C++.

102.11 SubArrays

Julia's `SubArray` type is a container encoding a "view" of a parent [AbstractArray](#). This page documents some of the design principles and implementation of `SubArrays`.

One of the major design goals is to ensure high performance for views of both [IndexLinear](#) and [IndexCartesian](#) arrays. Furthermore, views of `IndexLinear` arrays should themselves be `IndexLinear` to the extent that it is possible.

Index replacement

Consider making 2d slices of a 3d array:

```
julia> A = rand(2,3,4);

julia> S1 = view(A, :, 1, 2:3)
2×2 view(::Array{Float64, 3}, :, 1, 2:3) with eltype Float64:
 0.839622  0.711389
 0.967143  0.103929

julia> S2 = view(A, 1, :, 2:3)
3×2 view(::Array{Float64, 3}, 1, :, 2:3) with eltype Float64:
 0.839622  0.711389
 0.789764  0.806704
 0.566704  0.962715
```

view drops "singleton" dimensions (ones that are specified by an `Int`), so both `S1` and `S2` are two-dimensional `SubArrays`. Consequently, the natural way to index these is with `S1[i,j]`. To extract the value from the parent array `A`, the natural approach is to replace `S1[i,j]` with `A[i,1,(2:3)[j]]` and `S2[i,j]` with `A[1,i,(2:3)[j]]`.

The key feature of the design of `SubArrays` is that this index replacement can be performed without any runtime overhead.

SubArray design

Type parameters and fields

The strategy adopted is first and foremost expressed in the definition of the type:

```
struct SubArray{T,N,P,I,L} <: AbstractArray{T,N}
    parent::P
    indices::I
    offset1::Int      # for linear indexing and pointer, only valid when L==true
    stride1::Int      # used only for linear indexing
    ...
end
```

`SubArray` has 5 type parameters. The first two are the standard element type and dimensionality. The next is the type of the parent `AbstractArray`. The most heavily-used is the fourth parameter, a `Tuple` of the types of the indices for each dimension. The final one, `L`, is only provided as a convenience for dispatch; it's a boolean that represents whether the index types support fast linear indexing. More on that later.

If in our example above `A` is a `Array{Float64, 3}`, our `S1` case above would be a `SubArray{Float64,2,Array{Float64,3},Tuple{Base.Slice{Base.OneTo{Int64}}, Int64},true}`. Note in particular the tuple parameter, which stores the types of the indices used to create `S1`. Likewise,

```
julia> S1.indices
(Base.Slice{Base.OneTo{Int64}}, 1, 2:3)
```

Storing these values allows index replacement, and having the types encoded as parameters allows one to dispatch to efficient algorithms.

Index translation

Performing index translation requires that you do different things for different concrete `SubArray` types. For example, for `S1`, one needs to apply the `i, j` indices to the first and third dimensions of the parent array, whereas for `S2` one needs to apply them to the second and third. The simplest approach to indexing would be to do the type-analysis at runtime:

```
parentindices = Vector{Any}()
for thisindex in S.indices
    ...
    if isa(thisindex, Int)
        # Don't consume one of the input indices
        push!(parentindices, thisindex)
    elseif isa(thisindex, AbstractVector)
        # Consume an input index
```

```

        push!(parentindices, thisindex[inputindex[j]])
        j += 1
    elseif isa(thisindex, AbstractMatrix)
        # Consume two input indices
        push!(parentindices, thisindex[inputindex[j], inputindex[j+1]])
        j += 2
    elseif ...
end
S.parent[parentindices...]

```

Unfortunately, this would be disastrous in terms of performance: each element access would allocate memory, and involves the running of a lot of poorly-typed code.

The better approach is to dispatch to specific methods to handle each type of stored index. That's what `reindex` does: it dispatches on the type of the first stored index and consumes the appropriate number of input indices, and then it recurses on the remaining indices. In the case of `S1`, this expands to

```
| Base.reindex(S1, S1.indices, (i, j)) == (i, S1.indices[2], S1.indices[3][j])
```

for any pair of indices (i, j) (except `CartesianIndices` and arrays thereof, see below).

This is the core of a `SubArray`; indexing methods depend upon `reindex` to do this index translation. Sometimes, though, we can avoid the indirection and make it even faster.

Linear indexing

Linear indexing can be implemented efficiently when the entire array has a single stride that separates successive elements, starting from some offset. This means that we can pre-compute these values and represent linear indexing simply as an addition and multiplication, avoiding the indirection of `reindex` and (more importantly) the slow computation of the cartesian coordinates entirely.

For `SubArray` types, the availability of efficient linear indexing is based purely on the types of the indices, and does not depend on values like the size of the parent array. You can ask whether a given set of indices supports fast linear indexing with the internal `Base.viewindexing` function:

```

julia> Base.viewindexing(S1.indices)
IndexCartesian()

julia> Base.viewindexing(S2.indices)
IndexLinear()

```

This is computed during construction of the `SubArray` and stored in the `L` type parameter as a boolean that encodes fast linear indexing support. While not strictly necessary, it means that we can define dispatch directly on `SubArray{T,N,A,I,true}` without any intermediaries.

Since this computation doesn't depend on runtime values, it can miss some cases in which the stride happens to be uniform:

```

julia> A = reshape(1:4*2, 4, 2)
4×2 reshape{::UnitRange{Int64}, 4, 2} with eltype Int64:
 1  5

```

```

2 6
3 7
4 8

julia> diff(A[2:2:4,:][:])
3-element Vector{Int64}:
 2
 2
 2

```

A view constructed as `view(A, 2:2:4, :)` happens to have uniform stride, and therefore linear indexing indeed could be performed efficiently. However, success in this case depends on the size of the array: if the first dimension instead were odd,

```

julia> A = reshape(1:5*2, 5, 2)
5×2 reshape{::UnitRange{Int64}, 5, 2} with eltype Int64:
 1  6
 2  7
 3  8
 4  9
 5 10

julia> diff(A[2:2:4,:][:])
3-element Vector{Int64}:
 2
 3
 2

```

then `A[2:2:4, :]` does not have uniform stride, so we cannot guarantee efficient linear indexing. Since we have to base this decision purely on types encoded in the parameters of the `SubArray`, `S = view(A, 2:2:4, :)` cannot implement efficient linear indexing.

A few details

- Note that the `Base.reindex` function is agnostic to the types of the input indices; it simply determines how and where the stored indices should be reindexed. It not only supports integer indices, but it supports non-scalar indexing, too. This means that views of views don't need two levels of indirection; they can simply re-compute the indices into the original parent array!
- Hopefully by now it's fairly clear that supporting slices means that the dimensionality, given by the parameter `N`, is not necessarily equal to the dimensionality of the parent array or the length of the indices tuple. Neither do user-supplied indices necessarily line up with entries in the indices tuple (e.g., the second user-supplied index might correspond to the third dimension of the parent array, and the third element in the indices tuple).

What might be less obvious is that the dimensionality of the stored parent array must be equal to the number of effective indices in the indices tuple. Some examples:

```

A = reshape(1:35, 5, 7) # A 2d parent Array
S = view(A, 2:7)        # A 1d view created by linear indexing
S = view(A, :, :, 1:1)  # Appending extra indices is supported

```

Naively, you'd think you could just set `S.parent = A` and `S.indices = (:, :, 1:1)`, but supporting this dramatically complicates the reindexing process, especially for views of views. Not only do you need to dispatch on the types of the stored indices, but you need to examine whether a given index is the final one and "merge" any remaining stored indices together. This is not an easy task, and even worse: it's slow since it implicitly depends upon linear indexing.

Fortunately, this is precisely the computation that `ReshapedArray` performs, and it does so linearly if possible. Consequently, `view` ensures that the parent array is the appropriate dimensionality for the given indices by reshaping it if needed. The inner `SubArray` constructor ensures that this invariant is satisfied.

- `CartesianIndex` and arrays thereof throw a nasty wrench into the reindex scheme. Recall that `reindex` simply dispatches on the type of the stored indices in order to determine how many passed indices should be used and where they should go. But with `CartesianIndex`, there's no longer a one-to-one correspondence between the number of passed arguments and the number of dimensions that they index into. If we return to the above example of `Base.reindex(S1, S1.indices, (i, j))`, you can see that the expansion is incorrect for `i, j = CartesianIndex(), CartesianIndex(2,1)`. It should skip the `CartesianIndex()` entirely and return:

```
| (CartesianIndex(2,1)[1], S1.indices[2], S1.indices[3][CartesianIndex(2,1)[2]])
```

Instead, though, we get:

```
| (CartesianIndex(), S1.indices[2], S1.indices[3][CartesianIndex(2,1)])
```

Doing this correctly would require combined dispatch on both the stored and passed indices across all combinations of dimensionalities in an intractable manner. As such, `reindex` must never be called with `CartesianIndex` indices. Fortunately, the scalar case is easily handled by first flattening the `CartesianIndex` arguments to plain integers. Arrays of `CartesianIndex`, however, cannot be split apart into orthogonal pieces so easily. Before attempting to use `reindex`, `view` must ensure that there are no arrays of `CartesianIndex` in the argument list. If there are, it can simply "punt" by avoiding the `reindex` calculation entirely, constructing a nested `SubArray` with two levels of indirection instead.

102.12 isbits Union Optimizations

In Julia, the `Array` type holds both "bits" values as well as heap-allocated "boxed" values. The distinction is whether the value itself is stored inline (in the direct allocated memory of the array), or if the memory of the array is simply a collection of pointers to objects allocated elsewhere. In terms of performance, accessing values inline is clearly an advantage over having to follow a pointer to the actual value. The definition of "isbits" generally means any Julia type with a fixed, determinate size, meaning no "pointer" fields, see `?isbitstype`.

Julia also supports Union types, quite literally the union of a set of types. Custom Union type definitions can be extremely handy for applications wishing to "cut across" the nominal type system (i.e. explicit subtype relationships) and define methods or functionality on these, otherwise unrelated, set of types. A compiler challenge, however, is in determining how to treat these Union types. The naive approach (and indeed, what Julia itself did pre-0.7), is to simply make a "box" and then a pointer in the box to the actual value, similar to the previously mentioned "boxed" values. This is unfortunate, however, because of the number of small, primitive "bits" types (think `UInt8`, `Int32`, `Float64`, etc.) that would easily fit themselves inline in this "box" without needing any indirection for value access. There are two main ways Julia can take advantage of this optimization as of 0.7: `isbits Union` fields in types, and `isbits Union Arrays`.

isbits Union Structs

Julia now includes an optimization wherein "isbits Union" fields in types (`mutable struct`, `struct`, etc.) will be stored inline. This is accomplished by determining the "inline size" of the Union type (e.g. `Union{UInt8, Int16}` will have a size of two bytes, which represents the size needed of the largest Union type `Int16`), and in addition, allocating an extra "type tag byte" (`UInt8`), whose value signals the type of the actual value stored inline of the "Union bytes". The type tag byte value is the index of the actual value's type in the Union type's order of types. For example, a type tag value of `0x02` for a field with type `Union{Nothing, UInt8, Int16}` would indicate that an `Int16` value is stored in the 16 bits of the field in the structure's memory; a `0x01` value would indicate that a `UInt8` value was stored in the first 8 bits of the 16 bits of the field's memory. Lastly, a value of `0x00` signals that the nothing value will be returned for this field, even though, as a singleton type with a single type instance, it technically has a size of 0. The type tag byte for a type's Union field is stored directly after the field's computed Union memory.

isbits Union Arrays

Julia can now also store "isbits Union" values inline in an Array, as opposed to requiring an indirection box. The optimization is accomplished by storing an extra "type tag array" of bytes, one byte per array element, alongside the bytes of the actual array data. This type tag array serves the same function as the type field case: its value signals the type of the actual stored Union value in the array. In terms of layout, a Julia Array can include extra "buffer" space before and after its actual data values, which are tracked in the `a->offset` and `a->maxsize` fields of the `julia_array_t*` type. The "type tag array" is treated exactly as another `julia_array_t*`, but which shares the same `a->offset`, `a->maxsize`, and `a->len` fields. So the formula to access an isbits Union Array's type tag bytes is `a->data + (a->maxsize - a->offset) * a->elsize + a->offset`; i.e. the Array's `a->data` pointer is already shifted by `a->offset`, so correcting for that, we follow the data all the way to the max of what it can hold `a->maxsize`, then adjust by `a->offset` more bytes to account for any present "front buffering" the array might be doing. This layout in particular allows for very efficient resizing operations as the type tag data only ever has to move when the actual array's data has to move.

102.13 System Image Building

Building the Julia system image

Julia ships with a precompiled system image containing the contents of the Base module, named `sys.ji`. This file is also precompiled into a shared library called `sys.{so,dll,dylib}` on as many platforms as possible, so as to give vastly improved startup times. On systems that do not ship with a precompiled system image file, one can be generated from the source files shipped in Julia's `DATAROOTDIR/julia/base` folder.

Julia will by default generate its system image on half of the available system threads. This may be controlled by the `JULIA_IMAGE_THREADS` environment variable.

This operation is useful for multiple reasons. A user may:

- Build a precompiled shared library system image on a platform that did not ship with one, thereby improving startup times.
- Modify Base, rebuild the system image and use the new Base next time Julia is started.
- Include a `userimg.jl` file that includes packages into the system image, thereby creating a system image that has packages embedded into the startup environment.

The `PackageCompiler.jl` package contains convenient wrapper functions to automate this process.

System image optimized for multiple microarchitectures

The system image can be compiled simultaneously for multiple CPU microarchitectures under the same instruction set architecture (ISA). Multiple versions of the same function may be created with minimum dispatch point inserted into shared functions in order to take advantage of different ISA extensions or other microarchitecture features. The version that offers the best performance will be selected automatically at runtime based on available CPU features.

Specifying multiple system image targets

A multi-microarchitecture system image can be enabled by passing multiple targets during system image compilation. This can be done either with the `JULIA_CPU_TARGET` make option or with the `-C` command line option when running the compilation command manually. Multiple targets are separated by `;` in the option string. The syntax for each target is a CPU name followed by multiple features separated by `,`. All features supported by LLVM are supported and a feature can be disabled with a `-` prefix. (`+` prefix is also allowed and ignored to be consistent with LLVM syntax). Additionally, a few special features are supported to control the function cloning behavior.

Note

It is good practice to specify either `clone_all` or `base(<n>)` for every target apart from the first one. This makes it explicit which targets have all functions cloned, and which targets are based on other targets. If this is not done, the default behavior is to not clone every function, and to use the first target's function definition as the fallback when not cloning a function.

1. `clone_all`

By default, only functions that are the most likely to benefit from the microarchitecture features will be cloned. When `clone_all` is specified for a target, however, **all** functions in the system image will be cloned for the target. The negative form `-clone_all` can be used to prevent the built-in heuristic from cloning all functions.

2. `base(<n>)`

Where `<n>` is a placeholder for a non-negative number (e.g. `base(0)`, `base(1)`). By default, a partially cloned (i.e. not `clone_all`) target will use functions from the default target (first one specified) if a function is not cloned. This behavior can be changed by specifying a different base with the `base(<n>)` option. The `n`th target (0-based) will be used as the base target instead of the default (0th) one. The base target has to be either 0 or another `clone_all` target. Specifying a non-`clone_all` target as the base target will cause an error.

3. `opt_size`

This causes the function for the target to be optimized for size when there isn't a significant runtime performance impact. This corresponds to `-Os` GCC and Clang option.

4. `min_size`

This causes the function for the target to be optimized for size that might have a significant runtime performance impact. This corresponds to `-Oz` Clang option.

As an example, at the time of this writing, the following string is used in the creation of the official x86_64 Julia binaries downloadable from julialang.org:

```
| generic;sandybridge,-xsaveopt,clone_all;haswell,-rdrnd,base(1)
```

This creates a system image with three separate targets; one for a generic x86_64 processor, one with a sandybridge ISA (explicitly excluding xsaveopt) that explicitly clones all functions, and one targeting the haswell ISA, based off of the sandybridge sysimg version, and also excluding rdrnd. When a Julia implementation loads the generated sysimg, it will check the host processor for matching CPU capability flags, enabling the highest ISA level possible. Note that the base level (generic) requires the cx16 instruction, which is disabled in some virtualization software and must be enabled for the generic target to be loaded. Alternatively, a sysimg could be generated with the target generic, -cx16 for greater compatibility, however note that this may cause performance and stability problems in some code.

Implementation overview

This is a brief overview of different part involved in the implementation. See code comments for each components for more implementation details.

1. System image compilation

The parsing and cloning decision are done in `src/processor*`. We currently support cloning of function based on the present of loops, simd instructions, or other math operations (e.g. fast-math, fma, muladd). This information is passed on to `src/llvm-multiversioning.cpp` which does the actual cloning. In addition to doing the cloning and insert dispatch slots (see comments in `MultiVersioning::runOnModule` for how this is done), the pass also generates metadata so that the runtime can load and initialize the system image correctly. A detailed description of the metadata is available in `src/processor.h`.

2. System image loading

The loading and initialization of the system image is done in `src/processor*` by parsing the metadata saved during system image generation. Host feature detection and selection decision are done in `src/processor_*.cpp` depending on the ISA. The target selection will prefer exact CPU name match, larger vector register size, and larger number of features. An overview of this process is in `src/processor.cpp`.

102.14 Package Images

Julia package images provide object (native code) caches for Julia packages. They are similar to Julia's [system image](#) and support many of the same features. In fact the underlying serialization format is the same, and the system image is the base image that the package images are build against.

High-level overview

Package images are shared libraries that contain both code and data. Like `.ji` cache files, they are generated per package. The data section contains both global data (global variables in the package) as well as the necessary metadata about what methods and types are defined by the package. The code section contains native objects that cache the final output of Julia's LLVM-based compiler.

The command line option `--pkgimages=no` can be used to turn off object caching for this session. Note that this means that cache files have to likely be regenerated. See [JULIA_MAX_NUM_PRECOMPILE_FILES](#) for the upper limit of variants Julia caches per default.

Note

While the package images present themselves as native shared libraries, they are only an approximation thereof. You will not be able to link against them from a native program and they must be loaded from Julia.

Linking

Since the package images contain native code, we must run a linker over them before we can use them. You can set the environment variable `JULIA_VERBOSE_LINKING` to `true` to make the package image linking process verbose.

Furthermore, we cannot assume that the user has a working system linker installed. Therefore, Julia ships with LLD, the LLVM linker, to provide a working out of the box experience. In `base/linking.jl`, we implement a limited interface to be able to link package images on all supported platforms.

Quirks

Despite LLD being a multi-platform linker, it does not provide a consistent interface across platforms. Furthermore, it is meant to be used from `clang` or another compiler driver, we therefore reimplement some of the logic from `llvm-project/clang/lib/Driver/ToolChains`. Thankfully one can use `lld -flavor` to set `lld` to the right platform

Windows To avoid having to deal with `link.exe` we use `-flavor gnu`, effectively turning `lld` into a cross-linker from a `mingw32` environment. Windows DLLs are required to contain a `_DllMainCRTStartup` function and to minimize our dependence on `mingw32` libraries, we inject a stub definition ourselves.

MacOS Dynamic libraries on macOS need to link against `-lSystem`. On recent macOS versions, `-lSystem` is only available for linking when Xcode is available. To that effect we link with `-undefined dynamic_lookup`.

Package images optimized for multiple microarchitectures

Similar to [multi-versioning](#) for system images, package images support multi-versioning. If you are in a heterogeneous environment, with a unified cache, you can set the environment variable `JULIA_CPU_TARGET=generic` to multi-version the object caches.

Flags that impact package image creation and selection

These are the Julia command line flags that impact cache selection. Package images that were created with different flags will be rejected.

- `-g, --debug-info`: Exact match required since it changes code generation.
- `--check-bounds`: Exact match required since it changes code generation.
- `--inline`: Exact match required since it changes code generation.
- `--pkgimages`: To allow running without object caching enabled.
- `-O, --optimize`: Reject package images generated for a lower optimization level, but allow for higher optimization levels to be loaded.

102.15 Working with LLVM

This is not a replacement for the LLVM documentation, but a collection of tips for working on LLVM for Julia.

Overview of Julia to LLVM Interface

Julia dynamically links against LLVM by default. Build with `USE_LLVM_SHLIB=0` to link statically.

The code for lowering Julia AST to LLVM IR or interpreting it directly is in directory `src/`.

| File | Description |
|---|--|
| <code>aotcompile.cpp</code> | Legacy pass manager pipeline, compiler C-interface entry |
| <code>builtins.c</code> | Builtin functions |
| <code>ccall.cpp</code> | Lowering ccall |
| <code>cgutils.cpp</code> | Lowering utilities, notably for array and tuple accesses |
| <code>codegen.cpp</code> | Top-level of code generation, pass list, lowering builtins |
| <code>debuginfo.cpp</code> | Tracks debug information for JIT code |
| <code>disasm.cpp</code> | Handles native object file and JIT code disassembly |
| <code>gf.c</code> | Generic functions |
| <code>intrinsics.cpp</code> | Lowering intrinsics |
| <code>jitlayers.cpp</code> | JIT-specific code, ORC compilation layers/utilities |
| <code>llvm-alloc-helpers.cpp</code> | Julia-specific escape analysis |
| <code>llvm-alloc-opt.cpp</code> | Custom LLVM pass to demote heap allocations to the stack |
| <code>llvm-cpufeatures.cpp</code> | Custom LLVM pass to lower CPU-based functions (e.g. <code>haveFMA</code>) |
| <code>llvm-demote-float16.cpp</code> | Custom LLVM pass to lower 16b float ops to 32b float ops |
| <code>llvm-final-gc-lowering.cpp</code> | Custom LLVM pass to lower GC calls to their final form |
| <code>llvm-gc-invariant-verifier.cpp</code> | Custom LLVM pass to verify Julia GC invariants |
| <code>llvm-julia-licm.cpp</code> | Custom LLVM pass to hoist/sink Julia-specific intrinsics |
| <code>llvm-late-gc-lowering.cpp</code> | Custom LLVM pass to root GC-tracked values |
| <code>llvm-lower-handlers.cpp</code> | Custom LLVM pass to lower try-catch blocks |
| <code>llvm-muladd.cpp</code> | Custom LLVM pass for fast-match FMA |
| <code>llvm-multiversing.cpp</code> | Custom LLVM pass to generate sysimg code on multiple architectures |
| <code>llvm-propagate-addrspaces.cpp</code> | Custom LLVM pass to canonicalize addrspaces |
| <code>llvm-ptls.cpp</code> | Custom LLVM pass to lower TLS operations |
| <code>llvm-remove-addrspaces.cpp</code> | Custom LLVM pass to remove Julia addrspaces |
| <code>llvm-remove-ni.cpp</code> | Custom LLVM pass to remove Julia non-integral addrspaces |
| <code>llvm-simdloop.cpp</code> | Custom LLVM pass for @simd |
| <code>pipeline.cpp</code> | New pass manager pipeline, pass pipeline parsing |
| <code>sys.c</code> | I/O and operating system utility functions |

Some of the `.cpp` files form a group that compile to a single object.

The difference between an intrinsic and a builtin is that a builtin is a first class function that can be used like any other Julia function. An intrinsic can operate only on unboxed data, and therefore its arguments must be statically typed.

Alias Analysis

Julia currently uses LLVM's [Type Based Alias Analysis](#). To find the comments that document the inclusion relationships, look for `static MDNode*` in `src/codegen.cpp`.

The `-O` option enables LLVM's [Basic Alias Analysis](#).

Building Julia with a different version of LLVM

The default version of LLVM is specified in `deps/llvm.version`. You can override it by creating a file called `Make.user` in the top-level directory and adding a line to it such as:

```
| LLVM_VER = 13.0.0
```

Besides the LLVM release numerals, you can also use `DEPS_GIT = llvm` in combination with `USE_BINARYBUILDER_LLVM = 0` to build against the latest development version of LLVM.

You can also specify to build a debug version of LLVM, by setting either `LLVM_DEBUG = 1` or `LLVM_DEBUG = Release` in your `Make.user` file. The former will be a fully unoptimized build of LLVM and the latter will produce an optimized build of LLVM. Depending on your needs the latter will suffice and it quite a bit faster. If you use `LLVM_DEBUG = Release` you will also want to set `LLVM_ASSERTIONS = 1` to enable diagnostics for different passes. Only `LLVM_DEBUG = 1` implies that option by default.

Passing options to LLVM

You can pass options to LLVM via the environment variable `JULIA_LLVM_ARGS`. Here are example settings using bash syntax:

- `export JULIA_LLVM_ARGS=-print-after-all` dumps IR after each pass.
- `export JULIA_LLVM_ARGS=-debug-only=loop-vectorize` dumps LLVM `DEBUG(...)` diagnostics for loop vectorizer. If you get warnings about "Unknown command line argument", rebuild LLVM with `LLVM_ASSERTIONS = 1`.
- `export JULIA_LLVM_ARGS=-help` shows a list of available options. `export JULIA_LLVM_ARGS=-help-hidden` shows even more.
- `export JULIA_LLVM_ARGS="-fatal-warnings -print-options"` is an example how to use multiple options.

Useful JULIA_LLVM_ARGS parameters

- `-print-after=PASS`: prints the IR after any execution of `PASS`, useful for checking changes done by a pass.
- `-print-before=PASS`: prints the IR before any execution of `PASS`, useful for checking the input to a pass.
- `-print-changed`: prints the IR whenever a pass changes the IR, useful for narrowing down which passes are causing problems.
- `-print-(before|after)=MARKER-PASS`: the Julia pipeline ships with a number of marker passes in the pipeline, which can be used to identify where problems or optimizations are occurring. A marker pass is defined as a pass which appears once in the pipeline and performs no transformations on the

IR, and is only useful for targeting print-before/print-after. Currently, the following marker passes exist in the pipeline:

- BeforeOptimization
 - BeforeEarlySimplification
 - AfterEarlySimplification
 - BeforeEarlyOptimization
 - AfterEarlyOptimization
 - BeforeLoopOptimization
 - BeforeLICM
 - AfterLICM
 - BeforeLoopSimplification
 - AfterLoopSimplification
 - AfterLoopOptimization
 - BeforeScalarOptimization
 - AfterScalarOptimization
 - BeforeVectorization
 - AfterVectorization
 - BeforeIntrinsicLowering
 - AfterIntrinsicLowering
 - BeforeCleanup
 - AfterCleanup
 - AfterOptimization
- -time-passes: prints the time spent in each pass, useful for identifying which passes are taking a long time.
 - -print-module-scope: used in conjunction with -print-(before|after), gets the entire module rather than the IR unit received by the pass
 - -debug: prints out a lot of debugging information throughout LLVM
 - -debug-only=NAME, prints out debugging statements from files with DEBUG_TYPE defined to NAME, useful for getting additional context about a problem

Debugging LLVM transformations in isolation

On occasion, it can be useful to debug LLVM's transformations in isolation from the rest of the Julia system, e.g. because reproducing the issue inside `julia` would take too long, or because one wants to take advantage of LLVM's tooling (e.g. `bugpoint`). To get unoptimized IR for the entire system image, pass the `--output-unopt-bc unopt.bc` option to the system image build process, which will output the unoptimized IR to an `unopt.bc` file. This file can then be passed to LLVM tools as usual. `libjulia` can function as an LLVM pass plugin and can be loaded into LLVM tools, to make julia-specific passes available in this environment. In addition, it exposes the `-julia` meta-pass, which runs the entire Julia pass-pipeline over the IR. As an example, to generate a system image with the old pass manager, one could do:

```
| opt -enable-new-pm=0 -load libjulia-codegen.so -julia -o opt.bc unopt.bc
| llc -o sys.o opt.bc
| cc -shared -o sys.so sys.o
```

To generate a system image with the new pass manager, one could do:

```
| opt -load-pass-plugin=libjulia-codegen.so --passes='julia' -o opt.bc unopt.bc
| llc -o sys.o opt.bc
| cc -shared -o sys.so sys.o
```

This system image can then be loaded by `julia` as usual.

It is also possible to dump an LLVM IR module for just one Julia function, using:

```
| fun, T = +, Tuple{Int,Int} # Substitute your function of interest here
| optimize = false
| open("plus.ll", "w") do file
|     println(file, InteractiveUtils._dump_function(fun, T, false, false, false, true, :att,
| ↪ optimize, :default))
| end
```

These files can be processed the same way as the unoptimized sysimg IR shown above.

Improving LLVM optimizations for Julia

Improving LLVM code generation usually involves either changing Julia lowering to be more friendly to LLVM's passes, or improving a pass.

If you are planning to improve a pass, be sure to read the [LLVM developer policy](#). The best strategy is to create a code example in a form where you can use LLVM's `opt` tool to study it and the pass of interest in isolation.

1. Create an example Julia code of interest.
2. Use `JULIA_LLVM_ARGS=-print-after-all` to dump the IR.
3. Pick out the IR at the point just before the pass of interest runs.
4. Strip the debug metadata and fix up the TBAA metadata by hand.

The last step is labor intensive. Suggestions on a better way would be appreciated.

The jllcall calling convention

Julia has a generic calling convention for unoptimized code, which looks somewhat as follows:

```
| jl_value_t *any_unoptimized_call(jl_value_t *, jl_value_t **, int);
```

where the first argument is the boxed function object, the second argument is an on-stack array of arguments and the third is the number of arguments. Now, we could perform a straightforward lowering and emit an `alloca` for the argument array. However, this would betray the SSA nature of the uses at the call site, making optimizations (including GC root placement), significantly harder. Instead, we emit it as follows:

```
| call %jl_value_t *@julia.call(jl_value_t *(*)(...) @any_unoptimized_call, %jl_value_t *%arg1, %
|   jl_value_t *%arg2)
```

This allows us to retain the SSA-ness of the uses throughout the optimizer. GC root placement will later lower this call to the original C ABI.

GC root placement

GC root placement is done by an LLVM pass late in the pass pipeline. Doing GC root placement this late enables LLVM to make more aggressive optimizations around code that requires GC roots, as well as allowing us to reduce the number of required GC roots and GC root store operations (since LLVM doesn't understand our GC, it wouldn't otherwise know what it is and is not allowed to do with values stored to the GC frame, so it'll conservatively do very little). As an example, consider an error path

```
| if some_condition()
|   #= Use some variables maybe =#
|   error("An error occurred")
| end
```

During constant folding, LLVM may discover that the condition is always false, and can remove the basic block. However, if GC root lowering is done early, the GC root slots used in the deleted block, as well as any values kept alive in those slots only because they were used in the error path, would be kept alive by LLVM. By doing GC root lowering late, we give LLVM the license to do any of its usual optimizations (constant folding, dead code elimination, etc.), without having to worry (too much) about which values may or may not be GC tracked.

However, in order to be able to do late GC root placement, we need to be able to identify a) which pointers are GC tracked and b) all uses of such pointers. The goal of the GC placement pass is thus simple:

Minimize the number of needed GC roots/stores to them subject to the constraint that at every safepoint, any live GC-tracked pointer (i.e. for which there is a path after this point that contains a use of this pointer) is in some GC slot.

Representation

The primary difficulty is thus choosing an IR representation that allows us to identify GC-tracked pointers and their uses, even after the program has been run through the optimizer. Our design makes use of three LLVM features to achieve this:

- Custom address spaces
- Operand Bundles
- Non-integral pointers

Custom address spaces allow us to tag every point with an integer that needs to be preserved through optimizations. The compiler may not insert casts between address spaces that did not exist in the original program and it must never change the address space of a pointer on a load/store/etc operation. This allows us to annotate which pointers are GC-tracked in an optimizer-resistant way. Note that metadata would not be able to achieve the same purpose. Metadata is supposed to always be discardable without altering the

semantics of the program. However, failing to identify a GC-tracked pointer alters the resulting program behavior dramatically - it'll probably crash or return wrong results. We currently use three different address spaces (their numbers are defined in `src/codegen_shared.cpp`):

- **GC Tracked Pointers (currently 10):** These are pointers to boxed values that may be put into a GC frame. It is loosely equivalent to a `j1_value_t*` pointer on the C side. N.B. It is illegal to ever have a pointer in this address space that may not be stored to a GC slot.
- **Derived Pointers (currently 11):** These are pointers that are derived from some GC tracked pointer. Uses of these pointers generate uses of the original pointer. However, they need not themselves be known to the GC. The GC root placement pass **MUST** always find the GC tracked pointer from which this pointer is derived and use that as the pointer to root.
- **Callee Rooted Pointers (currently 12):** This is a utility address space to express the notion of a callee rooted value. All values of this address space **MUST** be storable to a GC root (though it is possible to relax this condition in the future), but unlike the other pointers need not be rooted if passed to a call (they do still need to be rooted if they are live across another safepoint between the definition and the call).
- **Pointers loaded from tracked object (currently 13):** This is used by arrays, which themselves contain a pointer to the managed data. This data area is owned by the array, but is not a GC-tracked object by itself. The compiler guarantees that as long as this pointer is live, the object that this pointer was loaded from will keep being live.

Invariants

The GC root placement pass makes use of several invariants, which need to be observed by the frontend and are preserved by the optimizer.

First, only the following address space casts are allowed:

- **0->{Tracked,Derived,CalleeRooted}:** It is allowable to decay an untracked pointer to any of the others. However, do note that the optimizer has broad license to not root such a value. It is never safe to have a value in address space 0 in any part of the program if it is (or is derived from) a value that requires a GC root.
- **Tracked->Derived:** This is the standard decay route for interior values. The placement pass will look for these to identify the base pointer for any use.
- **Tracked->CalleeRooted:** Addrspace `CalleeRooted` serves merely as a hint that a GC root is not required. However, do note that the `Derived->CalleeRooted` decay is prohibited, since pointers should generally be storable to a GC slot, even in this address space.

Now let us consider what constitutes a use:

- Loads whose loaded values is in one of the address spaces
- Stores of a value in one of the address spaces to a location
- Stores to a pointer in one of the address spaces
- Calls for which a value in one of the address spaces is an operand

- Calls in jllcall ABI, for which the argument array contains a value
- Return instructions.

We explicitly allow load/stores and simple calls in address spaces Tracked/Derived. Elements of jllcall argument arrays must always be in address space Tracked (it is required by the ABI that they are valid `jll_value_t*` pointers). The same is true for return instructions (though note that struct return arguments are allowed to have any of the address spaces). The only allowable use of an address space CalleeRooted pointer is to pass it to a call (which must have an appropriately typed operand).

Further, we disallow `getelementptr` in address space Tracked. This is because unless the operation is a noop, the resulting pointer will not be validly storable to a GC slot and may thus not be in this address space. If such a pointer is required, it should be decayed to address space Derived first.

Lastly, we disallow `inttoptr/ptrtoint` instructions in these address spaces. Having these instructions would mean that some i64 values are really GC tracked. This is problematic, because it breaks that stated requirement that we're able to identify GC-relevant pointers. This invariant is accomplished using the LLVM "non-integral pointers" feature, which is new in LLVM 5.0. It prohibits the optimizer from making optimizations that would introduce these operations. Note we can still insert static constants at JIT time by using `inttoptr` in address space 0 and then decaying to the appropriate address space afterwards.

Supporting `ccall`

One important aspect missing from the discussion so far is the handling of `ccall`. `ccall` has the peculiar feature that the location and scope of a use do not coincide. As an example consider:

```
A = randn(1024)
ccall(:foo, Cvoid, (Ptr{Float64},), A)
```

In lowering, the compiler will insert a conversion from the array to the pointer which drops the reference to the array value. However, we of course need to make sure that the array does stay alive while we're doing the `ccall`. To understand how this is done, first recall the lowering of the above code:

```
return $(Expr(:foreigncall, :(:foo), Cvoid, svec(Ptr{Float64}), 0, :(:ccall), Expr(:foreigncall,
↪ :(:jll_array_ptr), Ptr{Float64}, svec(Any), 0, :(:ccall), :(:A)), :(:A)))
```

The last `:(A)`, is an extra argument list inserted during lowering that informs the code generator which Julia level values need to be kept alive for the duration of this `ccall`. We then take this information and represent it in an "operand bundle" at the IR level. An operand bundle is essentially a fake use that is attached to the call site. At the IR level, this looks like so:

```
call void inttoptr (i64 ... to void (double*)) (double* %5) [ "jll_roots"(%jll_value_t addrspace
(10)* %A) ]
```

The GC root placement pass will treat the `jll_roots` operand bundle as if it were a regular operand. However, as a final step, after the GC roots are inserted, it will drop the operand bundle to avoid confusing instruction selection.

Supporting `pointer_from_objref`

`pointer_from_objref` is special because it requires the user to take explicit control of GC rooting. By our above invariants, this function is illegal, because it performs an address space cast from 10 to 0. However, it can be useful, in certain situations, so we provide a special intrinsic:

```
| declared %jl_value_t *julia.pointer_from_objref(%jl_value_t addrspace(10)*)
```

which is lowered to the corresponding address space cast after GC root lowering. Do note however that by using this intrinsic, the caller assumes all responsibility for making sure that the value in question is rooted. Further this intrinsic is not considered a use, so the GC root placement pass will not provide a GC root for the function. As a result, the external rooting must be arranged while the value is still tracked by the system. I.e. it is not valid to attempt to use the result of this operation to establish a global root - the optimizer may have already dropped the value.

Keeping values alive in the absence of uses

In certain cases it is necessary to keep an object alive, even though there is no compiler-visible use of said object. This may be case for low level code that operates on the memory-representation of an object directly or code that needs to interface with C code. In order to allow this, we provide the following intrinsics at the LLVM level:

```
| token @llvm.julia.gc_preserve_begin(...)
| void @llvm.julia.gc_preserve_end(token)
```

(The `llvm.` in the name is required in order to be able to use the token type). The semantics of these intrinsics are as follows: At any safepoint that is dominated by a `gc_preserve_begin` call, but that is not not dominated by a corresponding `gc_preserve_end` call (i.e. a call whose argument is the token returned by a `gc_preserve_begin` call), the values passed as arguments to that `gc_preserve_begin` will be kept live. Note that the `gc_preserve_begin` still counts as a regular use of those values, so the standard lifetime semantics will ensure that the values will be kept alive before entering the preserve region.

102.16 `printf()` and `stdio` in the Julia runtime**Libuv wrappers for `stdio`**

`julia.h` defines `libuv` wrappers for the `stdio.h` streams:

```
| uv_stream_t *JL_STDIN;
| uv_stream_t *JL_STDOUT;
| uv_stream_t *JL_STDERR;
```

... and corresponding output functions:

```
| int jl_printf(uv_stream_t *s, const char *format, ...);
| int jl_vprintf(uv_stream_t *s, const char *format, va_list args);
```

These `printf` functions are used by the `.c` files in the `src/` and `cli/` directories wherever `stdio` is needed to ensure that output buffering is handled in a unified way.

In special cases, like signal handlers, where the full `libuv` infrastructure is too heavy, `jl_safe_printf()` can be used to `write(2)` directly to `STDERR_FILENO`:

```
| void jl_safe_printf(const char *str, ...);
```

Interface between JL_STD* and Julia code

`Base.stdin`, `Base.stdout` and `Base.stderr` are bound to the JL_STD* libuv streams defined in the runtime.

Julia's `__init__()` function (in `base/sysimg.jl`) calls `reinit_stdio()` (in `base/stream.jl`) to create Julia objects for `Base.stdin`, `Base.stdout` and `Base.stderr`.

`reinit_stdio()` uses `ccall` to retrieve pointers to JL_STD* and calls `jl_uv_handle_type()` to inspect the type of each stream. It then creates a Julia `Base.IOStream`, `Base.TTY` or `Base.PipeEndpoint` object to represent each stream, e.g.:

```
$ julia -e 'println(typeof((stdin, stdout, stderr)))'
Tuple{Base.TTY,Base.TTY,Base.TTY}

$ julia -e 'println(typeof((stdin, stdout, stderr)))' < /dev/null 2>/dev/null
Tuple{IOStream,Base.TTY,IOStream}

$ echo hello | julia -e 'println(typeof((stdin, stdout, stderr)))' | cat
Tuple{Base.PipeEndpoint,Base.PipeEndpoint,Base.TTY}
```

The `Base.read` and `Base.write` methods for these streams use `ccall` to call libuv wrappers in `src/jl_uv.c`, e.g.:

```
stream.jl: function write(s::IO, p::Ptr, nb::Integer)
               -> ccall(:jl_uv_write, ...)
jl_uv.c:      -> int jl_uv_write(uv_stream_t *stream, ...)
               -> uv_write(uvw, stream, buf, ...)
```

printf() during initialization

The libuv streams relied upon by `jl_printf()` etc., are not available until midway through initialization of the runtime (see `init.c`, `init_stdio()`). Error messages or warnings that need to be printed before this are routed to the standard C library `fwrite()` function by the following mechanism:

In `sys.c`, the JL_STD* stream pointers are statically initialized to integer constants: `STD*_FILENO` (0, 1 and 2). In `jl_uv.c` the `jl_uv_puts()` function checks its `uv_stream_t*` stream argument and calls `fwrite()` if stream is set to `STDOUT_FILENO` or `STDERR_FILENO`.

This allows for uniform use of `jl_printf()` throughout the runtime regardless of whether or not any particular piece of code is reachable before initialization is complete.

Legacy ios.c library

The `src/support/ios.c` library is inherited from [femtolisp](#). It provides cross-platform buffered file IO and in-memory temporary buffers.

`ios.c` is still used by:

- `src/flisp/*.c`
- `src/dump.c` – for serialization file IO and for memory buffers.
- `src/staticdata.c` – for serialization file IO and for memory buffers.

- `base/iostream.jl` – for file IO (see `base/fs.jl` for libuv equivalent).

Use of `ios.c` in these modules is mostly self-contained and separated from the libuv I/O system. However, there is [one place](#) where `femtolisp` calls through to `jl_printf()` with a legacy `ios_t` stream.

There is a hack in `ios.h` that makes the `ios_t.bm` field line up with the `uv_stream_t.type` and ensures that the values used for `ios_t.bm` do not overlap with valid `UV_HANDLE_TYPE` values. This allows `uv_stream_t` pointers to point to `ios_t` streams.

This is needed because `jl_printf()` caller `jl_static_show()` is passed an `ios_t` stream by `femtolisp`'s `fl_print()` function. Julia's `jl_uv_puts()` function has special handling for this:

```
if (stream->type > UV_HANDLE_TYPE_MAX) {
    return ios_write((ios_t*)stream, str, n);
}
```

102.17 Bounds checking

Like many modern programming languages, Julia uses bounds checking to ensure program safety when accessing arrays. In tight inner loops or other performance critical situations, you may wish to skip these bounds checks to improve runtime performance. For instance, in order to emit vectorized (SIMD) instructions, your loop body cannot contain branches, and thus cannot contain bounds checks. Consequently, Julia includes an `@inbounds(...)` macro to tell the compiler to skip such bounds checks within the given block. User-defined array types can use the `@boundscheck(...)` macro to achieve context-sensitive code selection.

Eliding bounds checks

The `@boundscheck(...)` macro marks blocks of code that perform bounds checking. When such blocks are inlined into an `@inbounds(...)` block, the compiler may remove these blocks. The compiler removes the `@boundscheck` block only if it is inlined into the calling function. For example, you might write the method `sum` as:

```
function sum(A::AbstractArray)
    r = zero(eltype(A))
    for i in eachindex(A)
        @inbounds r += A[i]
    end
    return r
end
```

With a custom array-like type `MyArray` having:

```
@inline getindex(A::MyArray, i::Real) = (@boundscheck checkbounds(A, i); A.data[to_index(i)])
```

Then when `getindex` is inlined into `sum`, the call to `checkbounds(A, i)` will be elided. If your function contains multiple layers of inlining, only `@boundscheck` blocks at most one level of inlining deeper are eliminated. The rule prevents unintended changes in program behavior from code further up the stack.

Caution!

It is easy to accidentally expose unsafe operations with `@inbounds`. You might be tempted to write the above example as

```
function sum(A::AbstractArray)
    r = zero(eltype(A))
    for i in 1:length(A)
        @inbounds r += A[i]
    end
    return r
end
```

Which quietly assumes 1-based indexing and therefore exposes unsafe memory access when used with `OffsetArrays`:

```
julia> using OffsetArrays

julia> sum(OffsetArray([1, 2, 3], -10))
9164911648 # inconsistent results or segfault
```

While the original source of the error here is `1:length(A)`, the use of `@inbounds` increases the consequences from a bounds error to a less easily caught and debugged unsafe memory access. It is often difficult or impossible to prove that a method which uses `@inbounds` is safe, so one must weigh the benefits of performance improvements against the risk of segfaults and silent misbehavior, especially in public facing APIs.

Propagating inbounds

There may be certain scenarios where for code-organization reasons you want more than one layer between the `@inbounds` and `@boundscheck` declarations. For instance, the default `getindex` methods have the chain `getindex(A::AbstractArray, i::Real)` calls `getindex(IndexStyle(A), A, i)` calls `_getindex(::IndexLinear, A, i)`.

To override the "one layer of inlining" rule, a function may be marked with `Base.@propagate_inbounds` to propagate an inbounds context (or out of bounds context) through one additional layer of inlining.

The bounds checking call hierarchy

The overall hierarchy is:

- `checkbounds(A, I...)` which calls
 - `checkbounds(Bool, A, I...)` which calls
 - * `checkbounds_indices(Bool, axes(A), I)` which recursively calls
 - `checkindex` for each dimension

Here `A` is the array, and `I` contains the "requested" indices. `axes(A)` returns a tuple of "permitted" indices of `A`.

`checkbounds(A, I...)` throws an error if the indices are invalid, whereas `checkbounds{Bool}(A, I...)` returns `false` in that circumstance. `checkbounds_indices` discards any information about the array other than its axes tuple, and performs a pure indices-vs-indices comparison: this allows relatively few compiled methods to serve a huge variety of array types. Indices are specified as tuples, and are usually compared in a 1-1 fashion with individual dimensions handled by calling another important function, `checkindex`: typically,

```
| checkbounds_indices{Bool}(IA1, IA...), (I1, I...)) = checkindex{Bool}(IA1, I1) &
|                                     checkbounds_indices{Bool}(IA, I)
```

so `checkindex` checks a single dimension. All of these functions, including the unexported `checkbounds_indices` have docstrings accessible with `? .`

If you have to customize bounds checking for a specific array type, you should specialize `checkbounds{Bool}(A, I...)`. However, in most cases you should be able to rely on `checkbounds_indices` as long as you supply useful axes for your array type.

If you have novel index types, first consider specializing `checkindex`, which handles a single index for a particular dimension of an array. If you have a custom multidimensional index type (similar to `CartesianIndex`), then you may have to consider specializing `checkbounds_indices`.

Note this hierarchy has been designed to reduce the likelihood of method ambiguities. We try to make `checkbounds` the place to specialize on array type, and try to avoid specializations on index types; conversely, `checkindex` is intended to be specialized only on index type (especially, the last argument).

Emit bounds checks

Julia can be launched with `--check-bounds={yes|no|auto}` to emit bounds checks always, never, or respect `@inbounds` declarations.

102.18 Proper maintenance and care of multi-threading locks

The following strategies are used to ensure that the code is dead-lock free (generally by addressing the 4th Coffman condition: circular wait).

1. structure code such that only one lock will need to be acquired at a time
2. always acquire shared locks in the same order, as given by the table below
3. avoid constructs that expect to need unrestricted recursion

Locks

Below are all of the locks that exist in the system and the mechanisms for using them that avoid the potential for deadlocks (no Ostrich algorithm allowed here):

The following are definitely leaf locks (level 1), and must not try to acquire any other lock:

- safepoint

Note that this lock is acquired implicitly by `JL_LOCK` and `JL_UNLOCK`. use the `_NOGC` variants to avoid that for level 1 locks.

While holding this lock, the code must not do any allocation or hit any safe-points. Note that there are safepoints when doing allocation, enabling / disabling GC, entering / restoring exception frames, and taking / releasing locks.

- `shared_map`
- `finalizers`
- `pagealloc`
- `gcpermlock`
- `flisp`
- `jlinstackwalk` (Win32)
- `ResourcePool{<?>::mutex`
- `RLST_mutex`
- `jllockedstream::mutex`
- `debuginfo_asynsafe`
- `inferencetimingmutex`
- `ExecutionEngine::SessionLock`

`flisp` itself is already threadsafe, this lock only protects the `j1_ast_context_list_t` pool likewise, the `ResourcePool{<?>::mutexes` just protect the associated resource pool

The following is a leaf lock (level 2), and only acquires level 1 locks (safepoint) internally:

- `typecache`
- `Module->lock`
- `JLDebuginfoPlugin::PluginMutex`
- `newlyinferredmutex`

The following is a level 3 lock, which can only acquire level 1 or level 2 locks internally:

- `Method->>writelock`

The following is a level 4 lock, which can only recurse to acquire level 1, 2, or 3 locks:

- `MethodTable->>writelock`

No Julia code may be called while holding a lock above this point.

`orc::ThreadSafeContext` (TSCtx) locks occupy a special spot in the locking hierarchy. They are used to protect LLVM's global non-threadsafe state, but there may be an arbitrary number of them. By default, all of these locks may be treated as level 5 locks for the purposes of comparing with the rest of the hierarchy. Acquiring a TSCtx should only be done from the JIT's pool of TSCtx's, and all locks on that TSCtx should be released prior to returning it to the pool. If multiple TSCtx locks must be acquired at the same time (due to recursive compilation), then locks should be acquired in the order that the TSCtxs were borrowed from the pool.

The following is a level 5 lock

- JuliaOJIT::EmissionMutex

The following are a level 6 lock, which can only recurse to acquire locks at lower levels:

- codegen
- jlmodulesmutex

The following is an almost root lock (level end-1), meaning only the root lock may be held when trying to acquire it:

- typeinf
 - this one is perhaps one of the most tricky ones, since type-inference can be invoked from many points
 - currently the lock is merged with the codegen lock, since they call each other recursively

The following lock synchronizes IO operation. Be aware that doing any I/O (for example, printing warning messages or debug information) while holding any other lock listed above may result in pernicious and hard-to-find deadlocks. BE VERY CAREFUL!

- iolock
- Individual ThreadSynchronizers locks
 - this may continue to be held after releasing the iolock, or acquired without it, but be very careful to never attempt to acquire the iolock while holding it

The following is the root lock, meaning no other lock shall be held when trying to acquire it:

- toplevel
 - this should be held while attempting a top-level action (such as making a new type or defining a new method): trying to obtain this lock inside a staged function will cause a deadlock condition!
 - additionally, it's unclear if any code can safely run in parallel with an arbitrary toplevel expression, so it may require all threads to get to a safepoint first

Broken Locks

The following locks are broken:

- toplevel
 - doesn't exist right now
 - fix: create it
- Module->lock

This is vulnerable to deadlocks since it can't be certain it is acquired in sequence. Some operations (such as `import_module`) are missing a lock.

fix: replace with `jl_modules_mutex`?

- `loading.jl`: `require` and `register_root_module`

This file potentially has numerous problems.

fix: needs locks

Shared Global Data Structures

These data structures each need locks due to being shared mutable global state. It is the inverse list for the above lock priority list. This list does not include level 1 leaf resources due to their simplicity.

MethodTable modifications (`def`, `cache`) : MethodTable->writelock

Type declarations : toplevel lock

Type application : typecache lock

Global variable tables : Module->lock

Module serializer : toplevel lock

JIT & type-inference : codegen lock

MethodInstance/CodeInstance updates : Method->writelock, codegen lock

- These are set at construction and immutable:
 - `specTypes`
 - `sparam_vals`
 - `def`
- These are set by `jl_type_infer` (while holding codegen lock):
 - `cache`
 - `retype`
 - `inferred`

| * valid ages

- `inInference` flag:
 - optimization to quickly avoid recurring into `jl_type_infer` while it is already running
 - actual state (of setting `inferred`, then `fptr`) is protected by codegen lock
- Function pointers:
 - these transition once, from `NULL` to a value, while the codegen lock is held
- Code-generator cache (the contents of `functionObjectsDecls`):

- these can transition multiple times, but only while the codegen lock is held
- it is valid to use old version of this, or block for new versions of this, so races are benign, as long as the code is careful not to reference other data in the method instance (such as `rettype`) and assume it is coordinated, unless also holding the codegen lock

LLVMContext : codegen lock

Method : Method->writelock

- roots array (serializer and codegen)
- invoke / specializations / tfunc modifications

102.19 Arrays with custom indices

Conventionally, Julia's arrays are indexed starting at 1, whereas some other languages start numbering at 0, and yet others (e.g., Fortran) allow you to specify arbitrary starting indices. While there is much merit in picking a standard (i.e., 1 for Julia), there are some algorithms which simplify considerably if you can index outside the range `1:size(A,d)` (and not just `0:size(A,d)-1`, either). To facilitate such computations, Julia supports arrays with arbitrary indices.

The purpose of this page is to address the question, "what do I have to do to support such arrays in my own code?" First, let's address the simplest case: if you know that your code will never need to handle arrays with unconventional indexing, hopefully the answer is "nothing." Old code, on conventional arrays, should function essentially without alteration as long as it was using the exported interfaces of Julia. If you find it more convenient to just force your users to supply traditional arrays where indexing starts at one, you can add

```
| Base.require_one_based_indexing(arrays...)
```

where `arrays...` is a list of the array objects that you wish to check for anything that violates 1-based indexing.

Generalizing existing code

As an overview, the steps are:

- replace many uses of `size` with `axes`
- replace `1:length(A)` with `eachindex(A)`, or in some cases `LinearIndices(A)`
- replace explicit allocations like `Array{Int}(undef, size(B))` with `similar(Array{Int}, axes(B))`

These are described in more detail below.

Things to watch out for

Because unconventional indexing breaks many people's assumptions that all arrays start indexing with 1, there is always the chance that using such arrays will trigger errors. The most frustrating bugs would be incorrect results or segfaults (total crashes of Julia). For example, consider the following function:

```
function mycopy!(dest::AbstractVector, src::AbstractVector)
    length(dest) == length(src) || throw(DimensionMismatch("vectors must match"))
    # OK, now we're safe to use @inbounds, right? (not anymore!)
    for i = 1:length(src)
        @inbounds dest[i] = src[i]
    end
    dest
end
```

This code implicitly assumes that vectors are indexed from 1; if `dest` starts at a different index than `src`, there is a chance that this code would trigger a segfault. (If you do get segfaults, to help locate the cause try running julia with the option `--check-bounds=yes`.)

Using axes for bounds checks and loop iteration

`axes(A)` (reminiscent of `size(A)`) returns a tuple of `AbstractUnitRange{<:Integer}` objects, specifying the range of valid indices along each dimension of `A`. When `A` has unconventional indexing, the ranges may not start at 1. If you just want the range for a particular dimension `d`, there is `axes(A, d)`.

Base implements a custom range type, `OneTo`, where `OneTo(n)` means the same thing as `1:n` but in a form that guarantees (via the type system) that the lower index is 1. For any new `AbstractArray` type, this is the default returned by `axes`, and it indicates that this array type uses "conventional" 1-based indexing.

For bounds checking, note that there are dedicated functions `checkbounds` and `checkindex` which can sometimes simplify such tests.

Linear indexing (`LinearIndices`)

Some algorithms are most conveniently (or efficiently) written in terms of a single linear index, `A[i]` even if `A` is multi-dimensional. Regardless of the array's native indices, linear indices always range from `1:length(A)`. However, this raises an ambiguity for one-dimensional arrays (a.k.a., `AbstractVector`): does `v[i]` mean linear indexing, or Cartesian indexing with the array's native indices?

For this reason, your best option may be to iterate over the array with `eachindex(A)`, or, if you require the indices to be sequential integers, to get the index range by calling `LinearIndices(A)`. This will return `axes(A, 1)` if `A` is an `AbstractVector`, and the equivalent of `1:length(A)` otherwise.

By this definition, 1-dimensional arrays always use Cartesian indexing with the array's native indices. To help enforce this, it's worth noting that the index conversion functions will throw an error if `shape` indicates a 1-dimensional array with unconventional indexing (i.e., is a `Tuple{UnitRange}` rather than a tuple of `OneTo`). For arrays with conventional indexing, these functions continue to work the same as always.

Using `axes` and `LinearIndices`, here is one way you could rewrite `mycopy!`:

```
function mycopy!(dest::AbstractVector, src::AbstractVector)
    axes(dest) == axes(src) || throw(DimensionMismatch("vectors must match"))
    for i in LinearIndices(src)
```

```

        @inbounds dest[i] = src[i]
    end
    dest
end

```

Allocating storage using generalizations of similar

Storage is often allocated with `Array{Int}(undef, dims)` or `similar(A, args...)`. When the result needs to match the indices of some other array, this may not always suffice. The generic replacement for such patterns is to use `similar(storagetype, shape)`. `storagetype` indicates the kind of underlying "conventional" behavior you'd like, e.g., `Array{Int}` or `BitArray` or even `dims->zeros(Float32, dims)` (which would allocate an all-zeros array). `shape` is a tuple of `Integer` or `AbstractUnitRange` values, specifying the indices that you want the result to use. Note that a convenient way of producing an all-zeros array that matches the indices of `A` is simply `zeros(A)`.

Let's walk through a couple of explicit examples. First, if `A` has conventional indices, then `similar(Array{Int}, axes(A))` would end up calling `Array{Int}(undef, size(A))`, and thus return an array. If `A` is an `AbstractArray` type with unconventional indexing, then `similar(Array{Int}, axes(A))` should return something that "behaves like" an `Array{Int}` but with a shape (including indices) that matches `A`. (The most obvious implementation is to allocate an `Array{Int}(undef, size(A))` and then "wrap" it in a type that shifts the indices.)

Note also that `similar(Array{Int}, (axes(A, 2),))` would allocate an `AbstractVector{Int}` (i.e., 1-dimensional array) that matches the indices of the columns of `A`.

Writing custom array types with non-1 indexing

Most of the methods you'll need to define are standard for any `AbstractArray` type, see [Abstract Arrays](#). This page focuses on the steps needed to define unconventional indexing.

Custom AbstractUnitRange types

If you're writing a non-1 indexed array type, you will want to specialize `axes` so it returns a `UnitRange`, or (perhaps better) a custom `AbstractUnitRange`. The advantage of a custom type is that it "signals" the allocation type for functions like `similar`. If we're writing an array type for which indexing will start at 0, we likely want to begin by creating a new `AbstractUnitRange`, `ZeroRange`, where `ZeroRange(n)` is equivalent to `0:n-1`.

In general, you should probably not export `ZeroRange` from your package: there may be other packages that implement their own `ZeroRange`, and having multiple distinct `ZeroRange` types is (perhaps counterintuitively) an advantage: `ModuleA.ZeroRange` indicates that `similar` should create a `ModuleA.ZeroArray`, whereas `ModuleB.ZeroRange` indicates a `ModuleB.ZeroArray` type. This design allows peaceful coexistence among many different custom array types.

Note that the Julia package [CustomUnitRanges.jl](#) can sometimes be used to avoid the need to write your own `ZeroRange` type.

Specializing axes

Once you have your `AbstractUnitRange` type, then specialize `axes`:

```

Base.axes(A::ZeroArray) = map(n->ZeroRange(n), A.size)

```

where here we imagine that `ZeroArray` has a field called `size` (there would be other ways to implement this).

In some cases, the fallback definition for `axes(A, d)`:

```
| axes(A::AbstractArray{T,N}, d) where {T,N} = d <= N ? axes(A)[d] : OneTo(1)
```

may not be what you want: you may need to specialize it to return something other than `OneTo(1)` when `d > ndims(A)`. Likewise, in `Base` there is a dedicated function `axes1` which is equivalent to `axes(A, 1)` but which avoids checking (at runtime) whether `ndims(A) > 0`. (This is purely a performance optimization.) It is defined as:

```
| axes1(A::AbstractArray{T,0}) where {T} = OneTo(1)
| axes1(A::AbstractArray) = axes(A)[1]
```

If the first of these (the zero-dimensional case) is problematic for your custom array type, be sure to specialize it appropriately.

Specializing `similar`

Given your custom `ZeroRange` type, then you should also add the following two specializations for `similar`:

```
| function Base.similar(A::AbstractArray, T::Type, shape::Tuple{ZeroRange,Vararg{ZeroRange}})
|     # body
| end
|
| function Base.similar(f::Union{Function,DataType}, shape::Tuple{ZeroRange,Vararg{ZeroRange}})
|     # body
| end
```

Both of these should allocate your custom array type.

Specializing `reshape`

Optionally, define a method

```
| Base.reshape(A::AbstractArray, shape::Tuple{ZeroRange,Vararg{ZeroRange}}) = ...
```

and you can reshape an array so that the result has custom indices.

For objects that mimic `AbstractArray` but are not subtypes

`has_offset_axes` depends on having `axes` defined for the objects you call it on. If there is some reason you don't have an `axes` method defined for your object, consider defining a method

```
| Base.has_offset_axes(obj::MyNon1IndexedArraylikeObject) = true
```

This will allow code that assumes 1-based indexing to detect a problem and throw a helpful error, rather than returning incorrect results or segfaulting julia.

Catching errors

If your new array type triggers errors in other code, one helpful debugging step can be to comment out `@boundscheck` in your `getindex` and `setindex!` implementation. This will ensure that every element access checks bounds. Or, restart julia with `--check-bounds=yes`.

In some cases it may also be helpful to temporarily disable `size` and `length` for your new array type, since code that makes incorrect assumptions frequently uses these functions.

102.20 Module loading

`Base.require` is responsible for loading modules and it also manages the precompilation cache. It is the implementation of the `import` statement.

Experimental features

The features below are experimental and not part of the stable Julia API. Before building upon them inform yourself about the current thinking and whether they might change soon.

Module loading callbacks

It is possible to listen to the modules loaded by `Base.require`, by registering a callback.

```
loaded_packages = Channel{Symbol}()
callback = (mod::Symbol) -> put!(loaded_packages, mod)
push!(Base.package_callbacks, callback)
```

Please note that the symbol given to the callback is a non-unique identifier and it is the responsibility of the callback provider to walk the module chain to determine the fully qualified name of the loaded binding.

The callback below is an example of how to do that:

```
# Get the fully-qualified name of a module.
function module_fqn(name::Symbol)
    fqn = fullname(Base.root_module(name))
    return join(fqn, '.')
end
```

102.21 Inference

How inference works

In Julia compiler, "type inference" refers to the process of deducing the types of later values from the types of input values. Julia's approach to inference has been described in the blog posts below:

1. Shows a simplified implementation of the data-flow analysis algorithm, that Julia's type inference routine is based on.
2. Gives a high level view of inference with a focus on its inter-procedural convergence guarantee.
3. Explains a refinement on the algorithm introduced in 2.

Debugging compiler.jl

You can start a Julia session, edit `compiler/*.jl` (for example to insert print statements), and then replace `Core.Compiler` in your running session by navigating to base and executing `include("compiler/compiler.jl")`. This trick typically leads to much faster development than if you rebuild Julia for each change.

Alternatively, you can use the [Revise.jl](#) package to track the compiler changes by using the command `Revise.track(Core.Compiler)` at the beginning of your Julia session. As explained in the [Revise documentation](#), the modifications to the compiler will be reflected when the modified files are saved.

A convenient entry point into inference is `typeinf_code`. Here's a demo running inference on `convert(Int, UInt(1))`:

```
# Get the method
atypes = Tuple{Type{Int}, UInt} # argument types
mths = methods(convert, atypes) # worth checking that there is only one
m = first(mths)

# Create variables needed to call `typeinf_code`
interp = Core.Compiler.NativeInterpreter()
spams = Core.svec() # this particular method doesn't have type-parameters
optimize = true # run all inference optimizations
types = Tuple{typeof(convert), atypes.parameters...} # Tuple{typeof(convert), Type{Int}, UInt}
Core.Compiler.typeinf_code(interp, m, types, spams, optimize)
```

If your debugging adventures require a `MethodInstance`, you can look it up by calling `Core.Compiler.specialize_method` using many of the variables above. A `CodeInfo` object may be obtained with

```
# Returns the CodeInfo object for `convert(Int, ::UInt)`:
ci = (@code_typed convert(Int, UInt(1)))[1]
```

The inlining algorithm (`inline_worthy`)

Much of the hardest work for inlining runs in `ssa_inlining_pass!`. However, if your question is "why didn't my function inline?" then you will most likely be interested in `inline_worthy`, which makes a decision to inline the function call or not.

`inline_worthy` implements a cost-model, where "cheap" functions get inlined; more specifically, we inline functions if their anticipated run-time is not large compared to the time it would take to [issue a call](#) to them if they were not inlined. The cost-model is extremely simple and ignores many important details: for example, all for loops are analyzed as if they will be executed once, and the cost of an `if...else...end` includes the summed cost of all branches. It's also worth acknowledging that we currently lack a suite of functions suitable for testing how well the cost model predicts the actual run-time cost, although [BaseBenchmarks](#) provides a great deal of indirect information about the successes and failures of any modification to the inlining algorithm.

The foundation of the cost-model is a lookup table, implemented in `add_tfunc` and its callers, that assigns an estimated cost (measured in CPU cycles) to each of Julia's intrinsic functions. These costs are based on [standard ranges for common architectures](#) (see [Agner Fog's analysis](#) for more detail).

We supplement this low-level lookup table with a number of special cases. For example, an `:invoke` expression (a call for which all input and output types were inferred in advance) is assigned a fixed cost (currently 20 cycles). In contrast, a `:call` expression, for functions other than intrinsics/builtins, indicates that the

call will require dynamic dispatch, in which case we assign a cost set by `Params.inline_nonleaf_penalty` (currently set at 1000). Note that this is not a "first-principles" estimate of the raw cost of dynamic dispatch, but a mere heuristic indicating that dynamic dispatch is extremely expensive.

Each statement gets analyzed for its total cost in a function called `statement_cost`. You can display the cost associated with each statement as follows:

```
julia> Base.print_statement_costs(stdout, map, (typeof(sqrt), Tuple{Int},)) # map(sqrt, (2,))
map(f, t::Tuple{Any}) @ Base tuple.jl:273
 0 1 - %1 = Base.getfield(_3, 1, true)::Int64
 1 |   %2 = Base.sitofp(Float64, %1)::Float64
 2 |   %3 = Base.lt_float(%2, 0.0)::Bool
 0 |     goto #3 if not %3
 0 2 -     invoke Base.Math.throw_complex_domainerror(:sqrt::Symbol, %2::Float64)::Union{}
 0 |     unreachable
20 3 - %7 = Base.Math.sqrt_llvm(%2)::Float64
 0 |     goto #4
 0 4 -     goto #5
 0 5 - %10 = Core.tuple(%7)::Tuple{Float64}
 0 |     return %10
```

The line costs are in the left column. This includes the consequences of inlining and other forms of optimization.

102.22 Julia SSA-form IR

Background

Beginning in Julia 0.7, parts of the compiler use a new [SSA-form](#) intermediate representation (IR). Historically, the compiler would directly generate LLVM IR from a lowered form of the Julia AST. This form had most syntactic abstractions removed, but still looked a lot like an abstract syntax tree. Over time, in order to facilitate optimizations, SSA values were introduced to this IR and the IR was linearized (i.e. turned into a form where function arguments could only be SSA values or constants). However, non-SSA values (slots) remained in the IR due to the lack of Phi nodes in the IR (necessary for back-edges and re-merging of conditional control flow). This negated much of the usefulness of SSA form representation when performing middle end optimizations. Some heroic effort was put into making these optimizations work without a complete SSA form representation, but the lack of such a representation ultimately proved prohibitive.

New IR nodes

With the new IR representation, the compiler learned to handle four new IR nodes, Phi nodes, Pi nodes as well as PhiC nodes and Upsilon nodes (the latter two are only used for exception handling).

Phi nodes and Pi nodes

Phi nodes are part of generic SSA abstraction (see the link above if you're not familiar with the concept). In the Julia IR, these nodes are represented as:

```
struct PhiNode
    edges::Vector{Int32}
    values::Vector{Any}
end
```

where we ensure that both vectors always have the same length. In the canonical representation (the one handled by codegen and the interpreter), the edge values indicate come-from statement numbers (i.e. if edge has an entry of 15, there must be a goto, gotoifnot or implicit fall through from statement 15 that targets this phi node). Values are either SSA values or constants. It is also possible for a value to be unassigned if the variable was not defined on this path. However, undefinedness checks get explicitly inserted and represented as booleans after middle end optimizations, so code generators may assume that any use of a Phi node will have an assigned value in the corresponding slot. It is also legal for the mapping to be incomplete, i.e. for a Phi node to have missing incoming edges. In that case, it must be dynamically guaranteed that the corresponding value will not be used.

PiNodes encode statically proven information that may be implicitly assumed in basic blocks dominated by a given pi node. They are conceptually equivalent to the technique introduced in the paper [ABCD: Eliminating Array Bounds Checks on Demand](#) or the predicate info nodes in LLVM. To see how they work, consider, e.g.

```
%x::Union{Int, Float64} # %x is some Union{Int, Float64} typed ssa value
if isa(x, Int)
    # use x
else
    # use x
end
```

We can perform predicate insertion and turn this into:

```
%x::Union{Int, Float64} # %x is some Union{Int, Float64} typed ssa value
if isa(x, Int)
    %x_int = PiNode(x, Int)
    # use %x_int
else
    %x_float = PiNode(x, Float64)
    # use %x_float
end
```

Pi nodes are generally ignored in the interpreter, since they don't have any effect on the values, but they may sometimes lead to code generation in the compiler (e.g. to change from an implicitly union split representation to a plain unboxed representation). The main usefulness of PiNodes stems from the fact that path conditions of the values can be accumulated simply by def-use chain walking that is generally done for most optimizations that care about these conditions anyway.

PhiC nodes and Upsilon nodes

Exception handling complicates the SSA story moderately, because exception handling introduces additional control flow edges into the IR across which values must be tracked. One approach to do so, which is followed by LLVM, is to make calls which may throw exceptions into basic block terminators and add an explicit control flow edge to the catch handler:

```
invoke @function_that_may_throw() to label %regular unwind to %catch

regular:
# Control flow continues here
```

```
catch:
# Exceptions go here
```

However, this is problematic in a language like Julia, where at the start of the optimization pipeline, we do not know which calls throw. We would have to conservatively assume that every call (which in Julia is every statement) throws. This would have several negative effects. On the one hand, it would essentially reduce the scope of every basic block to a single call, defeating the purpose of having operations be performed at the basic block level. On the other hand, every catch basic block would have $n \cdot m$ phi node arguments (n , the number of statements in the critical region, m the number of live values through the catch block).

To work around this, we use a combination of Upsilon and PhiC nodes (the C standing for catch, written ϕ^c in the IR pretty printer, because unicode subscript c is not available). There are several ways to think of these nodes, but perhaps the easiest is to think of each PhiC as a load from a unique store-many, read-once slot, with Upsilon being the corresponding store operation. The PhiC has an operand list of all the Upsilon nodes that store to its implicit slot. The Upsilon nodes however, do not record which PhiC node they store to. This is done for more natural integration with the rest of the SSA IR. E.g. if there are no more uses of a PhiC node, it is safe to delete it, and the same is true of an Upsilon node. In most IR passes, PhiC nodes can be treated like Phi nodes. One can follow use-def chains through them, and they can be lifted to new PhiC nodes and new Upsilon nodes (in the same places as the original Upsilon nodes). The result of this scheme is that the number of Upsilon nodes (and PhiC arguments) is proportional to the number of assigned values to a particular variable (before SSA conversion), rather than the number of statements in the critical region.

To see this scheme in action, consider the function

```
@noinline opaque() = invokelatest(identity, nothing) # Something opaque
function foo()
    local y
    x = 1
    try
        y = 2
        opaque()
        y = 3
        error()
    catch
    end
    (x, y)
end
```

The corresponding IR (with irrelevant types stripped) is:

```
1 -      nothing::Nothing
2 - %2  = $(Expr(:enter, #4))
3 - %3  =  $\Upsilon$  (false)|
      %4  =  $\Upsilon$  (#undef)|
      %5  =  $\Upsilon$  (1)|
      %6  =  $\Upsilon$  (true)|
      %7  =  $\Upsilon$  (2)|
          invoke Main.opaque()::Any|
      %9  =  $\Upsilon$  (true)|
      %10 =  $\Upsilon$  (3)|
          invoke Main.error()::Union{ }└─
```

```

    $(Expr(:unreachable))::Union{}
4 -- %13 =  $\phi^c$  (%3, %6, %9)::Bool |
    %14 =  $\phi^c$  (%4, %7, %10)::Core.Compiler.MaybeUndef{Int64} |
    %15 =  $\phi^c$  (%5)::Core.Const{1}  $\perp$ 
    $(Expr(:leave, 1))
5 --    $(Expr(:pop_exception, :(%2))):Any |
    $(Expr(:throw_undef_if_not, :y, :(%13))):Any |
    %19 = Core.tuple(%15, %14)  $\perp$ 
    return %19

```

Note in particular that every value live into the critical region gets an ϕ node at the top of the critical region. This is because catch blocks are considered to have an invisible control flow edge from outside the function. As a result, no SSA value dominates the catch blocks, and all incoming values have to come through a ϕ node.

Main SSA data structure

The main SSAIR data structure is worthy of discussion. It draws inspiration from LLVM and Webkit's B3 IR. The core of the data structure is a flat vector of statements. Each statement is implicitly assigned an SSA value based on its position in the vector (i.e. the result of the statement at idx 1 can be accessed using `SSAValue(1)` etc). For each SSA value, we additionally maintain its type. Since, SSA values are definitionally assigned only once, this type is also the result type of the expression at the corresponding index. However, while this representation is rather efficient (since the assignments don't need to be explicitly encoded), it of course carries the drawback that order is semantically significant, so reorderings and insertions change statement numbers. Additionally, we do not keep use lists (i.e. it is impossible to walk from a def to all its uses without explicitly computing this map—def lists however are trivial since you can look up the corresponding statement from the index), so the LLVM-style RAUW (replace-all-uses-with) operation is unavailable.

Instead, we do the following:

- We keep a separate buffer of nodes to insert (including the position to insert them at, the type of the corresponding value and the node itself). These nodes are numbered by their occurrence in the insertion buffer, allowing their values to be immediately used elsewhere in the IR (i.e. if there are 12 statements in the original statement list, the first new statement will be accessible as `SSAValue(13)`).
- RAUW style operations are performed by setting the corresponding statement index to the replacement value.
- Statements are erased by setting the corresponding statement to nothing (this is essentially just a special-case convention of the above).
- If there are any uses of the statement being erased, they will be set to nothing.

There is a `compact!` function that compacts the above data structure by performing the insertion of nodes in the appropriate place, trivial copy propagation, and renaming of uses to any changed SSA values. However, the clever part of this scheme is that this compaction can be done lazily as part of the subsequent pass. Most optimization passes need to walk over the entire list of statements, performing analysis or modifications along the way. We provide an `IncrementalCompact` iterator that can be used to iterate over the statement list. It will perform any necessary compaction and return the new index of the node, as

well as the node itself. It is legal at this point to walk def-use chains, as well as make any modifications or deletions to the IR (insertions are disallowed however).

The idea behind this arrangement is that, since the optimization passes need to touch the corresponding memory anyway and incur the corresponding memory access penalty, performing the extra housekeeping should have comparatively little overhead (and save the overhead of maintaining these data structures during IR modification).

102.23 EscapeAnalysis

`Core.Compiler.EscapeAnalysis` is a compiler utility module that aims to analyze escape information of [Julia's SSA-form IR](#) a.k.a. `IRCode`.

This escape analysis aims to:

- leverage Julia's high-level semantics, especially reason about escapes and aliasing via inter-procedural calls
- be versatile enough to be used for various optimizations including [alias-aware SROA](#), [early finalize insertion](#), [copy-free ImmutableArray construction](#), stack allocation of mutable objects, and so on.
- achieve a simple implementation based on a fully backward data-flow analysis implementation as well as a new lattice design that combines orthogonal lattice properties

Try it out!

You can give a try to the escape analysis by loading the `EAUtils.jl` utility script that define the convenience entries `code_escapes` and `@code_escapes` for testing and debugging purposes:

```
julia> include(normpath(Sys.BINDIR, "..", "share", "julia", "test", "compiler", "EscapeAnalysis",
↳ "EAUtils.jl")); using .EAUtils

julia> mutable struct SafeRef{T}
           x::T
       end

julia> Base.getindex(x::SafeRef) = x.x;

julia> Base.setindex!(x::SafeRef, v) = x.x = v;

julia> Base.isassigned(x::SafeRef) = true;

julia> get'(x) = isassigned(x) ? x[] : throw(x);

julia> result = code_escapes((String,String,String,String)) do s1, s2, s3, s4
           r1 = Ref{s1}
```

```

    r2 = Ref(s2)
    r3 = SafeRef(s3)
    try
        s1 = get'(r1)
        ret = sizeof(s1)
    catch err
        global GV = err # will definitely escape `r1`
    end
    s2 = get'(r2)      # still `r2` doesn't escape fully
    s3 = get'(r3)      # still `r3` doesn't escape fully
    s4 = sizeof(s4)    # the argument `s4` doesn't escape here
    return s2, s3, s4
end
#1(X _2::String, ↑_3::String, ↑_4::String, ✓_5::String) in Main at REPL[7]:2
X 1 — %1 = %new(Base.RefValue{String}, _2)::Base.RefValue{String}
*'| %2 = %new(Base.RefValue{String}, _3)::Base.RefValue{String}
✓|_ %3 = %new(Main.SafeRef{String}, _4)::Main.SafeRef{String}

○|_ %33 = Core.sizeof(%25)::Int64
↑'| %34 = Core.tuple(%28, %32, %33)::Tuple{String, String, Int64}
○|_ return %34

```

The symbols in the side of each call argument and SSA statements represents the following meaning:

- ○ (plain): this value is not analyzed because escape information of it won't be used anyway (when

the object is `isbitstype` for example)

- ✓ (green or cyan): this value never escapes (`has_no_escape(result.state[x])` holds), colored blue if it has arg escape also (`has_arg_escape(result.state[x])` holds)
- † (blue or yellow): this value can escape to the caller via return (`has_return_escape(result.state[x])` holds), colored yellow if it has unhandled thrown escape also (`has_thrown_escape(result.state[x])` holds)
- X (red): this value can escape to somewhere the escape analysis can't reason about like escapes to a global memory (`has_all_escape(result.state[x])` holds)
- * (bold): this value's escape state is between the `ReturnEscape` and `AllEscape` in the partial order of `EscapeInfo`, colored yellow if it has unhandled thrown escape also (`has_thrown_escape(result.state[x])` holds)
- `: this value has additional object field / array element information in its `AliasInfo` property

Escape information of each call argument and SSA value can be inspected programmatically as like:

```
julia> result.state[Core.Argument(3)] # get EscapeInfo of `s2`
ReturnEscape

julia> result.state[Core.SSAValue(3)] # get EscapeInfo of `r3`
NoEscape`
```

Analysis Design

Lattice Design

`EscapeAnalysis` is implemented as a **data-flow analysis** that works on a lattice of `x::EscapeInfo`, which is composed of the following properties:

- `x.Analyzed::Bool`: not formally part of the lattice, only indicates `x` has not been analyzed or not
- `x.ReturnEscape::BitSet`: records SSA statements where `x` can escape to the caller via return
- `x.ThrownEscape::BitSet`: records SSA statements where `x` can be thrown as exception (used for the **exception handling** described below)
- `x.AliasInfo`: maintains all possible values that can be aliased to fields or array elements of `x` (used for the **alias analysis** described below)
- `x.ArgEscape::Int` (not implemented yet): indicates it will escape to the caller through `setfield!` on argument(s)

These attributes can be combined to create a partial lattice that has a finite height, given the invariant that an input program has a finite number of statements, which is assured by Julia's semantics. The clever part of this lattice design is that it enables a simpler implementation of lattice operations by allowing them to handle each lattice property separately¹.

Backward Escape Propagation

This escape analysis implementation is based on the data-flow algorithm described in the paper². The analysis works on the lattice of `EscapeInfo` and transitions lattice elements from the bottom to the top until every lattice element gets converged to a fixed point by maintaining a (conceptual) working set that contains program counters corresponding to remaining SSA statements to be analyzed. The analysis manages a single global state that tracks `EscapeInfo` of each argument and SSA statement, but also note that some flow-sensitivity is encoded as program counters recorded in `EscapeInfo`'s `ReturnEscape` property, which can be combined with domination analysis later to reason about flow-sensitivity if necessary.

One distinctive design of this escape analysis is that it is fully backward, i.e. escape information flows from usages to definitions. For example, in the code snippet below, EA first analyzes the statement `return %1` and imposes `ReturnEscape` on `%1` (corresponding to `obj`), and then it analyzes `%1 = %new(Base.RefValue{String}, _2)::Base.RefValue{String}` and propagates the `ReturnEscape` imposed on `%1` to the call argument `_2` (corresponding to `s`):

```
julia> code_escapes((String,)) do s
    obj = Ref(s)
    return obj
end
#3(↑ _2::String) in Main at REPL[1]:2
↑' 1 - %1 = %new(Base.RefValue{String}, _2)::Base.RefValue{String}
○ └─ return %1
```

The key observation here is that this backward analysis allows escape information to flow naturally along the use-def chain rather than control-flow³. As a result this scheme enables a simple implementation of escape analysis, e.g. `PhiNode` for example can be handled simply by propagating escape information imposed on a `PhiNode` to its predecessor values:

```
julia> code_escapes((Bool, String, String)) do cnd, s, t
    if cnd
        obj = Ref(s)
    else
        obj = Ref(t)
    end
    return obj
end
#5(✓ _2::Bool, ↑ _3::String, ↑ _4::String) in Main at REPL[1]:2
○ 1 - goto #3 if not _2
↑' 2 - %2 = %new(Base.RefValue{String}, _3)::Base.RefValue{String}
○ └─ goto #4
↑' 3 - %4 = %new(Base.RefValue{String}, _4)::Base.RefValue{String}
↑' 4 - %5 = φ (#2 => %2, #3 => %4)::Base.RefValue{String}
○ └─ return %5
```

Alias Analysis

`EscapeAnalysis` implements a backward field analysis in order to reason about escapes imposed on object fields with certain accuracy, and `x::EscapeInfo`'s `x.AliasInfo` property exists for this purpose. It records all possible values that can be aliased to fields of `x` at "usage" sites, and then the escape information of that recorded values are propagated to the actual field values later at "definition" sites. More specifically, the analysis records a value that may be aliased to a field of object by analyzing `getfield` call, and then it propagates its escape information to the field when analyzing `%new(...)` expression or `setfield!` call⁴.

```

julia> code_escapes((String,)) do s
    obj = SafeRef("init")
    obj[] = s
    v = obj[]
    return v
end
#7(↑ _2::String) in Main at REPL[1]:2
✓ 1 - %1 = %new(Main.SafeRef{String}, "init")::Main.SafeRef{String}
○ |     Base.setfield!(%1, :x, _2)::String
↑ |     %3 = Base.getfield(%1, :x)::String
○ |     return %3

```

In the example above, ReturnEscape imposed on %3 (corresponding to `v`) is not directly propagated to %1 (corresponding to `obj`) but rather that ReturnEscape is only propagated to `_2` (corresponding to `s`). Here %3 is recorded in %1's `AliasInfo` property as it can be aliased to the first field of %1, and then when analyzing `Base.setfield!(%1, :x, _2)::String`, that escape information is propagated to `_2` but not to %1.

So EscapeAnalysis tracks which IR elements can be aliased across a `getfield`-`%new`/`setfield!` chain in order to analyze escapes of object fields, but actually this alias analysis needs to be generalized to handle other IR elements as well. This is because in Julia IR the same object is sometimes represented by different IR elements and so we should make sure that those different IR elements that actually can represent the same object share the same escape information. IR elements that return the same object as their operand(s), such as `PhiNode` and `typeassert`, can cause that IR-level aliasing and thus requires escape information imposed on any of such aliased values to be shared between them. More interestingly, it is also needed for correctly reasoning about mutations on `PhiNode`. Let's consider the following example:

```

julia> code_escapes((Bool, String,)) do cond, x
    if cond
        φ2 = φ1 = SafeRef("foo")
    else
        φ2 = φ1 = SafeRef("bar")
    end
    φ2[] = x
    y = φ1[]
    return y
end
#9(✓ _2::Bool, ↑ _3::String) in Main at REPL[1]:2
○ 1 - goto #3 if not _2
✓ 2 - %2 = %new(Main.SafeRef{String}, "foo")::Main.SafeRef{String}
○ |     goto #4
✓ 3 - %4 = %new(Main.SafeRef{String}, "bar")::Main.SafeRef{String}
✓ 4 - %5 = φ (#2 => %2, #3 => %4)::Main.SafeRef{String}
✓ |   %6 = φ (#2 => %2, #3 => %4)::Main.SafeRef{String}
○ |     Base.setfield!(%5, :x, _3)::String
↑ |     %8 = Base.getfield(%6, :x)::String
○ |     return %8

```

`φ1 = %5` and `φ2 = %6` are aliased and thus ReturnEscape imposed on `%8 = Base.getfield(%6, :x)::String` (corresponding to `y = φ1[]`) needs to be propagated to `Base.setfield!(%5, :x, _3)::String` (corresponding to `φ2[] = x`). In order for such escape information to be propagated correctly, the analysis should recognize that the predecessors of `φ1` and `φ2` can be aliased as well and equalize their escape information.

One interesting property of such aliasing information is that it is not known at "usage" site but can only be derived at "definition" site (as aliasing is conceptually equivalent to assignment), and thus it doesn't naturally fit in a backward analysis. In order to efficiently propagate escape information between related values, `EscapeAnalysis.jl` uses an approach inspired by the escape analysis algorithm explained in an old JVM paper⁵. That is, in addition to managing escape lattice elements, the analysis also maintains an "equi"-alias set, a disjoint set of aliased arguments and SSA statements. The alias set manages values that can be aliased to each other and allows escape information imposed on any of such aliased values to be equalized between them.

Array Analysis

The alias analysis for object fields described above can also be generalized to analyze array operations. `EscapeAnalysis` implements handlings for various primitive array operations so that it can propagate escapes via `arrayref`-`arrayset` use-def chain and does not escape allocated arrays too conservatively:

```
julia> code_escapes((String,)) do s
    ary = Any[]
    push!(ary, SafeRef(s))
    return ary[1], length(ary)
end
#11(τ_2::String) in Main at REPL[1]:2
* 1 - %1 = $(Expr(:foreigncall, :(:jl_alloc_array_1d), Vector{Any}, svec(Any, Int64), 0,
↳ :(:ccall), Vector{Any}, 0, 0))::Vector{Any}
τ' | %2 = %new(Main.SafeRef{String}, _2)::Main.SafeRef{String}
○ | $(Expr(:foreigncall, :(:jl_array_grow_end), Nothing, svec(Any, UInt64), 0, :(:ccall),
↳ :(%1), 0x0000000000000001, 0x0000000000000001))::Nothing
○ | %4 = Base.arraylen(%1)::Int64
○ | Base.arrayset(false, %1, %2, %4)::Vector{Any}
τ' | %6 = Base.arrayref(true, %1, 1)::Any
○ | %7 = Base.arraylen(%1)::Int64
τ' | %8 = Core.tuple(%6, %7)::Tuple{Any, Int64}
○ | return %8
```

In the above example `EscapeAnalysis` understands that `%20` and `%2` (corresponding to the allocated object `SafeRef(s)`) are aliased via the `arrayset`-`arrayref` chain and imposes `ReturnEscape` on them, but not impose it on the allocated array `%1` (corresponding to `ary`). `EscapeAnalysis` still imposes `ThrownEscape` on `ary` since it also needs to account for potential escapes via `BoundsError`, but also note that such unhandled `ThrownEscape` can often be ignored when optimizing the `ary` allocation.

Furthermore, in cases when array index information as well as array dimensions can be known precisely, `EscapeAnalysis` is able to even reason about "per-element" aliasing via `arrayref`-`arrayset` chain, as `EscapeAnalysis` does "per-field" alias analysis for objects:

```
julia> code_escapes((String,String)) do s, t
    ary = Vector{Any}(undef, 2)
    ary[1] = SafeRef(s)
    ary[2] = SafeRef(t)
    return ary[1], length(ary)
end
#13(τ_2::String, * _3::String) in Main at REPL[1]:2
* 1 - %1 = $(Expr(:foreigncall, :(:jl_alloc_array_1d), Vector{Any}, svec(Any, Int64), 0,
↳ :(:ccall), Vector{Any}, 2, 2))::Vector{Any}
```

```

↑' | %2 = %new(Main.SafeRef{String}, _2)::Main.SafeRef{String}
○ |   Base.arrayset(true, %1, %2, 1)::Vector{Any}
*' | %4 = %new(Main.SafeRef{String}, _3)::Main.SafeRef{String}
○ |   Base.arrayset(true, %1, %4, 2)::Vector{Any}
↑' | %6 = Base.arrayref(true, %1, 1)::Any
○ | %7 = Base.arraylen(%1)::Int64
↑' | %8 = Core.tuple(%6, %7)::Tuple{Any, Int64}
○ |   return %8

```

Note that `ReturnEscape` is only imposed on `%2` (corresponding to `SafeRef(s)`) but not on `%4` (corresponding to `SafeRef(t)`). This is because the allocated array's dimension and indices involved with all `arrayref/arrayset` operations are available as constant information and `EscapeAnalysis` can understand that `%6` is aliased to `%2` but never be aliased to `%4`. In this kind of case, the succeeding optimization passes will be able to replace `Base.arrayref(true, %1, 1)::Any` with `%2` (a.k.a. "load-forwarding") and eventually eliminate the allocation of array `%1` entirely (a.k.a. "scalar-replacement").

When compared to object field analysis, where an access to object field can be analyzed trivially using type information derived by inference, array dimension isn't encoded as type information and so we need an additional analysis to derive that information. `EscapeAnalysis` at this moment first does an additional simple linear scan to analyze dimensions of allocated arrays before firing up the main analysis routine so that the succeeding escape analysis can precisely analyze operations on those arrays.

However, such precise "per-element" alias analysis is often hard. Essentially, the main difficulty inherit to array is that array dimension and index are often non-constant:

- loop often produces loop-variant, non-constant array indices
- (specific to vectors) array resizing changes array dimension and invalidates its constant-ness

Let's discuss those difficulties with concrete examples.

In the following example, `EscapeAnalysis` fails the precise alias analysis since the index at the `Base.arrayset(false, %4, %8, %6)::Vector{Any}` is not (trivially) constant. Especially `Any[nothing, nothing]` forms a loop and calls that `arrayset` operation in a loop, where `%6` is represented as a ϕ -node value (whose value is control-flow dependent). As a result, `ReturnEscape` ends up imposed on both `%23` (corresponding to `SafeRef(s)`) and `%25` (corresponding to `SafeRef(t)`), although ideally we want it to be imposed only on `%23` but not on `%25`:

```

julia> code_escapes((String,String)) do s, t
    ary = Any[nothing, nothing]
    ary[1] = SafeRef(s)
    ary[2] = SafeRef(t)
    return ary[1], length(ary)
end
#15(↑_2::String, ↑_3::String) in Main at REPL[1]:2
*' 1 - %1 = $(Expr(:foreigncall, :(:jl_alloc_array_1d), Vector{Any}, svec(Any, Int64), 0,
↳ :(:ccall), Vector{Any}, 2, 2))::Vector{Any}
○ ┌   goto #7 if not true
○ 2 - %3 = φ (#1 => 1, #6 => %11)::Int64
○ |   %4 = φ (#1 => 1, #6 => %12)::Int64
○ |   Base.arrayset(false, %1, nothing, %3)::Vector{Any}
○ |   %6 = (%4 == 2)::Bool

```

```

○  ┌      goto #4 if not %6
○ 3 ─      goto #5
○ 4 ─ %9 = Base.add_int(%4, 1)::Int64
○  ┌      goto #5
○ 5 ─ %11 = φ (#4 => %9)::Int64
○  ┌      %12 = φ (#4 => %9)::Int64
○  ┌      %13 = φ (#3 => true, #4 => false)::Bool
○  ┌      %14 = Base.not_int(%13)::Bool
○  ┌      goto #7 if not %14
○ 6 ─      goto #2
○ 7 ─      goto #8
↑' 8 ─ %18 = %new(Main.SafeRef{String}, _2)::Main.SafeRef{String}
○  ┌      Base.arrayset(true, %1, %18, 1)::Vector{Any}
↑'  ┌      %20 = %new(Main.SafeRef{String}, _3)::Main.SafeRef{String}
○  ┌      Base.arrayset(true, %1, %20, 2)::Vector{Any}
↑'  ┌      %22 = Base.arrayref(true, %1, 1)::Any
○  ┌      %23 = Base.arraylen(%1)::Int64
↑'  ┌      %24 = Core.tuple(%22, %23)::Tuple{Any, Int64}
○  ┌      return %24

```

The next example illustrates how vector resizing makes precise alias analysis hard. The essential difficulty is that the dimension of allocated array %1 is first initialized as 0, but it changes by the two `:jl_array_grow_end` calls afterwards. `EscapeAnalysis` currently simply gives up precise alias analysis whenever it encounters any array resizing operations and so `ReturnEscape` is imposed on both %2 (corresponding to `SafeRef(s)`) and %20 (corresponding to `SafeRef(t)`):

```

julia> code_escapes((String,String)) do s, t
    ary = Any[]
    push!(ary, SafeRef(s))
    push!(ary, SafeRef(t))
    ary[1], length(ary)
end
#17(↑ _2::String, ↑ _3::String) in Main at REPL[1]:2
*' 1 ─ %1 = $(Expr(:foreigncall, :(:jl_alloc_array_1d), Vector{Any}, svec(Any, Int64), 0,
↳ :(:ccall), Vector{Any}, 0, 0))::Vector{Any}
↑'  ┌      %2 = %new(Main.SafeRef{String}, _2)::Main.SafeRef{String}
○  ┌      $(Expr(:foreigncall, :(:jl_array_grow_end), Nothing, svec(Any, UInt64), 0,
↳ :(:ccall), :(%1), 0x0000000000000001, 0x0000000000000001))::Nothing
○  ┌      %4 = Base.arraylen(%1)::Int64
○  ┌      Base.arrayset(false, %1, %2, %4)::Vector{Any}
↑'  ┌      %6 = %new(Main.SafeRef{String}, _3)::Main.SafeRef{String}
○  ┌      $(Expr(:foreigncall, :(:jl_array_grow_end), Nothing, svec(Any, UInt64), 0,
↳ :(:ccall), :(%1), 0x0000000000000001, 0x0000000000000001))::Nothing
○  ┌      %8 = Base.arraylen(%1)::Int64
○  ┌      Base.arrayset(false, %1, %6, %8)::Vector{Any}
↑'  ┌      %10 = Base.arrayref(true, %1, 1)::Any
○  ┌      %11 = Base.arraylen(%1)::Int64
↑'  ┌      %12 = Core.tuple(%10, %11)::Tuple{Any, Int64}
○  ┌      return %12

```

In order to address these difficulties, we need inference to be aware of array dimensions and propagate array dimensions in a flow-sensitive way⁶, as well as come up with nice representation of loop-variant

values.

EscapeAnalysis at this moment quickly switches to the more imprecise analysis that doesn't track precise index information in cases when array dimensions or indices are trivially non constant. The switch can naturally be implemented as a lattice join operation of `EscapeInfo.AliasInfo` property in the data-flow analysis framework.

Exception Handling

It would be also worth noting how `EscapeAnalysis` handles possible escapes via exceptions. Naively it seems enough to propagate escape information imposed on `the_exception` object to all values that may be thrown in a corresponding try block. But there are actually several other ways to access to the exception object in Julia, such as `Base.current_exceptions` and `rethrow`. For example, escape analysis needs to account for potential escape of `r` in the example below:

```
julia> const GR = Ref{Any}();

julia> @noinline function rethrow_escape!()
    try
        rethrow()
    catch err
        GR[] = err
    end
end;

julia> get'(x) = isassigned(x) ? x[] : throw(x);

julia> code_escapes() do
    r = Ref{String}()
    local t
    try
        t = get'(r)
    catch err
        t = typeof(err) # `err` (which `r` aliases to) doesn't escape here
        rethrow_escape!() # but `r` escapes here
    end
    return t
end

#19() in Main at REPL[4]:2
X 1 — %1 = %new(Base.RefValue{String})::Base.RefValue{String}
◉ 2 — %2 = $(Expr(:enter, #8))
◉ 3 — %3 = Base.isdefined(%1, :x)::Bool
◉ ┌   goto #5 if not %3
X 4 — %5 = Base.getfield(%1, :x)::String
◉ ┌   goto #6
◉ 5 —   Main.throw(%1)::Union{}
◉ ┌   unreachable
◉ 6 —   $(Expr(:leave, 1))
◉ 7 —   goto #10
◉ 8 —   $(Expr(:leave, 1))
```

```

✓ 9 — %12 = $(Expr(:the_exception))::Any
X |   %13 = Main.typeof(%12)::DataType
X |       invoke Main.rethrow_escape!()::Any
○ |       $(Expr(:pop_exception, :(%2)))::Any
X 10 — %16 = φ (#7 => %5, #9 => %13)::Union{DataType, String}
○ |       return %16

```

It requires a global analysis in order to correctly reason about all possible escapes via existing exception interfaces. For now we always propagate the topmost escape information to all potentially thrown objects conservatively, since such an additional analysis might not be worthwhile to do given that exception handling and error path usually don't need to be very performance sensitive, and also optimizations of error paths might be very ineffective anyway since they are often even "unoptimized" intentionally for latency reasons.

`x::EscapeInfo`'s `x.ThrownEscape` property records SSA statements where `x` can be thrown as an exception. Using this information `EscapeAnalysis` can propagate possible escapes via exceptions limitedly to only those may be thrown in each try region:

```

julia> result = code_escapes((String,String)) do s1, s2
    r1 = Ref{s1}
    r2 = Ref{s2}
    local ret
    try
        s1 = get'(r1)
        ret = sizeof(s1)
    catch err
        global GV = err # will definitely escape `r1`
    end
    s2 = get'(r2)      # still `r2` doesn't escape fully
    return s2
end

#21(X _2::String, ↑_3::String) in Main at REPL[1]:2

    └───┬─── unreachable
    ○ 14 - return %21

```

Analysis Usage

`analyze_escapes` is the entry point to analyze escape information of SSA-IR elements.

Most optimizations like SROA (`sroa_pass!`) are more effective when applied to an optimized source that the inlining pass (`ssa_inlining_pass!`) has simplified by resolving inter-procedural calls and expanding callee sources. Accordingly, `analyze_escapes` is also able to analyze post-inlining IR and collect escape information that is useful for certain memory-related optimizations.

However, since certain optimization passes like inlining can change control flows and eliminate dead code, they can break the inter-procedural validity of escape information. In particularity, in order to collect inter-procedurally valid escape information, we need to analyze a pre-inlining IR.

Because of this reason, `analyze_escapes` can analyze `IRCode` at any Julia-level optimization stage, and especially, it is supposed to be used at the following two stages:

- `IPO_EA`: analyze pre-inlining IR to generate IPO-valid escape information cache
- `Local_EA`: analyze post-inlining IR to collect locally-valid escape information

Escape information derived by `IPO_EA` is transformed to the `ArgEscapeCache` data structure and cached globally. By passing an appropriate `get_escape_cache` callback to `analyze_escapes`, the escape analysis can improve analysis accuracy by utilizing cached inter-procedural information of non-inlined callees that has been derived by previous `IPO_EA`. More interestingly, it is also valid to use `IPO_EA` escape information for type inference, e.g., inference accuracy can be improved by forming `Const/PartialStruct/MustAlias` of mutable object.

Since the computational cost of `analyze_escapes` is not that cheap, both `IPO_EA` and `Local_EA` are better to run only when there is any profitability. Currently `EscapeAnalysis` provides the `is_ipo_profitable` heuristic to check a profitability of `IPO_EA`.

`Core.Compiler.EscapeAnalysis.analyze_escapes` - Function.

```

└ analyze_escapes(ir::IRCode, nargs::Int, call_resolved::Bool, get_escape_cache::Callable)
  -> estate::EscapeState

```

Analyzes escape information in `ir`:

- `nargs`: the number of actual arguments of the analyzed call
- `call_resolved`: if interprocedural calls are already resolved by `ssa_inlining_pass!`
- `get_escape_cache(::Union{InferenceResult,MethodInstance}) -> Union{Nothing,ArgEscapeCache}`: retrieves cached argument escape information

[source](#)

`Core.Compiler.EscapeAnalysis.EscapeState` - Type.

```
| estate::EscapeState
```

Extended lattice that maps arguments and SSA values to escape information represented as [EscapeInfo](#).
Escape information imposed on SSA IR element `x` can be retrieved by `estate[x]`.

[source](#)

`Core.Compiler.EscapeAnalysis.EscapeInfo` – Type.

```
| x::EscapeInfo
```

A lattice for escape information, which holds the following properties:

- `x.Analyzed::Bool`: not formally part of the lattice, only indicates `x` has not been analyzed or not
- `x.ReturnEscape::Bool`: indicates `x` can escape to the caller via return
- `x.ThrownEscape::BitSet`: records SSA statement numbers where `x` can be thrown as exception:
 - `isempty(x.ThrownEscape)`: `x` will never be thrown in this call frame (the bottom)
 - `pc ∈ x.ThrownEscape`: `x` may be thrown at the SSA statement at `pc`
 - `-1 ∈ x.ThrownEscape`: `x` may be thrown at arbitrary points of this call frame (the top)

This information will be used by `escape_exception!` to propagate potential escapes via exception.

- `x.AliasInfo::Union{Bool, IndexableFields, IndexableElements, Unindexable}`: maintains all possible values that can be aliased to fields or array elements of `x`:
 - `x.AliasInfo === false` indicates the fields/elements of `x` aren't analyzed yet
 - `x.AliasInfo === true` indicates the fields/elements of `x` can't be analyzed, e.g. the type of `x` is not known or is not concrete and thus its fields/elements can't be known precisely
 - `x.AliasInfo::IndexableFields` records all the possible values that can be aliased to fields of object `x` with precise index information
 - `x.AliasInfo::IndexableElements` records all the possible values that can be aliased to elements of array `x` with precise index information
 - `x.AliasInfo::Unindexable` records all the possible values that can be aliased to fields/elements of `x` without precise index information
- `x.Liveness::BitSet`: records SSA statement numbers where `x` should be live, e.g. to be used as a call argument, to be returned to a caller, or preserved for `:foreigncall`:
 - `isempty(x.Liveness)`: `x` is never be used in this call frame (the bottom)
 - `0 ∈ x.Liveness` also has the special meaning that it's a call argument of the currently analyzed call frame (and thus it's visible from the caller immediately).
 - `pc ∈ x.Liveness`: `x` may be used at the SSA statement at `pc`
 - `-1 ∈ x.Liveness`: `x` may be used at arbitrary points of this call frame (the top)

There are utility constructors to create common `EscapeInfos`, e.g.,

- `NoEscape()`: the bottom(-like) element of this lattice, meaning it won't escape to anywhere
- `AllEscape()`: the topmost element of this lattice, meaning it will escape to everywhere

`analyze_escapes` will transition these elements from the bottom to the top, in the same direction as Julia's native type inference routine. An abstract state will be initialized with the bottom(-like) elements:

- the call arguments are initialized as `ArgEscape()`, whose Liveness property includes 0 to indicate that it is passed as a call argument and visible from a caller immediately
- the other states are initialized as `NotAnalyzed()`, which is a special lattice element that is slightly lower than `NoEscape`, but at the same time doesn't represent any meaning other than it's not analyzed yet (thus it's not formally part of the lattice)

source

`Core.Compiler.EscapeAnalysis.is_ipo_profitable` – Function.

```
| is_ipo_profitable(ir::IRCode, nargs::Int) -> Bool
```

Heuristically checks if there is any profitability to run the escape analysis on `ir` and generate IPO escape information cache. Specifically, this function examines if any call argument is "interesting" in terms of their escapability.

source

102.24 Static analyzer annotations for GC correctness in C code

Running the analysis

The analyzer plugin that drives the analysis ships with `julia`. Its source code can be found in `src/clangsa`. Running it requires the `clang` dependency to be build. Set the `BUILD_LLVM_CLANG` variable in your `Make.user` in order to build an appropriate version of `clang`. You may also want to use the prebuilt binaries using the `USE_BINARYBUILDER_LLVM` options.

Alternatively (or if these do not suffice), try

```
| make -C src install-analysis-deps
```

from `Julia`'s `toplevel` directory.

Afterwards, running the analysis over the source tree is as simple as running `make -C src analyzerc`.

¹Our type inference implementation takes the alternative approach, where each lattice property is represented by a special lattice element type object. It turns out that it started to complicate implementations of the lattice operations mainly because it often requires conversion rules between each lattice element type object. And we are working on [overhauling our type inference lattice implementation](#) with `EscapeInfo`-like lattice design.

²A Graph-Free approach to Data-Flow Analysis. Markas Mohnen, 2002, April. <https://api.semanticscholar.org/CorpusID:28519618>.

³Our type inference algorithm in contrast is implemented as a forward analysis, because type information usually flows from "definition" to "usage" and it is more natural and effective to propagate such information in a forward way.

⁴In some cases, however, object fields can't be analyzed precisely. For example, object may escape to somewhere `EscapeAnalysis` can't account for possible memory effects on it, or fields of the objects simply can't be known because of the lack of type information. In such cases `AliasInfo` property is raised to the topmost element within its own lattice order, and it causes succeeding field analysis to be conservative and escape information imposed on fields of an unanalyzable object to be propagated to the object itself.

⁵Escape Analysis in the Context of Dynamic Compilation and Deoptimization. Thomas Kotzmann and Hanspeter Mössenböck, 2005, June. <https://dl.acm.org/doi/10.1145/1064979.1064996>.

⁶Otherwise we will need yet another forward data-flow analysis on top of the escape analysis.

General Overview

Since Julia's GC is precise, it needs to maintain correct rooting information for any value that may be referenced at any time GC may occur. These places are known as safepoints and in the function local context, we extend this designation to any function call that may recursively end up at a safepoint.

In generated code, this is taken care of automatically by the GC root placement pass (see the chapter on GC rooting in the LLVM codegen devdocs). However, in C code, we need to inform the runtime of any GC roots manually. This is done using the following macros:

```
// The value assigned to any slot passed as an argument to these
// is rooted for the duration of this GC frame.
JL_GC_PUSH{1,...,6}(args...)
// The values assigned into the size `n` array `rts` are rooted
// for the duration of this GC frame.
JL_GC_PUSHARGS(rts, n)
// Pop a GC frame
JL_GC_POP
```

If these macros are not used where they need to be, or they are used incorrectly, the result is silent memory corruption. As such it is very important that they are placed correctly in all applicable code.

As such, we employ static analysis (and in particular the clang static analyzer) to help ensure that these macros are used correctly. The remainder of this document gives an overview of this static analysis and describes the support needed in the julia code base to make things work.

GC Invariants

There is two simple invariants correctness:

- All `JL_GC_PUSH` calls need to be followed by an appropriate `JL_GC_POP` (in practice we enforce this at the function level)
- If a value was previously not rooted at any safepoint, it may no longer be referenced afterwards

Of course the devil is in the details here. In particular to satisfy the second of the above conditions, we need to know:

- Which calls are safepoints and which are not
- Which values are rooted at any given safepoint and which are not
- When is a value referenced

For the second point in particular, we need to know which memory locations will be considered rooting at runtime (i.e. values assigned to such locations are rooted). This includes locations explicitly designated as such by passing them to one of the `JL_GC_PUSH` macros, globally rooted locations and values, as well as any location recursively reachable from one of those locations.

Static Analysis Algorithm

The idea itself is very simple, although the implementation is quite a bit more complicated (mainly due to a large number of special cases and intricacies of C and C++). In essence, we keep track of all locations that are rooting, all values that are rootable and any expression (assignments, allocations, etc) affect the rootedness of any rootable values. Then, at any safepoint, we perform a "symbolic GC" and poison any values that are not rooted at said location. If these values are later referenced, we emit an error.

The clang static analyzer works by constructing a graph of states and exploring this graph for sources of errors. Several nodes in this graph are generated by the analyzer itself (e.g. for control flow), but the definitions above augment this graph with our own state.

The static analyzer is interprocedural and can analyze control flow across function boundaries. However, the static analyzer is not fully recursive and makes heuristic decisions about which calls to explore (additionally some calls are cross-translation unit and invisible to the analyzer). In our case, our definition of correctness requires total information. As such, we need to annotate the prototypes of all function calls with whatever information the analysis required, even if that information would otherwise be available by interprocedural static analysis.

Luckily however, we can still use this interprocedural analysis to ensure that the annotations we place on a given function are indeed correct given the implementation of said function.

The analyzer annotations

These annotations are found in `src/support/analyzer_annotations.h`. They are only active when the analyzer is being used and expand either to nothing (for prototype annotations) or to no-ops (for function like annotations).

JL_NOTSAFEPPOINT

This is perhaps the most common annotation, and should be placed on any function that is known not to possibly lead to reaching a GC safepoint. In general, it is only safe for such a function to perform arithmetic, memory accesses and calls to functions either annotated `JL_NOTSAFEPPOINT` or otherwise known not to be safepoints (e.g. function in the C standard library, which are hardcoded as such in the analyzer).

It is valid to keep values unrooted across calls to any function annotated with this attribute:

Usage Example:

```
void jl_get_one() JL_NOTSAFEPPOINT {
    return 1;
}

jl_value_t *example() {
    jl_value_t *val = jl_alloc_whatever();
    // This is valid, even though `val` is unrooted, because
    // jl_get_one is not a safepoint
    jl_get_one();
    return val;
}
```

JL_MAYBE_UNROOTED/JL_ROOTS_TEMPORARILY

When `JL_MAYBE_UNROOTED` is annotated as an argument on a function, indicates that said argument may be passed, even if it is not rooted. In the ordinary course of events, the julia ABI guarantees that callers root

values before passing them to callees. However, some functions do not follow this ABI and allow values to be passed to them even though they are not rooted. Note however, that this does not automatically imply that said argument will be preserved. The `ROOTS_TEMPORARILY` annotation provides the stronger guarantee that, not only may the value be unrooted when passed, it will also be preserved across any internal safepoints by the callee.

Note that `JL_NOTSAFEPPOINT` essentially implies `JL_MAYBE_UNROOTED/JL_ROOTS_TEMPORARILY`, because the rootedness of an argument is irrelevant if the function contains no safepoints.

One additional point to note is that these annotations apply on both the caller and the callee side. On the caller side, they lift rootedness restrictions that are normally required for julia ABI functions. On the callee side, they have the reverse effect of preventing these arguments from being considered implicitly rooted.

If either of these annotations is applied to the function as a whole, it applies to all arguments of the function. This should generally only be necessary for varargs functions.

Usage example:

```
JL_DLLEXPORT void JL_NORETURN jl_throw(jl_value_t *e JL_MAYBE_UNROOTED);
jl_value_t *jl_alloc_error();

void example() {
    // The return value of the allocation is unrooted. This would normally
    // be an error, but is allowed because of the above annotation.
    jl_throw(jl_alloc_error());
}
```

JL_PROPAGATES_ROOT

This annotation is commonly found on accessor functions that return one rootable object stored within another. When annotated on a function argument, it tells the analyzer that the root for that argument also applies to the value returned by the function.

Usage Example:

```
jl_value_t *jl_svecref(jl_svec_t *t JL_PROPAGATES_ROOT, size_t i) JL_NOTSAFEPPOINT;

size_t example(jl_svec_t *svec) {
    jl_value_t *val = jl_svecref(svec, 1)
    // This is valid, because, as annotated by the PROPAGATES_ROOT annotation,
    // jl_svecref propagates the rooted-ness from `svec` to `val`
    jl_gc_safepoint();
    return jl_unbox_long(val);
}
```

JL_ROOTING_ARGUMENT/JL_ROOTED_ARGUMENT

This is essentially the assignment counterpart to `JL_PROPAGATES_ROOT`. When assigning a value to a field of another value that is already rooted, the assigned value will inherit the root of the value it is assigned into.

Usage Example:

```
void jl_svecset(void *t JL_ROOTING_ARGUMENT, size_t i, void *x JL_ROOTED_ARGUMENT)
    JL_NOTSAFEPPOINT
```

```

size_t example(jl_svec_t *svec) {
    jl_value_t *val = jl_box_long(10000);
    jl_svecset(svec, val);
    // This is valid, because the annotations imply that the
    // jl_svecset propagates the rooted-ness from `svec` to `val`
    jl_gc_safepoint();
    return jl_unbox_long(val);
}

```

JL_GC_DISABLED

This annotation implies that this function is only called with the GC runtime-disabled. Functions of this kind are most often encountered during startup and in the GC code itself. Note that this annotation is checked against the runtime enable/disable calls, so clang will know if you lie. This is not a good way to disable processing of a given function if the GC is not actually disabled (use `ifdef __clang_analyzer__` for that if you must).

Usage example:

```

void jl_do_magic() JL_GC_DISABLED {
    // Wildly allocate here with no regard for roots
}

void example() {
    int en = jl_gc_enable(0);
    jl_do_magic();
    jl_gc_enable(en);
}

```

JL_REQUIRE_ROOTED_SLOT

This annotation requires the caller to pass in a slot that is rooted (i.e. values assigned to this slot will be rooted).

Usage example:

```

void jl_do_processing(jl_value_t **slot JL_REQUIRE_ROOTED_SLOT) {
    *slot = jl_box_long(1);
    // Ok, only, because the slot was annotated as rooting
    jl_gc_safepoint();
}

void example() {
    jl_value_t *slot = NULL;
    JL_GC_PUSH1(&slot);
    jl_do_processing(&slot);
    JL_GC_POP();
}

```

JL_GLOBALLY_ROOTED

This annotation implies that a given value is always globally rooted. It can be applied to global variable declarations, in which case it will apply to the value of those variables (or values if the declaration is for an array), or to functions, in which case it will apply to the return value of such functions (e.g. for functions that always return some private, globally rooted value).

Usage example:

```
| extern JL_DLLEXPORT jl_datatype_t *jl_any_type JL_GLOBALLY_ROOTED;
| jl_ast_context_t *jl_ast_ctx(fl_context_t *fl) JL_GLOBALLY_ROOTED;
```

JL_ALWAYS_LEAFTYPE

This annotation is essentially equivalent to `JL_GLOBALLY_ROOTED`, except that it should only be used if those values are globally rooted by virtue of being a leaf type. The rooting of leaf types is a bit complicated. They are generally rooted through the `cache` field of the corresponding `TypeName`, which itself is rooted by the containing module (so they're rooted as long as the containing module is ok) and we can generally assume that leaf types are rooted where they are used, but we may refine this property in the future, so the separate annotation helps split out the reason for being globally rooted.

The analyzer also automatically detects checks for leaf type-ness and will not complain about missing GC roots on these paths.

```
| JL_DLLEXPORT jl_value_t *jl_apply_array_type(jl_value_t *type, size_t dim) JL_ALWAYS_LEAFTYPE;
```

JL_GC_PROMISE_ROOTED

This is a function-like annotation. Any value passed to this annotation will be considered rooted for the scope of the current function. It is designed as an escape hatch for analyzer inadequacy or complicated situations. However, it should be used sparingly, in favor of improving the analyzer itself.

```
| void example() {
|     jl_value_t *val = jl_alloc_something();
|     if (some_condition) {
|         // We happen to know for complicated external reasons
|         // that val is rooted under these conditions
|         JL_GC_PROMISE_ROOTED(val);
|     }
| }
```

Completeness of analysis

The analyzer only looks at local information. In particular, e.g. in the `PROPAGATES_ROOT` case above, it assumes that such memory is only modified in ways it can see, not in any called functions (unless it happens to decide to consider them in its analysis) and not in any concurrently running threads. As such, it may miss a few problematic cases, though in practice such concurrent modification is fairly rare. Improving the analyzer to handle more such cases may be an interesting topic for future work.

102.25 Garbage Collection in Julia

Introduction

Julia has a non-moving, partially concurrent, parallel, generational and mostly precise mark-sweep collector (an interface for conservative stack scanning is provided as an option for users who wish to call Julia from C).

Allocation

Julia uses two types of allocators, the size of the allocation request determining which one is used. Objects up to 2k bytes are allocated on a per-thread free-list pool allocator, while objects larger than 2k bytes are allocated through libc malloc.

Julia's pool allocator partitions objects on different size classes, so that a memory page managed by the pool allocator (which spans 4 operating system pages on 64bit platforms) only contains objects of the same size class. Each memory page from the pool allocator is paired with some page metadata stored on per-thread lock-free lists. The page metadata contains information such as whether the page has live objects at all, number of free slots, and offsets to the first and last objects in the free-list contained in that page. These metadata are used to optimize the collection phase: a page which has no live objects at all may be returned to the operating system without any need of scanning it, for example.

While a page that has no objects may be returned to the operating system, its associated metadata is permanently allocated and may outlive the given page. As mentioned above, metadata for allocated pages are stored on per-thread lock-free lists. Metadata for free pages, however, may be stored into three separate lock-free lists depending on whether the page has been mapped but never accessed (`page_pool_clean`), or whether the page has been lazily swept and it's waiting to be madvised by a background GC thread (`page_pool_lazily_freed`), or whether the page has been madvised (`page_pool_freed`).

Julia's pool allocator follows a "tiered" allocation discipline. When requesting a memory page for the pool allocator, Julia will:

- Try to claim a page from `page_pool_lazily_freed`, which contains pages which were empty on the last stop-the-world phase, but not yet madvised by a concurrent sweeper GC thread.
- If it failed claiming a page from `page_pool_lazily_freed`, it will try to claim a page from the `page_pool_clean`, which contains pages which were mmaped on a previous page allocation request but never accessed.
- If it failed claiming a page from `pool_page_clean` and from `page_pool_lazily_freed`, it will try to claim a page from `page_pool_freed`, which contains pages which have already been madvised by a concurrent sweeper GC thread and whose underlying virtual address can be recycled.
- If it failed in all of the attempts mentioned above, it will mmap a batch of pages, claim one page for itself, and insert the remaining pages into `page_pool_clean`.

Marking and Generational Collection

Julia's mark phase is implemented through a parallel iterative depth-first-search over the object graph. Julia's collector is non-moving, so object age information can't be determined through the memory region in which the object resides alone, but has to be somehow encoded in the object header or on a side table.

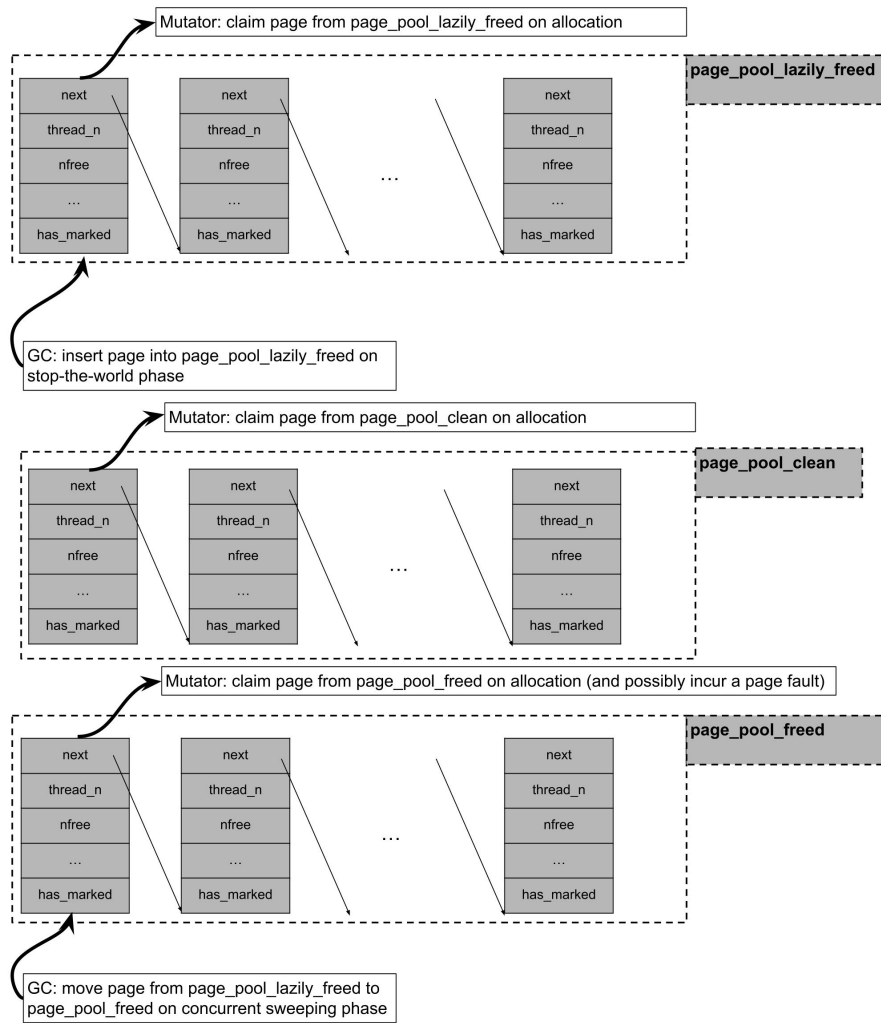

Figure 102.2: Diagram of tiered pool allocation

The lowest two bits of an object's header are used to store, respectively, a mark bit that is set when an object is scanned during the mark phase and an age bit for the generational collection.

Generational collection is implemented through sticky bits: objects are only pushed to the mark-stack, and therefore traced, if their mark-bits are not set. When objects reach the oldest generation, their mark-bits are not reset during the so-called "quick-sweep", which leads to these objects not being traced in a subsequent mark phase. A "full-sweep", however, causes the mark-bits of all objects to be reset, leading to all objects being traced in a subsequent mark phase. Objects are promoted to the next generation during every sweep phase they survive. On the mutator side, field writes are intercepted through a write barrier that pushes an object's address into a per-thread remembered set if the object is in the last generation, and if the object at the field being written is not. Objects in this remembered set are then traced during the mark phase.

Sweeping

Sweeping of object pools for Julia may fall into two categories: if a given page managed by the pool allocator contains at least one live object, then a free-list must be threaded through its dead objects; if a given page contains no live objects at all, then its underlying physical memory may be returned to the operating system through, for instance, the use of `madvise` system calls on Linux.

The first category of sweeping is currently serial and performed in the stop-the-world phase. For the second category of sweeping, if concurrent page sweeping is enabled through the flag `--gcthreads=X,1` we perform the `madvise` system calls in a background sweeper thread, concurrently with the mutator threads. During the stop-the-world phase of the collector, pool allocated pages which contain no live objects are initially pushed into the `pool_page_lazyly_freed`. The background sweeping thread is then woken up and is responsible for removing pages from `pool_page_lazyly_freed`, calling `madvise` on them, and inserting them into `pool_page_freed`. As described above, `pool_page_lazyly_freed` is also shared with mutator threads. This implies that on allocation-heavy multithreaded workloads, mutator threads would often avoid a page fault on allocation (coming from accessing a fresh `mmap`ed page or accessing a `madvised` page) by directly allocating from a page in `pool_page_lazyly_freed`, while the background sweeper thread needs to `madvise` a reduce number of pages given some of them were already claimed by the mutators.

Heuristics

GC heuristics tune the GC by changing the size of the allocation interval between garbage collections. If a GC was unproductive, then we increase the size of the allocation interval to allow objects more time to die. If a GC returns a lot of space we can shrink the interval. The goal is to find a steady state where we are allocating just about the same amount as we are collecting.

102.26 Fixing precompilation hangs due to open tasks or IO

On Julia 1.10 or higher, you might see the following message:

This may repeat. If it continues to repeat with no hints that it will resolve itself, you may have a "precompilation hang" that requires fixing. Even if it's transient, you might prefer to resolve it so that users will not be bothered by this warning. This page walks you through how to analyze and fix such issues.

If you follow the advice and hit `Ctrl-C`, you might see

```
^C Interrupted: Exiting precompilation...
1 dependency had warnings during precompilation: r
```

```
julia> using Test2
Precompiling Test2
Progress [> ] 0/2
Test1 Waiting for background task / IO / timer. Interrupt to inspect
```

Figure 102.3: Screenshot of precompilation hang

```
Test1 [ac89d554-e2ba-40bc-bc5c-de68b658c982] |
[pid 2745] waiting for IO to finish:|
Handle type      uv_handle_t->data|
timer            0x55580dec1e0->0x7f94c3a4c340
```

This message conveys two key pieces of information:

- the hang is occurring during precompilation of Test1, a dependency of Test2 (the package we were trying to load with `using Test2`)
- during precompilation of Test1, Julia created a Timer object (use `?Timer` if you're unfamiliar with Timers) which is still open; until that closes, the process is hung

If this is enough of a hint for you to figure out how `timer = Timer(args...)` is being created, one good solution is to add `wait(timer)` if `timer` eventually finishes on its own, or `close(timer)` if you need to force-close it, before the final end of the module.

However, there are cases that may not be that straightforward. Usually the best option is to start by determining whether the hang is due to code in Test1 or whether it is due to one of Test1's dependencies:

- Option 1: `Pkg.add("Aqua")` and use [Aqua.test_persistent_tasks](#). This should help you identify which package is causing the problem, after which the instructions [below](#) should be followed. If needed, you can create a `PkgId` as `Base.PkgId(UUID("..."), "Test1")`, where `...` comes from the `uuid` entry in `Test1/Project.toml`.
- Option 2: manually diagnose the source of the hang.

To manually diagnose:

1. `Pkg.develop("Test1")`
2. Comment out all the code included or defined in Test1, except the `using/import` statements.
3. Try using Test2 (or even using Test1 assuming that hangs too) again

Now we arrive at a fork in the road: either

- the hang persists, indicating it is [due to one of your dependencies](#)
- the hang disappears, indicating that it is [due to something in your code](#).

Diagnosing and fixing hangs due to a package dependency

Use a binary search to identify the problematic dependency: start by commenting out half your dependencies, then when you isolate which half is responsible comment out half of that half, etc. (You don't have to remove them from the project, just comment out the `using/import` statements.)

Once you've identified a suspect (here we'll call it `ThePackageYouThinkIsCausingTheProblem`), first try precompiling that package. If it also hangs during precompilation, continue chasing the problem backwards.

However, most likely `ThePackageYouThinkIsCausingTheProblem` will precompile fine. This suggests it's in the function `ThePackageYouThinkIsCausingTheProblem.__init__`, which does not run during precompilation of `ThePackageYouThinkIsCausingTheProblem` but does in any package that loads `ThePackageYouThinkIsCausingTheProblem`. To test this theory, set up a minimal working example (MWE), something like

```
(@v1.10) pkg> generate MWE
Generating project MWE:
  MWE\Project.toml
  MWE\src\MWE.jl
```

where the source code of `MWE.jl` is

```
module MWE
using ThePackageYouThinkIsCausingTheProblem
end
```

and you've added `ThePackageYouThinkIsCausingTheProblem` to MWE's dependencies.

If that MWE reproduces the hang, you've found your culprit: `ThePackageYouThinkIsCausingTheProblem.__init__` must be creating the `Timer` object. If the timer object can be safely closed, that's a good option. Otherwise, the most common solution is to avoid creating the timer while any package is being precompiled: add

```
ccall(:jl_generating_output, Cint, ()) == 1 && return nothing
```

as the first line of `ThePackageYouThinkIsCausingTheProblem.__init__`, and it will avoid doing any initialization in any Julia process whose purpose is to precompile packages.

Fixing package code to avoid hangs

Search your package for suggestive words (here like "Timer") and see if you can identify where the problem is being created. Note that a method definition like

```
maketimer() = Timer(timer -> println("hi"), 0; interval=1)
```

is not problematic in and of itself: it can cause this problem only if `maketimer` gets called while the module is being defined. This might be happening from a top-level statement such as

```
const GLOBAL_TIMER = maketimer()
```

or it might conceivably occur in a [precompile workload](#).

If you struggle to identify the causative lines, then consider doing a binary search: comment out sections of your package (or include lines to omit entire files) until you've reduced the problem in scope.

Chapter 103

Developing/debugging Julia's C code

103.1 Reporting and analyzing crashes (segfaults)

So you managed to break Julia. Congratulations! Collected here are some general procedures you can undergo for common symptoms encountered when something goes awry. Including the information from these debugging steps can greatly help the maintainers when tracking down a segfault or trying to figure out why your script is running slower than expected.

If you've been directed to this page, find the symptom that best matches what you're experiencing and follow the instructions to generate the debugging information requested. Table of symptoms:

- [Segfaults during bootstrap \(sysimg.jl\)](#)
- [Segfaults when running a script](#)
- [Errors during Julia startup](#)
- [Other generic segfaults or unreachables reached](#)

Version/Environment info

No matter the error, we will always need to know what version of Julia you are running. When Julia first starts up, a header is printed out with a version number and date. Please also include the output of `versioninfo()` (exported from the [InteractiveUtils](#) standard library) in any report you create:

```
julia> using InteractiveUtils

julia> versioninfo()
Julia Version 1.10.2
Commit bd47eca2c8a (2024-03-01 10:14 UTC)
Build Info:
  Official https://julialang.org/ release
Platform Info:
  OS: Linux (x86_64-linux-gnu)
  CPU: 4 × AMD EPYC 7763 64-Core Processor
  WORD_SIZE: 64
  LIBM: libopenlibm
```

```

LLVM: libLLVM-15.0.7 (ORCJIT, znver3)
Threads: 1 default, 0 interactive, 1 GC (on 4 virtual cores)
Environment:
  JULIA_DOCS =
↪ /home/runner/work/docs.julialang.org/docs.julialang.org/pdf/build/docs.julialang.org
  JULIA_SOURCE = /home/runner/work/docs.julialang.org/docs.julialang.org/pdf/build/julia
  JULIA_EXECUTABLE =
↪ /home/runner/work/docs.julialang.org/docs.julialang.org/pdf/build/julia-1.10.2-linux-
↪ x86_64/bin/julia

```

Segfaults during bootstrap (sysimg.jl)

Segfaults toward the end of the make process of building Julia are a common symptom of something going wrong while Julia is preparing the corpus of code in the `base/` folder. Many factors can contribute toward this process dying unexpectedly, however it is as often as not due to an error in the C-code portion of Julia, and as such must typically be debugged with a debug build inside of gdb. Explicitly:

Create a debug build of Julia:

```

$ cd <julia_root>
$ make debug

```

Note that this process will likely fail with the same error as a normal make incantation, however this will create a debug executable that will offer gdb the debugging symbols needed to get accurate backtraces. Next, manually run the bootstrap process inside of gdb:

```

$ cd base/
$ gdb -x ../contrib/debug_bootstrap.gdb

```

This will start gdb, attempt to run the bootstrap process using the debug build of Julia, and print out a backtrace if (when) it segfaults. You may need to hit <enter> a few times to get the full backtrace. Create a [gist](#) with the backtrace, the [version info](#), and any other pertinent information you can think of and open a new [issue](#) on Github with a link to the gist.

Segfaults when running a script

The procedure is very similar to [Segfaults during bootstrap \(sysimg.jl\)](#). Create a debug build of Julia, and run your script inside of a debugged Julia process:

```

$ cd <julia_root>
$ make debug
$ gdb --args usr/bin/julia-debug <path_to_your_script>

```

Note that gdb will sit there, waiting for instructions. Type `r` to run the process, and `bt` to generate a backtrace once it segfaults:

```

(gdb) r
Starting program: /home/sabae/src/julia/usr/bin/julia-debug ./test.jl
...
(gdb) bt

```

Create a [gist](#) with the backtrace, the [version info](#), and any other pertinent information you can think of and open a new [issue](#) on Github with a link to the gist.

Errors during Julia startup

Occasionally errors occur during Julia's startup process (especially when using binary distributions, as opposed to compiling from source) such as the following:

```
| $ julia  
| exec: error -5
```

These errors typically indicate something is not getting loaded properly very early on in the bootup phase, and our best bet in determining what's going wrong is to use external tools to audit the disk activity of the julia process:

- On Linux, use strace:

```
| $ strace julia
```

- On OSX, use dtruss:

```
| $ dtruss -f julia
```

Create a [gist](#) with the strace/ dtruss output, the [version info](#), and any other pertinent information and open a new [issue](#) on Github with a link to the gist.

Other generic segfaults or unreachables reached

As mentioned elsewhere, julia has good integration with rr for generating traces; this includes, on Linux, the ability to automatically run julia under rr and share the trace after a crash. This can be immensely helpful when debugging such crashes and is strongly encouraged when reporting crash issues to the JuliaLang/julia repo. To run julia under rr automatically, do:

```
| julia --bug-report=rr
```

To generate the rr trace locally, but not share, you can do:

```
| julia --bug-report=rr-local
```

Note that this only works on Linux. The blog post on [Time Travelling Bug Reporting](#) has many more details.

Glossary

A few terms have been used as shorthand in this guide:

- <julia_root> refers to the root directory of the Julia source tree; e.g. it should contain folders such as base, deps, src, test, etc.....

103.2 gdb debugging tips

Displaying Julia variables

Within gdb, any `julia_value_t*` object `obj` can be displayed using

```
| (gdb) call jl_(obj)
```

The object will be displayed in the julia session, not in the gdb session. This is a useful way to discover the types and values of objects being manipulated by Julia's C code.

Similarly, if you're debugging some of Julia's internals (e.g., `compiler.jl`), you can print `obj` using

```
| ccall(:jl_, Cvoid, (Any,), obj)
```

This is a good way to circumvent problems that arise from the order in which julia's output streams are initialized.

Julia's flisp interpreter uses `value_t` objects; these can be displayed with `call fl_print(fl_ctx, ios_stdout, obj)`.

Useful Julia variables for Inspecting

While the addresses of many variables, like singletons, can be useful to print for many failures, there are a number of additional variables (see `julia.h` for a complete list) that are even more useful.

- (when in `jl_apply_generic`) `mfunc` and `jl_uncompress_ast(mfunc->def, mfunc->code)` :: for figuring out a bit about the call-stack
- `jl_lineno` and `jl_filename` :: for figuring out what line in a test to go start debugging from (or figure out how far into a file has been parsed)
- `$1` :: not really a variable, but still a useful shorthand for referring to the result of the last gdb command (such as `print`)
- `jl_options` :: sometimes useful, since it lists all of the command line options that were successfully parsed
- `jl_uv_stderr` :: because who doesn't like to be able to interact with `stdio`

Useful Julia functions for Inspecting those variables

- `jl_gdblookup($rip)` :: For looking up the current function and line. (use `$eip` on i686 platforms)
- `jlbacktrace()` :: For dumping the current Julia backtrace stack to `stderr`. Only usable after `record_backtrace()` has been called.
- `jl_dump_llvm_value(Value*)` :: For invoking `Value->dump()` in gdb, where it doesn't work natively. For example, `f->linfo->functionObject`, `f->linfo->specFunctionObject`, and `to_function(f->linfo)`.
- `Type->dump()` :: only works in `lldb`. Note: add something like `;1` to prevent `lldb` from printing its prompt over the output

- `jl_eval_string("expr")` :: for invoking side-effects to modify the current state or to lookup symbols
- `jl_typeof(jl_value_t*)` :: for extracting the type tag of a Julia value (in gdb, call macro `define jl_typeof jl_typeof first`, or pick something short like `ty` for the first arg to define a shorthand)

Inserting breakpoints for inspection from gdb

In your gdb session, set a breakpoint in `jl_breakpoint` like so:

```
(gdb) break jl_breakpoint
```

Then within your Julia code, insert a call to `jl_breakpoint` by adding

```
ccall(:jl_breakpoint, Cvoid, (Any,), obj)
```

where `obj` can be any variable or tuple you want to be accessible in the breakpoint.

It's particularly helpful to back up to the `jl_apply` frame, from which you can display the arguments to a function using, e.g.,

```
(gdb) call jl_(args[0])
```

Another useful frame is `to_function(jl_method_instance_t *li, bool cstyle)`. The `jl_method_instance_t*` argument is a struct with a reference to the final AST sent into the compiler. However, the AST at this point will usually be compressed; to view the AST, call `jl_uncompress_ast` and then pass the result to `jl_`:

```
#2 0x00007ffff7928bf7 in to_function (li=0x2812060, cstyle=false) at codegen.cpp:584
584         abort();
(gdb) p jl_(jl_uncompress_ast(li, li->ast))
```

Inserting breakpoints upon certain conditions

Loading a particular file

Let's say the file is `sysimg.jl`:

```
(gdb) break jl_load if strcmp(fname, "sysimg.jl")==0
```

Calling a particular method

```
(gdb) break jl_apply_generic if strcmp((char*)(jl_symbol_name)(jl_gf_mtable(F)->name), "
method_to_break")==0
```

Since this function is used for every call, you will make everything 1000x slower if you do this.

Dealing with signals

Julia requires a few signals to function properly. The profiler uses `SIGUSR2` for sampling and the garbage collector uses `SIGSEGV` for threads synchronization. If you are debugging some code that uses the profiler or multiple threads, you may want to let the debugger ignore these signals since they can be triggered very often during normal operations. The command to do this in GDB is (replace `SIGSEGV` with `SIGUSR2` or other signals you want to ignore):

```
(gdb) handle SIGSEGV noprint nostop pass
```

The corresponding LLDB command is (after the process is started):

```
(lldb) pro hand -p true -s false -n false SIGSEGV
```

If you are debugging a segfault with threaded code, you can set a breakpoint on `jl_critical_error` (`sigdie_handler` should also work on Linux and BSD) in order to only catch the actual segfault rather than the GC synchronization points.

Debugging during Julia's build process (bootstrap)

Errors that occur during make need special handling. Julia is built in two stages, constructing `sys0` and `sys.ji`. To see what commands are running at the time of failure, use `make VERBOSE=1`.

At the time of this writing, you can debug build errors during the `sys0` phase from the base directory using:

```
julia/base$ gdb --args ../usr/bin/julia-debug -C native --build ../usr/lib/julia/sys0 sysimg.jl
```

You might need to delete all the files in `usr/lib/julia/` to get this to work.

You can debug the `sys.ji` phase using:

```
julia/base$ gdb --args ../usr/bin/julia-debug -C native --build ../usr/lib/julia/sys -J ../usr/lib/julia/sys0.ji sysimg.jl
```

By default, any errors will cause Julia to exit, even under `gdb`. To catch an error "in the act", set a breakpoint in `jl_error` (there are several other useful spots, for specific kinds of failures, including: `jl_too_few_args`, `jl_too_many_args`, and `jl_throw`).

Once an error is caught, a useful technique is to walk up the stack and examine the function by inspecting the related call to `jl_apply`. To take a real-world example:

```
Breakpoint 1, jl_throw (e=0x7ffdf42de400) at task.c:802
802 {
(gdb) p jl_(e)
ErrorException("auto_unbox: unable to determine argument type")
$2 = void
(gdb) bt 10
#0  jl_throw (e=0x7ffdf42de400) at task.c:802
#1  0x00007ffff65412fe in jl_error (str=0x7ffde56be000 <_j_str267> "auto_unbox:
    unable to determine argument type")
    at builtins.c:39
#2  0x00007ffde56bd01a in julia_convert_16886 ()
#3  0x00007ffff6541154 in jl_apply (f=0x7ffdf367f630, args=0x7ffffffffffc2b0, nargs=2) at julia.h
    :1281
...
```

The most recent `jl_apply` is at frame #3, so we can go back there and look at the AST for the function `julia_convert_16886`. This is the unique name for some method of `convert`. `f` in this frame is a `jl_function_t*`, so we can look at the type signature, if any, from the `specTypes` field:

```
(gdb) f 3
#3  0x00007ffff6541154 in jl_apply (f=0x7ffdf367f630, args=0x7ffffffffffc2b0, nargs=2) at julia.h
    :1281
```

```

1281         return f->fpPtr((jl_value_t*)f, args, nargs);
(gdb) p f->linfo->specTypes
$4 = (jl_tupletype_t *) 0x7ffdf39b1030
(gdb) p jl_( f->linfo->specTypes )
Tuple{Type{Float32}, Float64}          # <-- type signature for julia_convert_16886

```

Then, we can look at the AST for this function:

```

(gdb) p jl_( jl_uncompress_ast(f->linfo, f->linfo->ast) )
Expr(:lambda, Array{Any, 1}[:s29, :x], Array{Any, 1}[Array{Any, 1}[], Array{Any, 1}[Array{Any, 1}[:s29, :Any, 0], Array{Any, 1}[:x, :Any, 0]], Array{Any, 1}[], 0], Expr(:body,
Expr(:line, 90, :float.jl)::Any,
Expr(:return, Expr(:call, :box, :Float32, Expr(:call, :fpPtr, :Float32, :x)::Any)::Any)::Any)::Any)

```

Finally, and perhaps most usefully, we can force the function to be recompiled in order to step through the codegen process. To do this, clear the cached functionObject from the `jl_lambda_info_t`:

```

(gdb) p f->linfo->functionObject
$8 = (void *) 0x1289d070
(gdb) set f->linfo->functionObject = NULL

```

Then, set a breakpoint somewhere useful (e.g. `emit_function`, `emit_expr`, `emit_call`, etc.), and run codegen:

```

(gdb) p jl_compile(f)
... # your breakpoint here

```

Debugging precompilation errors

Module precompilation spawns a separate Julia process to precompile each module. Setting a breakpoint or catching failures in a precompile worker requires attaching a debugger to the worker. The easiest approach is to set the debugger watch for new process launches matching a given name. For example:

```

(gdb) attach -w -n julia-debug

```

or:

```

(lldb) process attach -w -n julia-debug

```

Then run a script/command to start precompilation. As described earlier, use conditional breakpoints in the parent process to catch specific file-loading events and narrow the debugging window. (some operating systems may require alternative approaches, such as following each fork from the parent process)

Mozilla's Record and Replay Framework (rr)

Julia now works out of the box with `rr`, the lightweight recording and deterministic debugging framework from Mozilla. This allows you to replay the trace of an execution deterministically. The replayed execution's address spaces, register contents, syscall data etc are exactly the same in every run.

A recent version of `rr` (3.1.0 or higher) is required.

Reproducing concurrency bugs with rr

rr simulates a single-threaded machine by default. In order to debug concurrent code you can use `rr record --chaos` which will cause rr to simulate between one to eight cores, chosen randomly. You might therefore want to set `JULIA_NUM_THREADS=8` and rerun your code under rr until you have caught your bug.

103.3 Using Valgrind with Julia

Valgrind is a tool for memory debugging, memory leak detection, and profiling. This section describes things to keep in mind when using Valgrind to debug memory issues with Julia.

General considerations

By default, Valgrind assumes that there is no self modifying code in the programs it runs. This assumption works fine in most instances but fails miserably for a just-in-time compiler like julia. For this reason it is crucial to pass `--smc-check=all-non-file` to valgrind, else code may crash or behave unexpectedly (often in subtle ways).

In some cases, to better detect memory errors using Valgrind it can help to compile julia with memory pools disabled. The compile-time flag `MEMDEBUG` disables memory pools in Julia, and `MEMDEBUG2` disables memory pools in FemtoLisp. To build julia with both flags, add the following line to `Make.user`:

```
| CFLAGS = -DMEMDEBUG -DMEMDEBUG2
```

Another thing to note: if your program uses multiple workers processes, it is likely that you want all such worker processes to run under Valgrind, not just the parent process. To do this, pass `--trace-children=yes` to valgrind.

Yet another thing to note: if using valgrind errors with `Unable to find compatible target in system image`, try rebuilding the sysimage with target generic or julia with `JULIA_CPU_TARGET=generic`.

Suppressions

Valgrind will typically display spurious warnings as it runs. To reduce the number of such warnings, it helps to provide a [suppressions file](#) to Valgrind. A sample suppressions file is included in the Julia source distribution at `contrib/valgrind-julia.supp`.

The suppressions file can be used from the `julia/` source directory as follows:

```
| $ valgrind --smc-check=all-non-file --suppressions=contrib/valgrind-julia.supp ./julia progname.  
| jl
```

Any memory errors that are displayed should either be reported as bugs or contributed as additional suppressions. Note that some versions of Valgrind are [shipped with insufficient default suppressions](#), so that may be one thing to consider before submitting any bugs.

Running the Julia test suite under Valgrind

It is possible to run the entire Julia test suite under Valgrind, but it does take quite some time (typically several hours). To do so, run the following command from the `julia/test/` directory:

```
| valgrind --smc-check=all-non-file --trace-children=yes --suppressions=$PWD/./contrib/valgrind-  
| julia.supp ../julia runtests.jl all
```

If you would like to see a report of "definite" memory leaks, pass the flags `--leak-check=full --show-leak-kinds=definite` to valgrind as well.

Additional spurious warnings

This section covers Valgrind warnings which cannot be added to the suppressions file yet are nonetheless safe to ignore.

Unhandled rr system calls

Valgrind will emit a warning if it encounters any of the [system calls that are specific to rr](#), the [Record and Replay Framework](#). In particular, a warning about an unhandled 1008 syscall will be shown when julia tries to detect whether it is running under rr:

```
--xxxxxx-- WARNING: unhandled amd64-linux syscall: 1008
--xxxxxx-- You may be able to write your own handler.
--xxxxxx-- Read the file README_MISSING_SYSCALL_OR_IOCTL.
--xxxxxx-- Nevertheless we consider this a bug. Please report
--xxxxxx-- it at http://valgrind.org/support/bug_reports.html.
```

This issue [has been reported](#) to the Valgrind developers as they have requested.

Caveats

Valgrind currently [does not support multiple rounding modes](#), so code that adjusts the rounding mode will behave differently when run under Valgrind.

In general, if after setting `--smc-check=all-non-file` you find that your program behaves differently when run under Valgrind, it may help to pass `--tool=none` to valgrind as you investigate further. This will enable the minimal Valgrind machinery but will also run much faster than when the full memory checker is enabled.

103.4 External Profiler Support

Julia provides explicit support for some external tracing profilers, enabling you to obtain a high-level overview of the runtime's execution behavior.

The currently supported profilers are:

- [Tracy](#)
- [Intel VTune \(ITTAPI\)](#)

Adding New Zones

To add new zones, use the `JL_TIMING` macro. You can find numerous examples throughout the codebase by searching for `JL_TIMING`. To add a new type of zone you add it to `JL_TIMING_OWNERS` (and possibly `JL_TIMING_EVENTS`).

Figure 103.1: Typical Tracy usage

Dynamically Enabling and Disabling Zones

The `JULIA_TIMING_SUBSYSTEMS` environment variable allows you to enable or disable zones for a specific Julia run. For instance, setting the variable to `+GC, -INFERENCE` will enable the GC zones and disable the INFERENCE zones.

Tracy Profiler

Tracy is a flexible profiler that can be optionally integrated with Julia.

A typical Tracy session might look like this:

Building Julia with Tracy

To enable Tracy integration, build Julia with the extra option `WITH_TRACY=1` in the `Make.user` file.

Installing the Tracy Profile Viewer

The easiest way to obtain the profile viewer is by adding the `TracyProfiler_jll` package and launching the profiler with:

```
| run(TracyProfiler_jll.tracy())
```

Note

On macOS, you may want to set the `TRACY_DPI_SCALE` environment variable to 1.0 if the UI elements in the profiler appear excessively large.

To run a "headless" instance that saves the trace to disk, use `TracyProfiler_jll.capture() -o mytracefile.tracy` instead.

For information on using the Tracy UI, refer to the Tracy manual.

Profiling Julia with Tracy

A typical workflow for profiling Julia with Tracy involves starting Julia using:

```
| JULIA_WAIT_FOR_TRACY=1 ./julia -e '[...]
```

The environment variable ensures that Julia waits until it has successfully connected to the Tracy profiler before continuing execution. Afterward, use the Tracy profiler UI, click Connect, and Julia execution should resume and profiling should start.

Profiling package precompilation with Tracy

To profile a package precompilation process it is easiest to explicitly call into `Base.compilecache` with the package you want to precompile:

```
| pkg = Base.identify_package("SparseArrays")
| withenv("JULIA_WAIT_FOR_TRACY" => 1, "TRACY_PORT" => 9001) do
|     Base.compilecache(pkg)
| end
```

Here, we use a custom port for tracy which makes it easier to find the correct client in the Tracy UI to connect to.

Adding metadata to zones

The various `jl_timing_show_*` and `jl_timing_printf` functions can be used to attach a string (or strings) to a zone. For example, the trace zone for inference shows the method instance that is being inferred.

The `TracyCZoneColor` function can be used to set the color of a certain zone. Search through the codebase to see how it is used.

Viewing Tracy files in your browser

Visit <https://topolarity.github.io/trace-viewer/> for an (experimental) web viewer for Tracy traces.

You can open a local `.tracy` file or provide a URL from the web (e.g. a file in a Github repo). If you load a trace file from the web, you can also share the page URL directly with others, enabling them to view the same trace.

Enabling stack trace samples

To enable call stack sampling in Tracy, build Julia with these options in your `Make.user` file:

```
WITH_TRACY := 1
WITH_TRACY_CALLSTACKS := 1
USE_BINARYBUILDER_LIBTRACYCLIENT := 0
```

You may also need to run `make -C deps clean-libtracyclient` to force a re-build of Tracy.

This feature has a significant impact on trace size and profiling overhead, so it is recommended to leave call stack sampling off when possible, especially if you intend to share your trace files online.

Note that the Julia JIT runtime does not yet have integration for Tracy's symbolification, so Julia functions will typically be unknown in these stack traces.

Intel VTune (ITTAPI) Profiler

This section is yet to be written.

103.5 Sanitizer support

[Sanitizers](#) can be used in custom Julia builds to make it easier to detect certain kinds of errors in Julia's internal C/C++ code.

Address Sanitizer: easy build

From a source-checkout of Julia, you should be able to build a version supporting address sanitization in Julia and LLVM as follows:

```
$ mkdir /tmp/julia
$ contrib/asan/build.sh /tmp/julia/
```

Here we've chosen `/tmp/julia` as a build directory, but you can choose whatever you wish. Once built, run the workload you wish to test with `/tmp/julia/julia`. Memory bugs will result in errors.

If you require customization or further detail, see the documentation below.

General considerations

Using Clang's sanitizers obviously requires you to use Clang (`USECLANG=1`), but there's another catch: most sanitizers require a run-time library, provided by the host compiler, while the instrumented code generated by Julia's JIT relies on functionality from that library. This implies that the LLVM version of your host compiler must match that of the LLVM library used within Julia.

An easy solution is to have a dedicated build folder for providing a matching toolchain, by building with `BUILD_LLVM_CLANG=1`. You can then refer to this toolchain from another build folder by specifying `USECLANG=1` while overriding the `CC` and `CXX` variables.

The sanitizers error out when they detect a shared library being opened using `RTLD_DEEPBIND` (ref: [google/sanitizers#611](#)). Since [libblastrampoline](#) by default uses `RTLD_DEEPBIND`, we need to set the environment variable `LBT_USE_RTLD_DEEPBIND=0` when using a sanitizer.

To use one of the sanitizers set `SANITIZE=1` and then the appropriate flag for the sanitizer you want to use.

On macOS, this might need some extra flags also to work. Altogether, it might look like this, plus one or more of the `SANITIZE_*` flags listed below:

```
make -C deps USE_BINARYBUILDER_LLVM=0 LLVM_VER=svn stage-llvm

make -C src SANITIZE=1 USECLANG=1 \
  CC=~+/deps/scratch/llvm-svn/build_Release/bin/clang \
  CXX=~+/deps/scratch/llvm-svn/build_Release/bin/clang++ \
  CPPFLAGS="-isysroot $(xcode-select -p)/Platforms/MacOSX.platform/Developer/SDKs/MacOSX.sdk" \
  CXXFLAGS="-isystem $(xcode-select -p)/Toolchains/XcodeDefault.xctoolchain/usr/include/c++/v1"
```

(or put these into your `Make.user`, so you don't need to remember them every time).

Address Sanitizer (ASAN)

For detecting or debugging memory bugs, you can use Clang's [address sanitizer \(ASAN\)](#). By compiling with `SANITIZE_ADDRESS=1` you enable ASAN for the Julia compiler and its generated code. In addition, you can specify `LLVM_SANITIZE=1` to sanitize the LLVM library as well. Note that these options incur a high performance and memory cost. For example, using ASAN for Julia and LLVM makes `testall1` take 8-10 times as long while using 20 times as much memory (this can be reduced to respectively a factor of 3 and 4 by using the options described below).

By default, Julia sets the `allow_user_segv_handler=1` ASAN flag, which is required for signal delivery to work properly. You can define other options using the `ASAN_OPTIONS` environment flag, in which case you'll need to repeat the default option mentioned before. For example, memory usage can be reduced by specifying `fast_unwind_on_malloc=0` and `malloc_context_size=2`, at the cost of backtrace accuracy. For now, Julia also sets `detect_leaks=0`, but this should be removed in the future.

Example setup

Step 1: Install toolchain Checkout a Git worktree (or create out-of-tree build directory) at `$TOOLCHAIN_WORKTREE` and create a config file `$TOOLCHAIN_WORKTREE/Make.user` with

```
USE_BINARYBUILDER_LLVM=1
BUILD_LLVM_CLANG=1
```

Run:

```
cd $TOOLCHAIN_WORKTREE
make -C deps install-llvm install-clang install-llvm-tools
```

to install toolchain binaries in `$TOOLCHAIN_WORKTREE/usr/tools`

Step 2: Build Julia with ASAN Checkout a Git worktree (or create out-of-tree build directory) at `$BUILD_WORKTREE` and create a config file `$BUILD_WORKTREE/Make.user` with

```
TOOLCHAIN=$(TOOLCHAIN_WORKTREE)/usr/tools

# use our new toolchain
USECLANG=1
override CC=$(TOOLCHAIN)/clang
override CXX=$(TOOLCHAIN)/clang++
export ASAN_SYMBOLIZER_PATH=$(TOOLCHAIN)/llvm-symbolizer
```

```

USE_BINARYBUILDER_LLVM=1

override SANITIZE=1
override SANITIZE_ADDRESS=1

# make the GC use regular malloc/frees, which are hooked by ASAN
override WITH_GC_DEBUG_ENV=1

# default to a debug build for better line number reporting
override JULIA_BUILD_MODE=debug

# make ASAN consume less memory
export ASAN_OPTIONS=detect_leaks=0:fast_unwind_on_malloc=0:allow_user_segv_handler=1:
    malloc_context_size=2

JULIA_PRECOMPILE=1

# tell libblastrampoline to not use RTLD_DEEPBIND
export LBT_USE_RTLD_DEEPBIND=0

```

Run:

```

cd $BUILD_WORKTREE
make debug

```

to build `julia-debug` with ASAN.

Memory Sanitizer (MSAN)

For detecting use of uninitialized memory, you can use Clang's [memory sanitizer \(MSAN\)](#) by compiling with `SANITIZE_MEMORY=1`.

Thread Sanitizer (TSAN)

For debugging data-races and other threading related issues you can use Clang's [thread sanitizer \(TSAN\)](#) by compiling with `SANITIZE_THREAD=1`.

103.6 Instrumenting Julia with DTrace, and bpftrace

DTrace and bpftrace are tools that enable lightweight instrumentation of processes. You can turn the instrumentation on and off while the process is running, and with instrumentation off the overhead is minimal.

Julia 1.8

Support for probes was added in Julia 1.8

Note

This documentation has been written from a Linux perspective, most of this should hold on Mac OS/Darwin and FreeBSD.

Enabling support

On Linux install the systemtap package that has a version of dttrace and create a Make.user file containing

```
| WITH_DTRACE=1
```

to enable USDT probes.

Verifying

```
> readelf -n usr/lib/libjulia-internal.so.1

Adding probes in libjulia

Probes are declared in dtraces format in the file src/uprobes.d. The generated header file is included in src/julia_internal.h and if you add probes you should provide a noop implementation there.

The header will contain a semaphore *_ENABLED and the actual call to the probe. If the probe arguments are expensive to compute you should first check if the probe is enabled and then compute the arguments and call the probe.

```
| if (JL_PROBE_{PROBE}_ENABLED())
|     auto expensive_arg = ...;
|     JL_PROBE_{PROBE}(expensive_arg);
```

If your probe has no arguments it is preferred to not include the semaphore check. With USDT probes enabled the cost of a semaphore is a memory load, irrespective of the fact that the probe is enabled or not.

```
#define JL_PROBE_GC_BEGIN_ENABLED() __builtin_expect (julia_gc__begin_semaphore, 0)
__extension__ extern unsigned short julia_gc__begin_semaphore __attribute__ ((unused))
__attribute__ ((section (".probes")));
```

Whereas the probe itself is a noop sled that will be patched to a trampoline to the probe handler.

Available probes

GC probes

1. `julia:gc__begin`: GC begins running on one thread and triggers stop-the-world.
2. `julia:gc__stop_the_world`: All threads have reached a safepoint and GC runs.
3. `julia:gc__mark__begin`: Beginning the mark phase
4. `julia:gc__mark_end(scanned_bytes, perm_scanned)`: Mark phase ended
5. `julia:gc__sweep_begin(full)`: Starting sweep
6. `julia:gc__sweep_end`: Sweep phase finished
7. `julia:gc__end`: GC is finished, other threads continue work
8. `julia:gc__finalizer`: Initial GC thread has finished running finalizers

Task runtime probes

1. `julia:rt__run__task(task)`: Switching to task `task` on current thread.
2. `julia:rt__pause__task(task)`: Switching from task `task` on current thread.
3. `julia:rt__new__task(parent, child)`: Task `parent` created task `child` on current thread.
4. `julia:rt__start__task(task)`: Task `task` started for the first time with a new stack.
5. `julia:rt__finish__task(task)`: Task `task` finished and will no longer execute.
6. `julia:rt__start__process__events(task)`: Task `task` started processing libuv events.
7. `julia:rt__finish__process__events(task)`: Task `task` finished processing libuv events.

Task queue probes

1. `julia:rt__taskq__insert(ptls, task)`: Thread `ptls` attempted to insert `task` into a PARTR multiq.
2. `julia:rt__taskq__get(ptls, task)`: Thread `ptls` popped `task` from a PARTR multiq.

Thread sleep/wake probes

1. `julia:rt__sleep__check__wake(ptls, old_state)`: Thread (PTLS ptls) waking up, previously in state `old_state`.
2. `julia:rt__sleep__check__wakeup(ptls)`: Thread (PTLS ptls) woke itself up.
3. `julia:rt__sleep__check__sleep(ptls)`: Thread (PTLS ptls) is attempting to sleep.
4. `julia:rt__sleep__check__taskq__wake(ptls)`: Thread (PTLS ptls) fails to sleep due to tasks in PARTR multiq.
5. `julia:rt__sleep__check__task__wake(ptls)`: Thread (PTLS ptls) fails to sleep due to tasks in Base workqueue.
6. `julia:rt__sleep__check__uv__wake(ptls)`: Thread (PTLS ptls) fails to sleep due to libuv wakeup.

Probe usage examples**GC stop-the-world latency**

An example bpftrace script is given in `contrib/gc_stop_the_world_latency.bt` and it creates a histogram of the latency for all threads to reach a safepoint.

Running this Julia code, with `julia -t 2`

```
using Base.Threads

fib(x) = x <= 1 ? 1 : fib(x-1) + fib(x-2)

beaver = @spawn begin
    while true
        fib(30)
        # This safepoint is necessary until #41616, since otherwise this
        # loop will never yield to GC.
        GC.safepoint()
    end
end

allocator = @spawn begin
    while true
        zeros(1024)
    end
end

wait(allocator)
```

and in a second terminal

```
> sudo contrib/bpftrace/gc_stop_the_world_latency.bt
Attaching 4 probes...
Tracing Julia GC Stop-The-World Latency... Hit Ctrl-C to end.
^C

@usecs[1743412]:
```

and it's still the same task we were monitoring! Of course, we can remove this filter to see all newly-created tasks just as easily:

```
sudo bpftrace -p 997825 -e 'usdt:usr/lib/libjulia-internal.so:julia:rt__new__task { printf("Task: %x\n", arg0); }'
```

```
Task: 4d088010
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
Task: 4dc4e290
```

We can see our root task, and the newly-spawned task as the parent of the ten even newer tasks.

Thundering herd detection

Task runtimes can often suffer from the "thundering herd" problem: when some work is added to a quiet task runtime, all threads may be woken up from their slumber, even if there isn't enough work for each thread to process. This can cause extra latency and CPU cycles while all threads awaken (and simultaneously go back to sleep, not finding any work to execute).

We can see this problem illustrated with bpftrace quite easily. First, in one terminal we start Julia with multiple threads (6 in this example), and get the PID of that process:

```
> julia -t 6

      _ _ _ _ _
     ( ) | ( ) ( ) | Documentation: https://docs.julialang.org
      _ _ _ _ _ | Type "?" for help, "]?" for Pkg help.
     | | | | | / _ \ |
     | | | | | ( _ | | Version 1.6.2 (2021-07-14)
     / | \ _ ' | _ | \ _ ' | Official https://julialang.org/ release
    | _ /      |

l> getpid()
997825
```

And in another terminal we start bpftrace monitoring our process, specifically probing the `rt__sleep__check__wake` hook:

```
sudo bpftrace -p 997825 -e 'usdt:usr/lib/libjulia-internal.so:julia:rt__sleep__check__wake { printf("Thread wake up! %x\n", arg0); }'
```

Now, we create and execute a single task in Julia:

```
Threads.@spawn 1+1
```

And in bpftrace we see printed out something like:

```
| Thread wake up! 3f926100
```

```
Thread wake up! 3ebd5140
Thread wake up! 3f876130
Thread wake up! 3e2711a0
Thread wake up! 3e312190
```

Even though we only spawned a single task (which only one thread could process at a time), we woke up all of our other threads! In the future, a smarter task runtime might only wake up a single thread (or none at all; the spawning thread could execute this task!), and we should see this behavior go away.

Task Monitor with BPFnative.jl

BPFnative.jl is able to attach to USDT probe points just like `bpfttrace`. There is a demo available for monitoring the task runtime, GC, and thread sleep/wake transitions [here](#).

Notes on using `bpfttrace`

An example probe in the `bpfttrace` format looks like:

```
usdt:usr/lib/libjulia-internal.so:julia:gc__begin
{
  @start[pid] = nsecs;
}
```

The probe declaration takes the kind `usdt`, then either the path to the library or the PID, the provider name `julia` and the probe name `gc__begin`. Note that I am using a relative path to the `libjulia-internal.so`, but this might need to be an absolute path on a production system.

Chapter 104

Building Julia

104.1 Building Julia (Detailed)

Downloading the Julia source code

If you are behind a firewall, you may need to use the `https` protocol instead of the `git` protocol:

```
| git config --global url."https://".insteadOf git://
```

Be sure to also configure your system to use the appropriate proxy settings, e.g. by setting the `https_proxy` and `http_proxy` variables.

Building Julia

When compiled the first time, the build will automatically download pre-built [external dependencies](#). If you prefer to build all the dependencies on your own, or are building on a system that cannot access the network during the build process, add the following in `Make.user`:

```
| USE_BINARYBUILDER=0
```

Building Julia requires 5GiB if building all dependencies and approximately 4GiB of virtual memory.

To perform a parallel build, use `make -j N` and supply the maximum number of concurrent processes. If the defaults in the build do not work for you, and you need to set specific make parameters, you can save them in `Make.user`, and place the file in the root of your Julia source. The build will automatically check for the existence of `Make.user` and use it if it exists.

You can create out-of-tree builds of Julia by specifying `make 0=<build-directory>` configure on the command line. This will create a directory mirror, with all of the necessary Makefiles to build Julia, in the specified directory. These builds will share the source files in Julia and `deps/src/cache`. Each out-of-tree build directory can have its own `Make.user` file to override the global `Make.user` file in the top-level folder.

If everything works correctly, you will see a Julia banner and an interactive prompt into which you can enter expressions for evaluation. (Errors related to libraries might be caused by old, incompatible libraries sitting around in your `PATH`. In this case, try moving the `julia` directory earlier in the `PATH`). Note that most of the instructions above apply to unix systems.

To run Julia from anywhere you can:

- add an alias (in bash: `echo "alias julia='/path/to/install/folder/bin/julia'" >> ~/.bashrc` && `source ~/.bashrc`), or
- add a soft link to the julia executable in the julia directory to `/usr/local/bin` (or any suitable directory already in your path), or
- add the julia directory to your executable path for this shell session (in bash: `export PATH="$(pwd):$PATH"` ; in csh or tcsh:

```
set path= ( $path $cwd ) ), or
```

- add the julia directory to your executable path permanently (e.g. in `.bash_profile`), or
- write `prefix=/path/to/install/folder` into `Make.user` and then run `make install`. If there is a version of Julia already installed in this folder, you should delete it before running `make install`.

Some of the options you can set to control the build of Julia are listed and documented at the beginning of the file `Make.inc`, but you should never edit it for this purpose, use `Make.user` instead.

Julia's Makefiles define convenient automatic rules called `print-<VARNAME>` for printing the value of variables, replacing `<VARNAME>` with the name of the variable to print the value of. For example

```
$ make print-JULIA_PRECOMPILE
JULIA_PRECOMPILE=1
```

These rules are useful for debugging purposes.

Now you should be able to run Julia like this:

```
| julia
```

If you are building a Julia package for distribution on Linux, macOS, or Windows, take a look at the detailed notes in [distributing.md](#).

Updating an existing source tree

If you have previously downloaded julia using `git clone`, you can update the existing source tree using `git pull` rather than starting anew:

```
| cd julia
| git pull && make
```

Assuming that you had made no changes to the source tree that will conflict with upstream updates, these commands will trigger a build to update to the latest version.

General troubleshooting

1. Over time, the base library may accumulate enough changes such that the bootstrapping process in building the system image will fail. If this happens, the build may fail with an error like

```
*** This error is usually fixed by running 'make clean'. If the error persists, try 'make
cleanall' ***
```

As described, running `make clean && make` is usually sufficient. Occasionally, the stronger cleanup done by `make cleanall` is needed.

2. New versions of external dependencies may be introduced which may occasionally cause conflicts with existing builds of older versions.
 - a. Special `make` targets exist to help wipe the existing build of a dependency. For example, `make -C deps clean-llvm` will clean out the existing build of `llvm` so that `llvm` will be rebuilt from the downloaded source distribution the next time `make` is called. `make -C deps distclean-llvm` is a stronger wipe which will also delete the downloaded source distribution, ensuring that a fresh copy of the source distribution will be downloaded and that any new patches will be applied the next time `make` is called.
 - b. To delete existing binaries of `julia` and all its dependencies, delete the `./usr` directory in the source tree.
3. If you've updated macOS recently, be sure to run `xcode-select --install` to update the command line tools. Otherwise, you could run into errors for missing headers and libraries, such as `ld: library not found for -lcrt1.10.6.o`.
4. If you've moved the source directory, you might get errors such as `CMake Error: The current CMakeCache.txt directory ... is different than the directory ... where CMakeCache.txt was created.`, in which case you may delete the offending dependency under `deps`
5. In extreme cases, you may wish to reset the source tree to a pristine state. The following `git` commands may be helpful:

```
git reset --hard #Forcibly remove any changes to any files under version control
git clean -x -f -d #Forcibly remove any file or directory not under version control
```

To avoid losing work, make sure you know what these commands do before you run them. `git` will not be able to undo these changes!

Platform-Specific Notes

Notes for various operating systems:

- [Linux](#)
- [macOS](#)
- [Windows](#)
- [FreeBSD](#)

Notes for various architectures:

- [ARM](#)

Required Build Tools and External Libraries

Building Julia requires that the following software be installed:

- **[GNU make]** — building dependencies.
- **[gcc & g++][gcc]** (≥ 7.1) or **[Clang][clang]** (≥ 5.0 , ≥ 9.3 for Apple Clang) — compiling and linking C, C++.
- **[libatomic][gcc]** — provided by **[gcc]** and needed to support atomic operations.
- **[python]** (≥ 2.7) — needed to build LLVM.
- **[gfortran]** — compiling and linking Fortran libraries.
- **[perl]** — preprocessing of header files of libraries.
- **[wget], [curl], or [fetch]** (FreeBSD) — to automatically download external libraries.
- **[m4]** — needed to build GMP.
- **[awk]** — helper tool for Makefiles.
- **[patch]** — for modifying source code.
- **[cmake]** ($\geq 3.4.3$) — needed to build libgit2.
- **[pkg-config]** — needed to build libgit2 correctly, especially for proxy support.
- **[powershell]** (≥ 3.0) — necessary only on Windows.
- **[which]** — needed for checking build dependencies.

On Debian-based distributions (e.g. Ubuntu), you can easily install them with `apt-get`:

```
sudo apt-get install build-essential libatomic1 python gfortran perl wget m4 cmake pkg-config
curl
```

Julia uses the following external libraries, which are automatically downloaded (or in a few cases, included in the Julia source repository) and then compiled from source the first time you run `make`. The specific version numbers of these libraries that Julia uses are listed in `deps/$(libname).version`:

- **[LLVM]** (15.0 + [patches](#)) — compiler infrastructure (see [note below](#)).
- **[FemtoLisp]** — packaged with Julia source, and used to implement the compiler front-end.
- **[libuv]** (custom fork) — portable, high-performance event-based I/O library.
- **[OpenLibm]** — portable libm library containing elementary math functions.
- **[DSFMT]** — fast Mersenne Twister pseudorandom number generator library.
- **[OpenBLAS]** — fast, open, and maintained [basic linear algebra subprograms (BLAS)]
- **[LAPACK]** — library of linear algebra routines for solving systems of simultaneous linear equations, least-squares solutions of linear systems of equations, eigenvalue problems, and singular value problems.

- **[MKL]** (optional) – OpenBLAS and LAPACK may be replaced by Intel's MKL library.
- **[SuiteSparse]** — library of linear algebra routines for sparse matrices.
- **[PCRE]** — Perl-compatible regular expressions library.
- **[GMP]** — GNU multiple precision arithmetic library, needed for BigInt support.
- **[MPFR]** — GNU multiple precision floating point library, needed for arbitrary precision floating point (BigFloat) support.
- **[libgit2]** — Git linkable library, used by Julia's package manager.
- **[curl]** — libcurl provides download and proxy support.
- **[libssh2]** — library for SSH transport, used by libgit2 for packages with SSH remotes.
- **[mbedtls]** — library used for cryptography and transport layer security, used by libssh2
- **[utf8proc]** — a library for processing UTF-8 encoded Unicode strings.
- **[LLVM libunwind]** — LLVM's fork of [libunwind], a library that determines the call-chain of a program.
- **[ITTAPI]** — Intel's Instrumentation and Tracing Technology and Just-In-Time API.

Build dependencies

If you already have one or more of these packages installed on your system, you can prevent Julia from compiling duplicates of these libraries by passing `USE_SYSTEM_...=1` to `make` or adding the line to `Make.user`. The complete list of possible flags can be found in `Make.inc`.

Please be aware that this procedure is not officially supported, as it introduces additional variability into the installation and versioning of the dependencies, and is recommended only for system package maintainers. Unexpected compile errors may result, as the build system will do no further checking to ensure the proper packages are installed.

LLVM

The most complicated dependency is LLVM, for which we require additional patches from upstream (LLVM is not backward compatible).

For packaging Julia with LLVM, we recommend either:

- bundling a Julia-only LLVM library inside the Julia package, or
- adding the patches to the LLVM package of the distribution.
 - A complete list of patches is available in on [Github](#) see the `julia-release/15.x` branch.
 - The only Julia-specific patch is the lib renaming (`llvm7-symver-jlprefix.patch`), which should not be applied to a system LLVM.
 - The remaining patches are all upstream bug fixes, and have been contributed into upstream LLVM.

Using an unpatched or different version of LLVM will result in errors and/or poor performance. You can build a different version of LLVM from a remote Git repository with the following options in the `Make.user` file:

```
# Force source build of LLVM
USE_BINARYBUILDER_LLVM = 0
# Use Git for fetching LLVM source code
# this is either `1` to get all of them
DEPS_GIT = 1
# or a space-separated list of specific dependencies to download with git
DEPS_GIT = llvm

# Other useful options:
#URL of the Git repository you want to obtain LLVM from:
# LLVM_GIT_URL = ...
#Name of the alternate branch to clone from git
# LLVM_BRANCH = julia-16.0.6-0
#SHA hash of the alterate commit to check out automatically
# LLVM_SHA1 = $(LLVM_BRANCH)
#List of LLVM targets to build. It is strongly recommended to keep at least all the
#default targets listed in `deps/llvm.mk`, even if you don't necessarily need all of them.
# LLVM_TARGETS = ...
#Use ccache for faster recompilation in case you need to restart a build.
# USECCACHE = 1
# CMAKE_GENERATOR=Ninja
# LLVM_ASSERTIONS=1
# LLVM_DEBUG=Symbols
```

The various build phases are controlled by specific files:

- `deps/llvm.version`: touch or change to checkout a new version, make `get-llvm check-llvm`
- `deps/srccache/llvm/source-extracted`: result of make `extract-llvm`
- `deps/llvm/build_Release*/build-configured`: result of make `configure-llvm`
- `deps/llvm/build_Release*/build-configured`: result of make `compile-llvm`

- `usr-staging/llvm/build_Release*.tgz`: result of `make stage-llvm` (regenerate with `make reinstall-llvm`)
- `usr/manifest/llvm`: result of `make install-llvm` (regenerate with `make uninstall-llvm`)
- `make version-check-llvm`: runs every time to warn the user if there are local modifications

Though Julia can be built with newer LLVM versions, support for this should be regarded as experimental and not suitable for packaging.

libuv

Julia uses a custom fork of libuv. It is a small dependency, and can be safely bundled in the same package as Julia, and will not conflict with the system library. Julia builds should not try to use the system libuv.

BLAS and LAPACK

As a high-performance numerical language, Julia should be linked to a multi-threaded BLAS and LAPACK, such as OpenBLAS or ATLAS, which will provide much better performance than the reference libblas implementations which may be default on some systems.

Source distributions of releases

Each pre-release and release of Julia has a "full" source distribution and a "light" source distribution.

The full source distribution contains the source code for Julia and all dependencies so that it can be built from source without an internet connection. The light source distribution does not include the source code of dependencies.

For example, `julia-1.0.0.tar.gz` is the light source distribution for the v1.0.0 release of Julia, while `julia-1.0.0-full.tar.gz` is the full source distribution.

Building Julia from source with a Git checkout of a stdlib

If you need to build Julia from source with a Git checkout of a stdlib, then use `make DEPS_GIT=NAME_OF_STDLIB` when building Julia.

For example, if you need to build Julia from source with a Git checkout of Pkg, then use `make DEPS_GIT=Pkg` when building Julia. The Pkg repo is in `stdlib/Pkg`, and created initially with a detached HEAD. If you're doing this from a pre-existing Julia repository, you may need to make `clean` beforehand.

If you need to build Julia from source with Git checkouts of more than one stdlib, then `DEPS_GIT` should be a space-separated list of the stdlib names. For example, if you need to build Julia from source with a Git checkout of Pkg, Tar, and Downloads, then use `make DEPS_GIT='Pkg Tar Downloads'` when building Julia.

Building an "assert build" of Julia

An "assert build" of Julia is a build that was built with both `FORCE_ASSERTIONS=1` and `LLVM_ASSERTIONS=1`. To build an assert build, define both of the following variables in your `Make.user` file:

```
FORCE_ASSERTIONS=1
LLVM_ASSERTIONS=1
```

Please note that assert builds of Julia will be slower than regular (non-assert) builds.

Building 32-bit Julia on a 64-bit machine

Occasionally, bugs specific to 32-bit architectures may arise, and when this happens it is useful to be able to debug the problem on your local machine. Since most modern 64-bit systems support running programs built for 32-bit ones, if you don't have to recompile Julia from source (e.g. you mainly need to inspect the behavior of a 32-bit Julia without having to touch the C code), you can likely use a 32-bit build of Julia for your system that you can obtain from the [official downloads page](#). However, if you do need to recompile Julia from source one option is to use a Docker container of a 32-bit system. At least for now, building a 32-bit version of Julia is relatively straightforward using [ubuntu 32-bit docker images](#). In brief, after setting up docker here are the required steps:

```
$ docker pull i386/ubuntu
$ docker run --platform i386 -i -t i386/ubuntu /bin/bash
```

At this point you should be in a 32-bit machine console (note that `uname` reports the host architecture, so will still say 64-bit, but this will not affect the Julia build). You can add packages and compile code; when you exit, all the changes will be lost, so be sure to finish your analysis in a single session or set up a copy/pastable script you can use to set up your environment.

From this point, you should

```
# apt update
```

(Note that `sudo` isn't installed, but neither is it necessary since you are running as `root`, so you can omit `sudo` from all commands.)

Then add all the [build dependencies](#), a console-based editor of your choice, `git`, and anything else you'll need (e.g., `gdb`, `rr`, etc). Pick a directory to work in and `git clone Julia`, check out the branch you wish to debug, and build Julia as usual.

Update the version number of a dependency

There are two types of builds

1. Build everything (`deps/` and `src/`) from source code. (Add `USE_BINARYBUILDER=0` to `Make.user`, see [Building Julia](#))
2. Build from source (`src/`) with pre-compiled dependencies (default)

When you want to update the version number of a dependency in `deps/`, you may want to use the following checklist:

```
### Check list

Version numbers:
- [ ] `deps/${libname}.version`: `LIBNAME_VER`, `LIBNAME_BRANCH`, `LIBNAME_SHA1` and `LIBNAME_JLL_VER`
- [ ] `stdlib/${LIBNAME_JLL_NAME}_jll/Project.toml`: `version`

Checksum:
- [ ] `deps/checksums/${libname}`
- [ ] `deps/checksums/${LIBNAME_JLL_NAME}-*/`: `md5` and `sha512`
```

```
Patches:
- [ ] `deps/$(libname).mk`
- [ ] `deps/patches/$(libname)-*.patch`
```

Note:

- For specific dependencies, some items in the checklist may not exist.
- For checksum file, it may be **a single file** without a suffix, or **a folder** containing two files.

Example: OpenLibm

1. Update Version numbers in `deps/openlibm.version`
 - `OPENLIBM_VER := 0.X.Y`
 - `OPENLIBM_BRANCH = v0.X.Y`
 - `OPENLIBM_SHA1 = new-sha1-hash`
2. Update Version number in `stdlib/OpenLibm_jll/Project.toml`
 - `version = "0.X.Y+0"`
3. Update checksums in `deps/checksums/openlibm`
 - `make -f contrib/refresh_checksums.mk openlibm`
4. Check if the patch files `deps/patches/openlibm-*.patch` exist
 - if patches don't exist, skip.
 - if patches exist, check if they have been merged into the new version and need to be removed.
When deleting a patch, remember to modify the corresponding Makefile file (`deps/openlibm.mk`).

104.2 Linux

- GCC version 4.7 or later is required to build Julia.
- To use external shared libraries not in the system library search path, set `USE_SYSTEM_XXX=1` and `LD_FLAGS=-Wl,-rpath,/path/to/dir/contains/libXXX.so` in `Make.user`.
- Instead of setting `LD_FLAGS`, putting the library directory into the environment variable `LD_LIBRARY_PATH` (at both compile and run time) also works.
- The `USE_SYSTEM_*` flags should be used with caution. These are meant only for troubleshooting, porting, and packaging, where package maintainers work closely with the Julia developers to make sure that Julia is built correctly. Production use cases should use the officially provided binaries. Issues arising from the use of these flags will generally not be accepted.
- See also the [external dependencies](#).

Architecture Customization

Julia can be built for a non-generic architecture by configuring the ARCH Makefile variable in a Make.user file. See the appropriate section of Make.inc for additional customization options, such as MARCH and JULIA_CPU_TARGET.

For example, to build for Pentium 4, set MARCH=pentium4 and install the necessary system libraries for linking. On Ubuntu, these may include lib32gfortran-6-dev, lib32gcc1, and lib32stdc++6, among others.

You can also set MARCH=native in Make.user for a maximum-performance build customized for the current machine CPU.

Linux Build Troubleshooting

| Problem | Possible Solution |
|---------------------------|--|
| OpenBLAS build failure | <p>Set one of the following build options in Make.user and build again: <ul style="list-style-type: none">OPENBLAS_TARGET_ARCH=BARCELONA (AMD CPUs) or OPENBLAS_TARGET_ARCH=NEHALEM (Intel CPUs)Set OPENBLAS_DYNAMIC_ARCH = 0 to disable compiling multiple architectures in a single binary.OPENBLAS_NO_AVX2 = 1 disables AVX2 instructions, allowing OpenBLAS to compile with OPENBLAS_DYNAMIC_ARCH = 1 using old versions of binutilsUSE_SYSTEM_BLAS=1 uses the system provided libblasSet LIBBLAS=-lopenblas and LIBBLASNAME=libopenblas to force the use of the system provided OpenBLAS when multiple BLAS versions are installed.</p> <p>If you get an error that looks like <code>../kernel/x86_64/dgemm_kernel_4x4_haswell.S:1709: Error: no such instruction: `vpermpd \$ 0xb1,%ymm0,%ymm0'</code>, then you need to set OPENBLAS_DYNAMIC_ARCH = 0 or OPENBLAS_NO_AVX2 = 1, or you need a newer version of binutils (2.18 or newer). (Issue #7653)</p> <p>If the linker cannot find gfortran and you get an error like <code>julia /usr/bin/x86_64-linux-gnu-ld: cannot find -lgfortran</code>, check the path with <code>gfortran -print-file-name=libgfortran.so</code> and use the output to export something similar to this: <code>export LDFLAGS=-L/usr/lib/gcc/x86_64-linux-gnu/8/</code>. See Issue #6150.</p> |
| Illegal Instruction error | <p>Check if your CPU supports AVX while your OS does not (e.g. through virtualization, as described in this issue).</p> |

104.3 macOS

You need to have the current Xcode command line utilities installed: run `xcode-select --install` in the terminal. You will need to rerun this terminal command after each macOS update, otherwise you may run into errors involving missing libraries or headers.

The dependent libraries are now built with [BinaryBuilder](#) and will be automatically downloaded. This is the preferred way to build Julia source. In case you want to build them all on your own, you will need a 64-bit gfortran to compile Julia dependencies.

```
| brew install gcc
```

If you have set LD_LIBRARY_PATH or DYLD_LIBRARY_PATH in your .bashrc or equivalent, Julia may be unable to find various libraries that come bundled with it. These environment variables need to be unset for Julia to work.

104.4 Windows

This file describes how to install, or build, and use Julia on Windows.

For more general information about Julia, please see the [main README](#) or the [documentation](#).

General Information for Windows

We highly recommend running Julia using a modern terminal application, in particular Windows Terminal, which can be installed from the [Microsoft Store](#).

Line endings

Julia uses binary-mode files exclusively. Unlike many other Windows programs, if you write `\n` to a file, you get a `\n` in the file, not some other bit pattern. This matches the behavior exhibited by other operating systems. If you have installed Git for Windows, it is suggested, but not required, that you configure your system Git to use the same convention:

```
git config --global core.eol lf
git config --global core.autocrlf input
```

or edit `%USERPROFILE%\.gitconfig` and add/edit the lines:

```
[core]
  eol = lf
  autocrlf = input
```

Binary distribution

For the binary distribution installation notes on Windows please see the instructions at <https://julialang.org/downloads/platform/#windows>.

Source distribution

Cygwin-to-MinGW cross-compiling

The recommended way of compiling Julia from source on Windows is by cross compiling from [Cygwin](#), using versions of the MinGW-w64 compilers available through Cygwin's package manager.

1. Download and run Cygwin setup for [32 bit](#) or [64 bit](#). Note, that you can compile either 32 or 64 bit Julia from either 32 or 64 bit Cygwin. 64 bit Cygwin has a slightly smaller but often more up-to-date selection of packages.

Advanced: you may skip steps 2-4 by running:

```
setup-x86_64.exe -s <url> -q -P cmake,gcc-g++,git,make,patch,curl,m4,python3,p7zip,mingw64-
i686-gcc-g++,mingw64-i686-gcc-fortran,mingw64-x86_64-gcc-g++,mingw64-x86_64-gcc-
fortran
:: replace <url> with a site from https://cygwin.com/mirrors.html
:: or run setup manually first and select a mirror
```

2. Select installation location and download mirror.
3. At the 'Select Packages' step, select the following:

1. From the Devel category: cmake, gcc-g++, git, make, patch
 2. From the Net category: curl
 3. From Interpreters (or Python) category: m4, python3
 4. From the Archive category: p7zip
 5. For 32 bit Julia, and also from the Devel category: mingw64-i686-gcc-g++ and mingw64-i686-gcc-fortran
 6. For 64 bit Julia, and also from the Devel category: mingw64-x86_64-gcc-g++ and mingw64-x86_64-gcc-fortran
4. Allow Cygwin installation to finish, then start from the installed shortcut a 'Cygwin Terminal', or 'Cygwin64 Terminal', respectively.
 5. Build Julia and its dependencies from source:

1. Get the Julia sources

```
git clone https://github.com/JuliaLang/julia.git
cd julia
```

Tip: If you get an error: cannot fork() for fetch-pack: Resource temporarily unavailable from git, add alias `git="env PATH=/usr/bin git"` to `~/.bashrc` and restart Cygwin.

2. Set the XC_HOST variable in Make.user to indicate MinGW-w64 cross compilation

```
echo 'XC_HOST = i686-w64-mingw32' > Make.user      # for 32 bit Julia
# or
echo 'XC_HOST = x86_64-w64-mingw32' > Make.user    # for 64 bit Julia
```

3. Start the build

```
make -j 4      # Adjust the number of threads (4) to match your build environment.
make -j 4 debug # This builds julia-debug.exe
```

```
> Protip: build both!
> ```sh
> make 0=julia-win32 configure
> make 0=julia-win64 configure
> echo 'XC_HOST = i686-w64-mingw32' > julia-win32/Make.user
> echo 'XC_HOST = x86_64-w64-mingw32' > julia-win64/Make.user
> echo 'ifeq ($(BUILDR00T),$(JULIAHOME))
>     $(error "in-tree build disabled")
>     endif' >> Make.user
> make -C julia-win32 # build for Windows x86 in julia-win32 folder
> make -C julia-win64 # build for Windows x86-64 in julia-win64 folder
> ```
```

6. Run Julia using the Julia executables directly

```
usr/bin/julia.exe
usr/bin/julia-debug.exe
```

Compiling with MinGW/MSYS2

MSYS2 provides a robust MSYS experience.

Note: MSYS2 requires **64 bit** Windows 7 or newer.

1. Install and configure **MSYS2**, Software Distribution and Building Platform for Windows.
 1. Download and run the latest installer for the **64-bit** distribution. The installer will have a name like `msys2-x86_64-yyyymmdd.exe`.
 2. Open MSYS2. Update package database and base packages: `sh pacman -Syu`
 3. Exit and restart MSYS2, Update the rest of the base packages: `sh pacman -Syu`
 4. Then install tools required to build julia: `“sh`

104.5 tools

```
pacman -S cmake diffutils git m4 make patch tar p7zip curl python
```

104.6 For 64 bit Julia, install x86_64

```
pacman -S mingw-w64-x86_64-gcc
```

104.7 For 32 bit Julia, install i686

```
pacman -S mingw-w64-i686-gcc ““
```

5. Configuration of MSYS2 is complete. Now exit the MSYS2 shell.
2. Build Julia and its dependencies with pre-build dependencies.
 1. Open a new **MINGW64/MINGW32 shell**. Currently we can't use both mingw32 and mingw64, so if you want to build the `x86_64` and `i686` versions, you'll need to build them in each environment separately.
 2. and clone the Julia sources `sh git clone https://github.com/JuliaLang/julia.git cd julia`
 3. Start the build `sh make -j$(nproc)`

Protip: build in dir

```
make O=julia-mingw-w64 configure
echo 'ifeq ($(BUILDDROOT),$(JULIAHOME))
    $(error "in-tree build disabled")
endif' >> Make.user
make -C julia-mingw-w64
```

Cross-compiling from Unix (Linux/Mac/WSL)

You can also use MinGW-w64 cross compilers to build a Windows version of Julia from Linux, Mac, or the Windows Subsystem for Linux (WSL).

First, you will need to ensure your system has the required dependencies. We need wine ($\geq 1.7.5$), a system compiler, and some downloaders. Note: a cygwin install might interfere with this method if using WSL.

On Ubuntu (on other Linux systems the dependency names are likely to be similar):

```
apt-get install wine-stable gcc wget p7zip-full winbind mingw-w64 gfortran-mingw-w64
dpkg --add-architecture i386 && apt-get update && apt-get install wine32 # add sudo to each if
needed
# switch all of the following to their "-posix" variants (interactively):
for pkg in i686-w64-mingw32-g++ i686-w64-mingw32-gcc i686-w64-mingw32-gfortran x86_64-w64-mingw32
-g++ x86_64-w64-mingw32-gcc x86_64-w64-mingw32-gfortran; do sudo update-alternatives --
config $pkg; done
```

On Mac: Install XCode, XCode command line tools, X11 (now [XQuartz](#)), and [MacPorts](#) or [Homebrew](#). Then run `port install wine wget mingw-w64`, or `brew install wine wget mingw-w64`, as appropriate.

Then run the build:

1. `git clone https://github.com/JuliaLang/julia.git julia-win32`
2. `cd julia-win32`
3. `echo override XC_HOST = i686-w64-mingw32 >> Make.user`
4. `make`
5. `make win-extras` (Necessary before running `make binary-dist`)
6. `make binary-dist` then `make exe` to create the Windows installer.
7. move the `julia-*.exe` installer to the target machine

If you are building for 64-bit windows, the steps are essentially the same. Just replace `i686` in `XC_HOST` with `x86_64`. (note: on Mac, wine only runs in 32-bit mode).

Debugging a cross-compiled build under wine

The most effective way to debug a cross-compiled version of Julia on the cross-compilation host is to install a windows version of gdb and run it under wine as usual. The pre-built packages available [as part of the MSYS2 project](#) are known to work. Apart from the GDB package you may also need the python and termcap packages. Finally, GDB's prompt may not work when launch from the command line. This can be worked around by prepending `wineconsole` to the regular GDB invocation.

After compiling

Compiling using one of the options above creates a basic Julia build, but not some extra components that are included if you run the full Julia binary installer. If you need these components, the easiest way to get them is to build the installer yourself using `make win-extras` followed by `make binary-dist` and `make exe`. Then running the resulting installer.

Windows Build Debugging

GDB hangs with cygwin mintty

- Run gdb under the windows console (cmd) instead. gdb [may not function properly](#) under mintty with non- cygwin applications. You can use `cmd /c` to start the windows console from mintty if necessary.

GDB not attaching to the right process

- Use the PID from the windows task manager or WINPID from the `ps` command instead of the PID from unix style command line tools (e.g. `pgrep`). You may need to add the PID column if it is not shown by default in the windows task manager.

GDB not showing the right backtrace

- When attaching to the julia process, GDB may not be attaching to the right thread. Use `info threads` command to show all the threads and `thread <threadno>` to switch threads.
- Be sure to use a 32 bit version of GDB to debug a 32 bit build of Julia, or a 64 bit version of GDB to debug a 64 bit build of Julia.

Build process is slow/eats memory/hangs my computer

- Disable the Windows [Superfetch](#) and [Program Compatibility Assistant](#) services, as they are known to have [spurious interactions](#) with MinGW/Cygwin.

As mentioned in the link above: excessive memory use by `svchost` specifically may be investigated in the Task Manager by clicking on the high-memory `svchost.exe` process and selecting Go to Services. Disable child services one-by-one until a culprit is found.

- Beware of [BLODA](#). The [vmmap](#) tool is indispensable for identifying such software conflicts. Use `vmmap` to inspect the list of loaded DLLs for `bash`, `mintty`, or another persistent process used to drive the build. Essentially any DLL outside of the Windows System directory is potential BLODA.

104.8 FreeBSD

Clang is the default compiler on FreeBSD 11.0-RELEASE and above. The remaining build tools are available from the Ports Collection, and can be installed using `pkg install git gcc gmake cmake pkgconf`. To build Julia, simply run `gmake`. (Note that `gmake` must be used rather than `make`, since `make` on FreeBSD corresponds to the incompatible BSD Make rather than GNU Make.)

As mentioned above, it is important to note that the `USE_SYSTEM_*` flags should be used with caution on FreeBSD. This is because many system libraries, and even libraries from the Ports Collection, link to the system's `libgcc_s.so.1`, or to another library which links to the system `libgcc_s`. This library declares its GCC version to be 4.6, which is too old to build Julia, and conflicts with other libraries when linking. Thus it is highly recommended to simply allow Julia to build all of its dependencies. If you do choose to use the `USE_SYSTEM_*` flags, note that `/usr/local` is not on the compiler path by default, so you may need to add `LD_FLAGS=-L/usr/local/lib` and `CPP_FLAGS=-I/usr/local/include` to your `Make.user`, though doing so may interfere with other dependencies.

Note that the x86 architecture does not support threading due to lack of compiler runtime library support, so you may need to set `JULIA_THREADS=0` in your `Make.user` if you're on a 32-bit system.

104.9 ARM (Linux)

Julia fully supports ARMv8 (AArch64) processors, and supports ARMv7 and ARMv6 (AArch32) with some caveats. This file provides general guidelines for compilation, in addition to instructions for specific devices.

A list of [known issues](#) for ARM is available. If you encounter difficulties, please create an issue including the output from `cat /proc/cpuinfo`.

32-bit (ARMv6, ARMv7)

Julia has been successfully compiled on several variants of the following ARMv6 & ARMv7 devices:

- ARMv7 / Cortex A15 Samsung Chromebooks running Ubuntu Linux under Crouton;
- [Raspberry Pi](#).
- [Odroid](#).

Julia requires at least the armv6 and vfpv2 instruction sets. It's recommended to use armv7-a. armv5 or soft float are not supported.

Raspberry Pi 1 / Raspberry Pi Zero

If the type of ARM CPU used in the Raspberry Pi is not detected by LLVM, then explicitly set the CPU target by adding the following to `Make.user`:

```
| JULIA_CPU_TARGET=arm1176jzf-s
```

To complete the build, you may need to increase the swap file size. To do so, edit `/etc/dphys-swapfile`, changing the line:

```
| CONF_SWAPSIZE=100
```

to:

```
| CONF_SWAPSIZE=512
```

before restarting the swapfile service:

```
| sudo /etc/init.d/dphys-swapfile stop  
| sudo /etc/init.d/dphys-swapfile start
```

Raspberry Pi 2

The type of ARM CPU used in the Raspberry Pi 2 is not detected by LLVM. Explicitly set the CPU target by adding the following to `Make.user`:

```
JULIA_CPU_TARGET=cortex-a7
```

Depending on the exact compiler and distribution, there might be a build failure due to unsupported inline assembly. In that case, add `MCPU=armv7-a` to `Make.user`.

AArch64 (ARMv8)

Julia has been successfully built on the following ARMv8 devices:

- [nVidia Jetson TX1 & TX2](#);
- [X-Gene 1](#);
- [Overdrive 3000](#);
- [Cavium ThunderX](#) on [packet.net](#).

Compilation on ARMv8-A requires that `Make.user` is configured as follows:

```
| MCPU=armv8-a
```

Starting from Julia v1.10, [JITLink](#) is automatically enabled on this architecture for all operating systems when linking to LLVM 15 or later versions. Due to a [bug in LLVM memory manager](#), non-trivial workloads may generate too many memory mappings that on Linux can exceed the limit of memory mappings (`mmap`) set in the file `/proc/sys/vm/max_map_count`, resulting in an error like

```
| JIT session error: Cannot allocate memory
```

Should this happen, ask your system administrator to increase the limit of memory mappings for example with the command

```
| sysctl -w vm.max_map_count=262144
```

nVidia Jetson TX2

Julia builds and runs on the [nVidia Jetson TX2](#) platform with minimal configuration changes.

After configuring `Make.user` as per the AArch64 instructions in this document, follow the general [build instructions](#). The majority of the build dependencies specified in the instructions are installed by the default configuration flashed by [Jetpack 3.0](#). The remaining tools can be installed by issuing the following command:

```
| sudo apt-get install gfortran wget cmake
```

A full parallel build, including LLVM, will complete in around two hours. All tests pass and CUDA functionality is available through, e.g., [CUDAdrv](#).

104.10 Binary distributions

These notes are for those wishing to compile a binary distribution of Julia for distribution on various platforms. We love users spreading Julia as far and wide as they can, trying it out on as wide an array of operating systems and hardware configurations as possible. As each platform has specific gotchas and processes that must be followed in order to create a portable, working Julia distribution, we have separated most of the notes by OS.

Note that while the code for Julia is [MIT-licensed, with a few exceptions](#), the distribution created by the techniques described herein will be GPL licensed, as various dependent libraries such as SuiteSparse are GPL licensed. We do hope to have a non-GPL distribution of Julia in the future.

Versioning and Git

The Makefile uses both the VERSION file and commit hashes and tags from the git repository to generate the base/version_git.jl with information we use to fill the splash screen and the versioninfo() output. If you for some reason don't want to have the git repository available when building you should pregenerate the base/version_git.jl file with:

```
| make -C base version_git.jl.phony
```

Julia has lots of build dependencies where we use patched versions that has not yet been included by the popular package managers. These dependencies will usually be automatically downloaded when you build, but if you want to be able to build Julia on a computer without internet access you should create a full-source-dist archive with the special make target

```
| make full-source-dist
```

that creates a julia-version-commit.tar.gz archive with all required dependencies.

When compiling a tagged release in the git repository, we don't display the branch/commit hash info in the splash screen. You can use this line to show a release description of up to 45 characters. To set this line you have to create a Make.user file containing:

```
| override TAGGED_RELEASE_BANNER = "my-package-repository build"
```

Target Architectures

By default, Julia optimizes its system image to the native architecture of the build machine. This is usually not what you want when building packages, as it will make Julia fail at startup on any machine with incompatible CPUs (in particular older ones with more restricted instruction sets).

We therefore recommend that you pass the MARCH variable when calling make, setting it to the baseline target you intend to support. This will determine the target CPU for both the Julia executable and libraries, and the system image (the latter can also be set using JULIA_CPU_TARGET). Typically useful values for x86 CPUs are x86-64 and core2 (for 64-bit builds) and pentium4 (for 32-bit builds). Unfortunately, CPUs older than Pentium 4 are currently not supported (see [this issue](#)).

The full list of CPU targets supported by LLVM can be obtained by running `llc -mattr=help`.

Linux

On Linux, `make binary-dist` creates a tarball that contains a fully functional Julia installation. If you wish to create a distribution package such as a .deb, or .rpm, some extra effort is needed. See the [julia-debian](#) repository for an example of what metadata is needed for creating .deb packages for Debian and Ubuntu-based systems. See the [Fedora package](#) for RPM-based distributions. Although we have not yet experimented with it, [Alien](#) could be used to generate Julia packages for various Linux distributions.

Julia supports overriding standard installation directories via `prefix` and other environment variables you can pass when calling `make` and `make install`. See `Make.inc` for their list. `DESTDIR` can also be used to force the installation into a temporary directory.

By default, Julia loads `$prefix/etc/julia/startup.jl` as an installation-wide initialization file. This file can be used by distribution managers to set up custom paths or initialization code. For Linux distribution packages, if `$prefix` is set to `/usr`, there is no `/usr/etc` to look into. This requires the path to Julia's private etc directory to be changed. This can be done via the `sysconfdir` make variable when building.

Simply pass `sysconfdir=/etc` to make when building and Julia will first check `/etc/julia/startup.jl` before trying `$prefix/etc/julia/startup.jl`.

OS X

To create a binary distribution on OSX, build Julia first, then `cd` to `contrib/mac/app`, and run `make` with the same `makevars` that were used with `make` when building Julia proper. This will then create a `.dmg` file in the `contrib/mac/app` directory holding a completely self-contained `Julia.app`.

Alternatively, Julia may be built as a framework by invoking `make` with the `darwinframework` target and `DARWIN_FRAMEWORK=1` set. For example, `make DARWIN_FRAMEWORK=1 darwinframework`.

Windows

Instructions for creating a Julia distribution on Windows are described in the [build devdocs for Windows](#).

Notes on BLAS and LAPACK

Julia builds OpenBLAS by default, which includes the BLAS and LAPACK libraries. On 32-bit architectures, Julia builds OpenBLAS to use 32-bit integers, while on 64-bit architectures, Julia builds OpenBLAS to use 64-bit integers (ILP64). It is essential that all Julia functions that call BLAS and LAPACK API routines use integers of the correct width.

Most BLAS and LAPACK distributions provided on Linux distributions, and even commercial implementations ship libraries that use 32-bit APIs. In many cases, a 64-bit API is provided as a separate library.

When using vendor provided or OS provided libraries, a `make` option called `USE_BLAS64` is available as part of the Julia build. When doing `make USE_BLAS64=0`, Julia will call BLAS and LAPACK assuming a 32-bit API, where all integers are 32-bit wide, even on a 64-bit architecture.

Other libraries that Julia uses, such as SuiteSparse also use BLAS and LAPACK internally. The APIs need to be consistent across all libraries that depend on BLAS and LAPACK. The Julia build process will build all these libraries correctly, but when overriding defaults and using system provided libraries, this consistency must be ensured.

Also note that Linux distributions sometimes ship several versions of OpenBLAS, some of which enable multithreading, and others only working in a serial fashion. For example, in Fedora, `libopenblas.so` is threaded, but `libopenblas.so` is not. We recommend using the former for optimal performance. To choose an OpenBLAS library whose name is different from the default `libopenblas.so`, pass `LIBBLAS=-l$(YOURBLAS)` and `LIBBLASNAME=lib$(YOURBLAS)` to `make`, replacing `$(YOURBLAS)` with the name of your library. You can also add `.so.0` to the name of the library if you want your package to work without requiring the unversioned `.so` symlink.

Finally, OpenBLAS includes its own optimized version of LAPACK. If you set `USE_SYSTEM_BLAS=1` and `USE_SYSTEM_LAPACK=1`, you should also set `LIBLAPACK=-l$(YOURBLAS)` and `LIBLAPACKNAME=lib$(YOURBLAS)`. Else, the reference LAPACK will be used and performance will typically be much lower.

Starting with Julia 1.7, Julia uses [libblastrampoline](#) to pick a different BLAS at runtime.

104.11 Point releasing 101

Creating a point/patch release consists of several distinct steps.

Backporting commits

Some pull requests are labeled "backport pending x.y", e.g. "backport pending 0.6". This designates that the next subsequent release tagged from the release-x.y branch should include the commit(s) in that pull request. Once the pull request is merged into master, each of the commits should be **cherry picked** to a dedicated branch that will ultimately be merged into release-x.y.

Creating a backports branch

First, create a new branch based on release-x.y. The typical convention for Julia branches is to prefix the branch name with your initials if it's intended to be a personal branch. For the sake of example, we'll say that the author of the branch is Jane Smith.

```
| git fetch origin  
| git checkout release-x.y  
| git rebase origin/release-x.y  
| git checkout -b js/backport-x.y
```

This ensures that your local copy of release-x.y is up to date with origin before you create a new branch from it.

Cherry picking commits

Now we do the actual backporting. Find all merged pull requests labeled "backport pending x.y" in the GitHub web UI. For each of these, scroll to the bottom where it says "someperson merged commit 123abc into master XX minutes ago". Note that the commit name is a link; if you click it, you'll be shown the contents of the commit. If this page shows that 123abc is a merge commit, go back to the PR page—we don't want merge commits, we want the actual commits. However, if this does not show a merge commit, it means that the PR was squash-merged. In that case, use the git SHA of the commit, listed next to commit on this page.

Once you have the SHA of the commit, cherry-pick it onto the backporting branch:

```
| git cherry-pick -x -e <sha>
```

There may be conflicts which need to be resolved manually. Once conflicts are resolved (if applicable), add a reference to the GitHub pull request that introduced the commit in the body of the commit message.

After all of the relevant commits are on the backports branch, push the branch to GitHub.

Checking for performance regressions

Point releases should never introduce performance regressions. Luckily the Julia benchmarking bot, Nanosoldier, can run benchmarks against any branch, not just master. In this case we want to check the benchmark results of js/backport-x.y against release-x.y. To do this, awaken the Nanosoldier from his robotic slumber using a comment on your backporting pull request:

```
| @nanosoldier `runbenchmarks(ALL, vs=":release-x.y")`
```

This will run all registered benchmarks on release-x.y and js/backport-x.y and produce a summary of results, marking all improvements and regressions.

If Nanosoldier finds any regressions, try verifying locally and rerun Nanosoldier if necessary. If the regressions are deemed to be real rather than just noise, you'll have to find a commit on master to backport

that fixes it if one exists, otherwise you should determine what caused the regression and submit a patch (or get someone who knows the code to submit a patch) to master, then backport the commit once that's merged. (Or submit a patch directly to the backport branch if appropriate.)

Building test binaries

After the backport PR has been merged into the `release-x.y` branch, update your local clone of Julia, then get the SHA of the branch using

```
git rev-parse origin/release-x.y
```

Keep that handy, as it's what you'll enter in the "Revision" field in the buildbot UI.

For now, all you need are binaries for Linux x86-64, since this is what's used for running PackageEvaluator. Go to <https://buildbot.julialang.org>, submit a job for `nuke_linux64`, then queue up a job for `package_linux64`, providing the SHA as the revision. When the packaging job completes, it will upload the binary to the `julia2` bucket on AWS. Retrieve the URL, as it will be used for PackageEvaluator.

Checking for package breakages

Point releases should never break packages, with the possible exception of packages that are doing some seriously questionable hacks using Base internals that are not intended to be user-facing. (In those cases, maybe have a word with the package author.)

Checking whether changes made in the forthcoming new version will break packages can be accomplished using [PackageEvaluator](#), often called "PkgEval" for short. PkgEval is what populates the status badges on GitHub repos and on pkg.julialang.org. It typically runs on one of the non-benchmarking nodes of Nanosoldier and uses Vagrant to perform its duties in separate, parallel VirtualBox virtual machines.

Setting up PackageEvaluator

Clone PackageEvaluator and create a branch called `backport-x.y.z`, and check it out. Note that the required changes are a little hacky and confusing, and hopefully that will be addressed in a future version of PackageEvaluator. The changes to make will be modeled off of [this commit](#).

The setup script takes its first argument as the version of Julia to run and the second as the range of package names (AK for packages named A-K, LZ for L-Z). The basic idea is that we're going to tweak that a bit to run only two versions of Julia, the current `x.y` release and our backport version, each with three ranges of packages.

In the linked diff, we're saying that if the second argument is LZ, use the binaries built from our backport branch, otherwise (AK) use the release binaries. Then we're using the first argument to run a section of the package list: A-F for input 0.4, G-N for 0.5, and O-Z for 0.6.

Running PackageEvaluator

To run PkgEval, find a hefty enough machine (such as Nanosoldier node 1), then run

```
git clone https://github.com/JuliaCI/PackageEvaluator.jl.git
cd PackageEvaluator.jl/scripts
git checkout backport-x.y.z
./runvagrant.sh
```

This produces some folders in the `scripts/` directory. The folder names and their contents are decoded below:

| Folder name | Julia version | Package range |
|-------------|---------------|---------------|
| 0.4AK | Release | A-F |
| 0.4LZ | Backport | A-F |
| 0.5AK | Release | G-N |
| 0.5LZ | Backport | G-N |
| 0.6AK | Release | O-Z |
| 0.6LZ | Backport | O-Z |

Investigating results

Once that's done, you can use `./summary.sh` from that same directory to produce a summary report of the findings. We'll do so for each of the folders to aggregate overall results by version.

```
./summary.sh 0.4AK/*.json > summary_release.txt
./summary.sh 0.5AK/*.json >> summary_release.txt
./summary.sh 0.6AK/*.json >> summary_release.txt
./summary.sh 0.4LZ/*.json > summary_backport.txt
./summary.sh 0.5LZ/*.json >> summary_backport.txt
./summary.sh 0.6LZ/*.json >> summary_backport.txt
```

Now we have two files, `summary_release.txt` and `summary_backport.txt`, containing the `PackageEvaluator` test results (pass/fail) for each package for the two versions.

To make these easier to ingest into a Julia, we'll convert them into CSV files then use the `DataFrames` package to process the results. To convert to CSV, copy each `.txt` file to a corresponding `.csv` file, then enter Vim and execute `ggVGI"<esc>` then `:%s/\.json /",/g`. (You don't have to use Vim; this just is one way to do it.) Now process the results with Julia code similar to the following.

```
using DataFrames

release = readtable("summary_release.csv", header=false, names=[:package, :release])
backport = readtable("summary_backport.csv", header=false, names=[:package, :backport])

results = join(release, backport, on=:package, kind=:outer)

for result in eachrow(results)
    a = result[:release]
    b = result[:backport]
    if (isna(a) && !isna(b)) || (isna(b) && !isna(a))
        color = :yellow
    elseif a != b && occursin("pass", b)
        color = :green
    elseif a != b
        color = :red
    else
        continue
    end
    printstyled(result[:package], ": Release ", a, " -> Backport ", b, "\n", color=color)
end
```

This will write color-coded lines to `stdout`. All lines in red must be investigated as they signify potential breakages caused by the backport version. Lines in yellow should be looked into since it means a package

ran on one version but not on the other for some reason. If you find that your backported branch is causing breakages, use `git bisect` to identify the problematic commits, `git revert` those commits, and repeat the process.

Merging backports into the release branch

After you have ensured that

- the backported commits pass all of Julia's unit tests,
- there are no performance regressions introduced by the backported commits as compared to the release branch, and
- the backported commits do not break any registered packages,

then the backport branch is ready to be merged into `release-x.y`. Once it's merged, go through and remove the "backport pending x.y" label from all pull requests containing the commits that have been backported. Do not remove the label from PRs that have not been backported.

The `release-x.y` branch should now contain all of the new commits. The last thing we want to do to the branch is to adjust the version number. To do this, submit a PR against `release-x.y` that edits the `VERSION` file to remove `-pre` from the version number. Once that's merged, we're ready to tag.

Tagging the release

It's time! Check out the `release-x.y` branch and make sure that your local copy of the branch is up to date with the remote branch. At the command line, run

```
| git tag v$(cat VERSION)
| git push --tags
```

This creates the tag locally and pushes it to GitHub.

After tagging the release, submit another PR to `release-x.y` to bump the patch number and add `-pre` back to the end. This denotes that the branch state reflects a prerelease version of the next point release in the `x.y` series.

Follow the remaining directions in the Makefile.

Signing binaries

Some of these steps will require secure passwords. To obtain the appropriate passwords, contact Elliot Saba (`staticfloat`) or Alex Arslan (`ararslan`). Note that code signing for each platform must be performed on that platform (e.g. Windows signing must be done on Windows, etc.).

Linux

Code signing must be done manually on Linux, but it's quite simple. First obtain the file `julia.key` from the `CodeSigning` folder in the `juliasecure` AWS bucket. Add this to your GnuPG keyring using

```
| gpg --import julia.key
```

This will require entering a password that you must obtain from Elliot or Alex. Next, set the trust level for the key to maximum. Start by entering a gpg session:

```
| gpg --edit-key julia
```

At the prompt, type `trust`, then when asked for a trust level, provide the maximum available (likely 5). Exit GnuPG.

Now, for each of the Linux tarballs that were built on the buildbots, enter

```
| gpg -u julia --armor --detach-sig julia-x.y.z-linux-<arch>.tar.gz
```

This will produce a corresponding `.asc` file for each tarball. And that's it!

macOS

Code signing should happen automatically on the macOS buildbots. However, it's important to verify that it was successful. On a system or virtual machine running macOS, download the `.dmg` file that was built on the buildbots. For the sake of example, say that the `.dmg` file is called `julia-x.y.z-osx.dmg`. Run

```
| mkdir ./jlmnt
| hdiutil mount -readonly -mountpoint ./jlmnt julia-x.y.z-osx.dmg
| codesign -v jlmnt/Julia-x.y.app
```

Be sure to note the name of the mounted disk listed when mounting! For the sake of example, we'll assume this is `disk3`. If the code signing verification exited successfully, there will be no output from the `codesign` step. If it was indeed successful, you can detach the `.dmg` now:

```
| hdiutil eject /dev/disk3
| rm -rf ./jlmnt
```

If you get a message like

```
Julia-x.y.app: code object is not signed at all
```

then you'll need to sign manually.

To sign manually, first retrieve the OS X certificates from the `CodeSigning` folder in the `juliasecure` bucket on AWS. Add the `.p12` file to your keychain using `Keychain.app`. Ask Elliot Saba (`staticfloat`) or Alex Arslan (`ararslan`) for the password for the key. Now run

```
| hdiutil convert julia-x.y.z-osx.dmg -format UDRW -o julia-x.y.z-osx_writable.dmg
| mkdir ./jlmnt
| hdiutil mount -mountpoint julia-x.y.z-osx_writable.dmg
| codesign -s "AFB379C0B4CBD9DB9A762797FC2AB5460A2B0DBE" --deep jlmnt/Julia-x.y.app
```

This may fail with a message like

```
Julia-x.y.app: resource fork, Finder information, or similar detritus not allowed
```

If that's the case, you'll need to remove extraneous attributes:

```
| xattr -cr jlmnt/Julia-x.y.app
```

Then retry code signing. If that produces no errors, retry verification. If all is now well, unmount the writable `.dmg` and convert it back to read-only:

```
hdiutil eject /dev/disk3
rm -rf ./jlmnt
hdiutil convert julia-x.y.z-osx_writable.dmg -format UDZO -o julia-x.y.z-osx_fixed.dmg
```

Verify that the resulting .dmg is in fact fixed by double clicking it. If everything looks good, eject it then drop the _fixed suffix from the name. And that's it!

Windows

Signing must be performed manually on Windows. First obtain the Windows 10 SDK, which contains the necessary signing utilities, from the Microsoft website. We need the SignTool utility which should have been installed somewhere like C:\Program Files (x86)\Windows Kits\10\App Certification Kit. Grab the Windows certificate files from CodeSigning on [juliasecure](http://juliasecure.com) and put them in the same directory as the executables. Open a Windows CMD window, cd to where all the files are, and run

```
set PATH=%PATH%;C:\Program Files (x86)\Windows Kits\10\App Certification Kit;
signtool sign /f julia-windows-code-sign_2017.p12 /p "PASSWORD" ^
/t http://timestamp.verisign.com/scripts/timestamp.dll ^
/v julia-x.y.z-win32.exe
```

Note that ^ is a line continuation character in Windows CMD and PASSWORD is a placeholder for the password for this certificate. As usual, contact Elliot or Alex for passwords. If there are no errors, we're all good!

Uploading binaries

Now that everything is signed, we need to upload the binaries to AWS. You can use a program like Cyberduck or the aws command line utility. The binaries should go in the julialang2 bucket in the appropriate folders. For example, Linux x86-64 goes in julialang2/bin/linux/x.y. Be sure to delete the current julia-x.y-latest-linux-<arch>.tar.gz file and replace it with a duplicate of julia-x.y.z-linux-<arch>.tar.gz.

We also need to upload the checksums for everything we've built, including the source tarballs and all release binaries. This is simple:

```
shasum -a 256 julia-x.y.z* | grep -v -e sha256 -e md5 -e asc > julia-x.y.z.sha256
md5sum julia-x.y.z* | grep -v -e sha256 -e md5 -e asc > julia-x.y.z.md5
```

Note that if you're running those commands on macOS, you'll get very slightly different output, which can be reformatted by looking at an existing file. Mac users will also need to use md5 -r instead of md5sum. Upload the .md5 and .sha256 files to julialang2/bin/checksums on AWS.

Ensure that the permissions on AWS for all uploaded files are set to "Everyone: READ."

For each file we've uploaded, we need to purge the Fastly cache so that the links on the website point to the updated files. As an example:

```
curl -X PURGE https://julialang-s3.julialang.org/bin/checksums/julia-x.y.z.sha256
```

Sometimes this isn't necessary but it's good to do anyway.

Chapter 105

Julia v1.10 Release Notes

105.1 New language features

- JuliaSyntax.jl is now used as the default parser, providing better diagnostics and faster parsing. Set environment variable JULIA_USE_FLISP_PARSER to 1 to switch back to the old parser if necessary (and if you find this necessary, please file an issue) ([#46372](#)).
- (U+297A, \leftarrowsubset) and (U+2977, \leftarrowless) may now be used as binary operators with arrow precedence ([#45962](#)).

105.2 Language changes

- When a task forks a child, the parent task's task-local RNG (random number generator) is no longer affected. The seeding of child based on the parent task also takes a more disciplined approach to collision resistance, using a design based on the SplitMix and DotMix splittable RNG schemes ([#49110](#)).
- A new more-specific rule for methods resolves ambiguities containing Union{ } in favor of the method defined explicitly to handle the Union{ } argument. This makes it possible to define methods to explicitly handle Union{ } without the ambiguities that commonly would result previously. This also lets the runtime optimize certain method lookups in a way that significantly improves load and inference times for heavily overloaded methods that dispatch on Types (such as traits and constructors). ([#49349](#))
- The "h bar" \hbar (\hslash U+210F) character is now treated as equivalent to \hbar (\hbar U+0127).
- The @simd macro now has more limited and clearer semantics: it only enables reordering and contraction of floating-point operations, instead of turning on all "fastmath" optimizations. If you observe performance regressions due to this change, you can recover previous behavior with @fastmath @simd, if you are OK with all the optimizations enabled by the @fastmath macro ([#49405](#)).
- When a method with keyword arguments is displayed in the stack trace view, the textual representation of the keyword arguments' type is simplified using the new @Kwargs{key1::Type1, ...} macro syntax ([#49959](#)).

105.3 Compiler/Runtime improvements

- The mark phase of the garbage collector is now multi-threaded ([#48600](#)).
- [JITLink](#) is enabled by default on Linux aarch64 when Julia is linked to LLVM 15 or later versions ([#49745](#)). This should resolve many segmentation faults previously observed on this platform.
- The precompilation process now uses pidfile locks and orchestrates multiple julia processes to only have one process spend effort precompiling while the others wait. Previously all would do the work and race to overwrite the cache files. ([#49052](#))

105.4 Command-line option changes

- New option `--gcthreads` to set how many threads will be used by the garbage collector ([#48600](#)). The default is $N/2$ where N is the number of worker threads (`--threads`) used by Julia.

105.5 Build system changes

- `SparseArrays` and `SuiteSparse` are no longer included in the default system image, so the core language no longer contains GPL libraries. However, these libraries are still included alongside the language in the standard binary distribution ([#44247](#), [#48979](#), [#49266](#)).

105.6 New library functions

- `tanpi` is now defined. It computes $\tan(\pi x)$ more accurately than `'tan(pix)'` ([#48575](#)).
- `fourthroot(x)` is now defined in `Base.Math` and can be used to compute the fourth root of x . It can also be accessed using the unicode character $\sqrt[4]{}$, which can be typed by `\fourthroot<tab>` ([#48899](#)).
- `Libc.memmove`, `Libc.memset`, and `Libc.memcpy` are now defined, whose functionality matches that of their respective C calls.
- `Base.isprecompiled(pkg::PkgId)` has been added, to identify whether a package has already been precompiled ([#50218](#)).

105.7 New library features

- `binomial(x, k)` now supports non-integer x ([#48124](#)).
- A `CartesianIndex` is now treated as a "scalar" for broadcasting ([#47044](#)).
- `printstyled` now supports italic output ([#45164](#)).
- `parent` and `parentindices` support `SubStrings`.
- `replace(string, pattern...)` now supports an optional `I0` argument to write the output to a stream rather than returning a string ([#48625](#)).
- `startswith` now supports seekable `I0` streams ([#43055](#)).

105.8 Standard library changes

- The `initialized=true` keyword assignment for `sortperm!` and `partialsortperm!` is now a no-op ([#47979](#)). It previously exposed unsafe behavior ([#47977](#)).
- Printing integral Rationals will skip the denominator in Rational-typed IO context (e.g. in arrays) ([#45396](#)).

Package Manager

- `Pkg.precompile` now accepts `timing` as a keyword argument which displays per package timing information for precompilation (e.g. `Pkg.precompile(timing=true)`).

LinearAlgebra

- `AbstractQ` no longer subtypes `AbstractMatrix`. Moreover, `adjoint(Q::AbstractQ)` no longer wraps `Q` in an `Adjoint` type, but instead in an `AdjointQ`, that itself subtypes `AbstractQ`. This change accounts for the fact that typically `AbstractQ` instances behave like function-based, matrix-backed linear operators, and hence don't allow for efficient indexing. Also, many `AbstractQ` types can act on vectors/matrices of different size, acting like a matrix with context-dependent size. With this change, `AbstractQ` has a well-defined API that is described in detail in the [Julia documentation](#) ([#46196](#)).
- Adjoints and transposes of `Factorization` objects are no longer wrapped in `Adjoint` and `Transpose` wrappers, respectively. Instead, they are wrapped in `AdjointFactorization` and `TransposeFactorization` types, which themselves subtype `Factorization` ([#46874](#)).
- New functions `hermitianpart` and `hermitianpart!` for extracting the Hermitian (real symmetric) part of a matrix ([#31836](#)).
- The norm of the adjoint or transpose of an `AbstractMatrix` now returns the norm of the parent matrix by default, matching the current behaviour for `AbstractVectors` ([#49020](#)).
- `eigen(A, B)` and `eigvals(A, B)`, where one of `A` or `B` is symmetric or Hermitian, are now fully supported ([#49533](#)).
- `eigvals/eigen(A, cholesky(B))` now computes the generalized eigenvalues (eigen: and eigenvectors) of `A` and `B` via Cholesky decomposition for positive definite `B`. Note: The second argument is the output of `cholesky`.

Printf

- Format specifiers now support dynamic width and precision, e.g. `%*s` and `%*.*g` ([#40105](#)).

REPL

- When stack traces are printed, the printed depth of types in function signatures will be limited to avoid overly verbose output ([#49795](#)).

Test

- The `@test_broken` macro (or `@test` with `broken=true`) now complains if the test expression returns a non-boolean value in the same way as a non-broken test ([#47804](#)).

- When a call to `@test` fails or errors inside a function, a larger stacktrace is now printed such that the location of the test within a `@testset` can be retrieved ([#49451](#)).

InteractiveUtils

- `code_native` and `@code_native` now default to intel syntax instead of AT&T.
- `@time_imports` now shows the timing of any module `__init__()`s that are run ([#49529](#)).

105.9 Deprecated or removed

- The `@pure` macro is now deprecated. Use `Base.@assume_effects :foldable` instead ([#48682](#)).
